Arginine vasopressin, an antidiuretic hormone, has emerged as a potential alternative to adrenergic vasopressors for the treatment of refractory vasodilatory shock. The mechanism of action of vasopressin has not been fully elucidated, but likely involves binding to V_1 receptors on vascular smooth muscle cells. Although it has minimal pressor activity in normal subjects, vasopressin has been shown to improve blood pressure in patients with sepsis [37] and in patients with vasodilatory shock after cardiopulmonary bypass [38] (Table 32.2). In these initial studies, vasopressin was initiated at a dose of 0.1 U per minute; for subjects maintaining a mean arterial pressure greater than 70 mm Hg, vasopressin was tapered to 0.01 U per minute and then discontinued. Notably, many patients in these studies were poorly responsive to intravenous catecholamine support and had inappropriately low vasopressin levels before treatment consistent with a defect in baroreflex-mediated vasopressin secretion. It remains unclear, however, whether the benefits of vasopressin are confined to patients with relative vasopressin deficiency, hypersensitivity, or both.

Russell et al. [39] randomized 778 patients with septic shock who were receiving a minimum of 5 μg per minute of norepinephrine to receive either low-dose vasopressin (0.01 to 0.03 U per minute) or norepinephrine (5 to 15 μg per minute) in addition to open-label vasopressors. After 28 days, there was no significant difference in mortality rates between the vasopressin and norepinephrine groups (35.4% and 39.3%, respectively; $p = 0.26$) (Fig. 32.3). However, in patients with less severe septic shock (prospectively defined as those receiving treatment with less than 15 μg per minute of norepinephrine), mortality was lower in the vasopressin group (26.5% vs. 35.7%, $p = 0.05$).

Vasopressin may also be effective in the treatment of cardiac arrest unresponsive to epinephrine and defibrillation [40]. Revised guidelines for advanced cardiovascular life support recommend vasopressin as an alternative to epinephrine for the treatment of adult shock-refractory ventricular fibrillation, as well as an adjunctive agent in the treatment of patients with vasodilatory shock, such as septic shock or sepsis syndrome, refractory to standard therapy [5]. A meta-analysis of cardiac arrest trials demonstrated no significant differences between vasopressin and epinephrine groups in failure of return of spontaneous circulation, death within 24 hours, or death before hospital discharge [41]. In a randomized clinical trial of 2,894 patients with out-of-hospital cardiac arrest receiving advanced cardiac life support, the combination of vasopressin (40 IU) and epinephrine (1 mg) did not improve outcomes compared to epinephrine alone: return of spontaneous circulation, 28.6% versus 29.5%; survival to hospital admission, 20.7% versus

21.3%; and survival to hospital discharge, 1.7% versus 2.3%; respectively [42]. In the setting of vasodilatory shock, vasopressin can be administered as a continuous infusion at 0.01 to 0.05 U per minute. Potential adverse effects of vasopressin include excess vasoconstriction causing end-organ ischemia including myocardial ischemia and hyponatremia. Cardiac output may also worsen owing to increased afterload.

Terlipressin is a synthetic long-acting analog of vasopressin that is currently undergoing clinical investigation [43]. In a recent pilot study of patients with septic shock despite adequate volume resuscitation, a continuous infusion of low-dose terlipressin (1.3 μg per kg per hour) was effective in reversing arterial hypotension and reducing catecholamine requirements [44]. Compared with vasopressin or norepinephrine, terlipressin was associated with less rebound hypotension upon discontinuation. Adverse effects associated with terlipressin include hypertension, bradycardia, skin pallor, and reduction in platelet count.

Adjunctive and Investigational Agents

In addition to the agents discussed previously, the phosphodiesterase inhibitor milrinone is commonly used in the management of acute decompensated heart failure. Milrinone increases cardiac contractility by directly inhibiting the breakdown of cyclic adenosine monophosphate, resulting in an increase in intracellular calcium [45]. In addition, phosphodiesterase inhibition in vascular smooth muscle causes systemic and pulmonary vasodilation [46]. Because milrinone does not require binding to adrenergic receptors to exert its effects, it is particularly useful in the treatment of patients taking β-adrenergic antagonists or those with advanced heart failure that may be resistant to β-agonist stimulation with dobutamine [35]. Milrinone is generally administered as an intravenous loading dose (50 μg per kg), followed by a continuous infusion at doses ranging from 0.25 to 0.75 μg per kg per minute. As it is renally excreted, milrinone should be dose-adjusted in renal failure; and in all patients, milrinone should be titrated cautiously, using invasive hemodynamic monitoring. Because it is a potent vasodilator, however, milrinone should be avoided in the treatment of patients with frank hypotension and is contraindicated in patients with severe aortic stenosis. Similarly, the use of levosimendan [47], a calcium sensitizer with phosphodiesterase and potassium channel inhibitor properties, may be limited by hypotension [48]. In a randomized, double-blind study of 1,327 patients with acute decompensated heart failure, intravenous levosimendan showed no benefit compared to dobutamine in reducing all-cause mortality at 180 days (26% vs. 28%, respectively; hazard ratio, 0.91; 95% confidence interval, 0.74 to 1.13; $p = 0.40$), and increased the incidence of atrial fibrillation [49]. Although approved for use in Europe, levosimendan remains investigational in the United States.

With the exception of vasopressin, all currently available vasopressors exert their action through stimulation of α-adrenergic receptors. This approach is often associated with worsening splanchnic perfusion, and in some patients may prove ineffective in restoring mean arterial pressure. Evidence of the central role of endothelium-derived nitric oxide (NO) in mediating vasodilation [50] led to the development of substances that interfere with NO production or activity. Several investigators have shown that analogs of L-arginine, the synthetic precursor of NO, can competitively inhibit the enzyme NO synthase, thereby decreasing NO production and increasing mean arterial pressure in patients with septic shock [51]. Others have shown that inhibition of guanylate cyclase, the target enzyme of NO, with methylene blue is effective in increasing mean arterial pressure, reducing the need for vasopressors and maintaining oxygen transport in septic shock [52]. Methylene blue has also been used successfully to treat refractory hypotension in patients with vasoplegia following cardiopulmonary bypass (Table 32.2) [53], and may be used to prevent vasoplegia in high-risk cardiac surgical patients [54]. However, the overall safety and efficacy of NO inhibition remains unproven. A large, randomized, placebo-controlled trial of the NO synthase inhibitor 546C88 in sepsis was stopped prematurely due to excess mortality at 28 days (59% vs. 49%, $p < 0.001$) in the active treatment arm [51]. As with adrenergic agents, lack of selectivity may have contributed to undesirable effects. More selective NO inhibitors are currently under investigation.

Another novel agent that has recently been approved for the treatment of patients with severe sepsis is recombinant human activated protein C (drotrecogin alfa activated) [55]. In the Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis study, 1,690 patients with systemic inflammation and organ failure owing to acute infection (71% of whom presented with shock) were randomized to receive drotrecogin alfa activated or placebo as a continuous infusion for 4 days [56]. Drotrecogin alfa activated reduced all-cause mortality by 19%, but tended to increase the risk of serious bleeding. Based on this study, drotrecogin alfa activated is recommended for the treatment of patients with severe sepsis and high risk of death (Apache II score greater than 25) (Table 32.2). The standard intravenous dosing is 24 μg per kg per hour for 96 hours, at a cost of approximately $6,000. In a subsequent study of patients with severe sepsis and low risk of death (Apache II score less than or equal to 25), there was no beneficial effect of drotrecogin alfa activated on either in-hospital or 28-day mortality [57]. The risk of serious bleeding was higher (2.4% vs. 1.2%, $p = 0.02$) in the drotrecogin alfa activated group. A randomized controlled study of drotrecogin alfa activated in children with severe sepsis also showed no benefit [58]. The 28-day mortality rates were 17.2% and 17.5% in the drotrecogin alfa activated and placebo groups, respectively ($p = 0.93$).

Several hormones including cortisol and thyroxine are known to play important roles in the maintenance of vascular tone, and their absolute or relative deficiency may contribute to hypotension in the critically ill patient. The adverse effects of hypothyroidism (see Chapter 103) and adrenal insufficiency (see Chapter 104) on central and peripheral hemodynamics have been well described. Although routine use of high-dose corticosteroids have not been shown to be beneficial in the treatment of sepsis, the administration of stress-dose steroids to patients suspected of having relative impairment of adrenocortical response may be helpful in restoring normal hemodynamics and improving outcomes.

In the 1990s, three small trials in patients with septic shock demonstrated decreased duration of shock with steroid treatment [59–61]. Subsequently, Annane et al. [62] randomized 300 patients with septic shock to receive hydrocortisone (50 mg intravenous bolus every 6 hours) and fludrocortisone (50 μg by mouth once daily) or matching placebos for 7 days. Patients were enrolled after undergoing a short corticotropin stimulation test. In the 229 nonresponders to corticotropin (i.e., with relative adrenal insufficiency), treatment with corticosteroids increased vasopressor withdrawal (57% vs. 40%, $p = 0.001$) and decreased mortality (53% vs. 63%, $p = 0.02$) at 28 days. There were no differences in outcomes between steroid and placebo groups in the corticotropin responders. Although this trial was criticized on both methodologic and clinical grounds, a subsequent meta-analysis (Fig. 32.4) showed that a 5- to 7-day course of physiologic hydrocortisone doses increased survival in patients with vasopressor-dependent septic shock [63].

In a more recent study, 499 patients with septic shock who remained hypotensive after fluid and vasopressor resuscitation were randomized to receive 50 mg of intravenous hydrocortisone or placebo every 6 hours for 5 days [64]. At 28 days, there was no significant difference in mortality between patients in

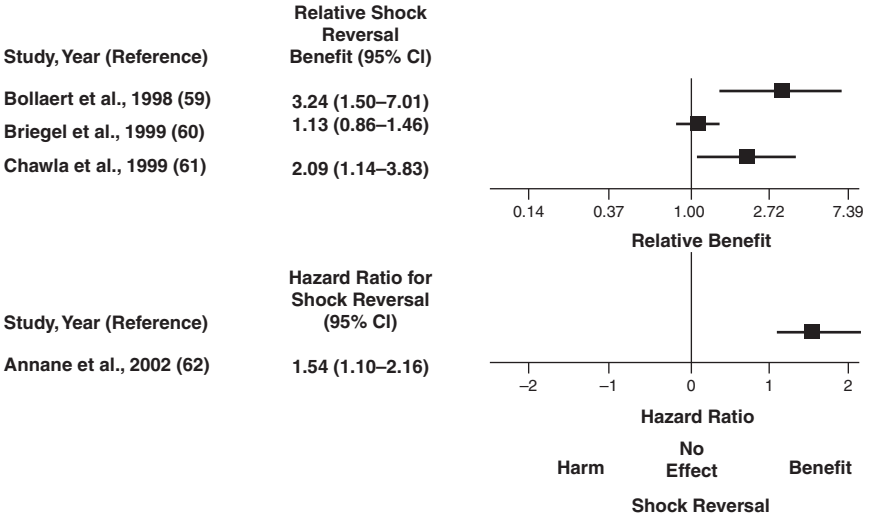

FIGURE 32.4. The relative benefit and hazard ratio (with 95% CI) of shock reversal for sepsis trials published after 1997. In three of the four trials, the discontinuation of vasopressor therapy with steroid treatment was significantly improved. [From Minneci PC, Deans KJ, Banks SM, et al: Meta-analysis: the effect of steroids on survival and shock during sepsis depends on the dose. *Ann Intern Med* 141:47–56, 2004, with permission.]

the two study groups whose plasma cortisol levels did not rise appropriately after administration of corticotropin (39.2% vs. 36.1% in the hydrocortisone and placebo groups, respectively; $p = 0.69$) or between those who had a response to corticotropin (28.8% vs. 28.7%, respectively; $p = 1.00$) (Fig. 32.5). As discussed previously, correction of relative vasopressin deficiency is an alternative or adjunctive therapeutic strategy in refractory shock.

Calcium

The routine use of intravenous calcium has been shown to have no benefit in the setting of cardiac arrest and may be detrimental by causing cellular injury [4]. Indications for acute calcium administration in the hypotensive patient include correction of clinically significant hyperkalemia (e.g., with acute kidney injury) or hypocalcemia (e.g., following multiple blood transfusions) and as an antidote to calcium channel blocker or beta-blocker overdose [65]. Calcium chloride (100 mg per mL in a 10-mL vial) is usually given as a slow intravenous push of 5 to 10 mL, and may be repeated as needed. Rapid intravenous administration of calcium may cause bradycardia or asystole particularly in patients receiving digoxin. In critically ill patients, ionized calcium rather than total calcium concentration should be followed.

CHOOSING AN AGENT

There are few large, randomized, well-controlled studies to guide the pharmacologic management of hypotension. The use of vasopressors and positive inotropes is generally based on data from animal studies and small, often poorly controlled clinical trials. Useful consensus recommendations can be found in the recently revised Advanced Cardiovascular Life Support guidelines [5] and the international guidelines for management of severe sepsis and septic shock updated in 2008 [2].

The selection of the appropriate vasoactive agent can be individualized with attention to the known or suspected underlying cause of hypotension (Table 32.3). However, the clinician is commonly faced with a patient who presents with life-threatening hypotension of unknown etiology. In this setting, it may be necessary to initiate a vasopressor as a temporizing measure even before the adequacy of intravascular volume repletion can be ensured. Consensus guidelines and expert panels recommend both dopamine and norepinephrine as first-line vasopressor agents. Although dopamine in moderate to high doses can provide both positive inotropic and vasopressor effects, arrhythmias may be provoked (see discussion of SOAP II later). For severe hypotension (systolic blood pressure less than 70 mm Hg), a more potent α_1-adrenergic agonist such as norepinephrine should be considered.

For the hypotensive patient with significant cardiac pump dysfunction (cardiac index less than 2.2 L per minute per m^2 associated with end-organ dysfunction), dobutamine should be considered. Milrinone is often not tolerated in this situation due to its vasodilating properties. With frank cardiogenic shock and concomitant vasoplegia, a drug with pressor action is usually needed. In this setting, vasopressin and norepinephrine can be used in combination with dobutamine. Rarely, epinephrine may be required. In patients with septic shock and related myocardial dysfunction, dobutamine can be added for additional inotropic support. Although dopamine is also often considered in such situations for its combined inotropic and pressor properties there has been recent concern of increased mortality when compared to norepinephrine in a subgroup of patients with cardiogenic shock in the recent SOAP II trial (see later).

Given the superior potency of norepinephrine and evidence of worsening splanchnic perfusion with high-dose dopamine, norepinephrine is emerging as the agent of choice for vasodilatory shock in sepsis [16]. Although in the landmark Sepsis Occurrence in Acutely Ill Patients (SOAP) II trial, there was no difference between the initial use of dopamine versus norepinephrine for shock in 28 day all-cause mortality, dopamine was associated with more adverse events, particularly atrial fibrillation [66]. Dopamine may be used as an alternate agent or in cases in which positive inotropic effects are desirable. Current experience with phenylephrine is insufficient to assess its efficacy relative to older agents, although its peripheral selectivity and lack of positive chronotropic effects make it a theoretically useful agent in cases in which tachycardia, tachyarrhythmias, or both limit the use of other drugs. Epinephrine is the least selective of the catecholamines and is occasionally added for refractory septic shock. Vasopressin is emerging as an alternative to adrenergic agents, but its use for hypotension may be limited to patients with hemodynamic collapse that is resistant to adequate fluid resuscitation and high-dose conventional vasopressors. For patients at high risk of death from sepsis (APACHE II score greater than 25) and low bleeding risk, recombinant human activated protein C is recommended [2,55]. For patients refractory to multiple pressors, including those status post cardiopulmonary bypass, a trial of methylene blue should be considered [52,53].

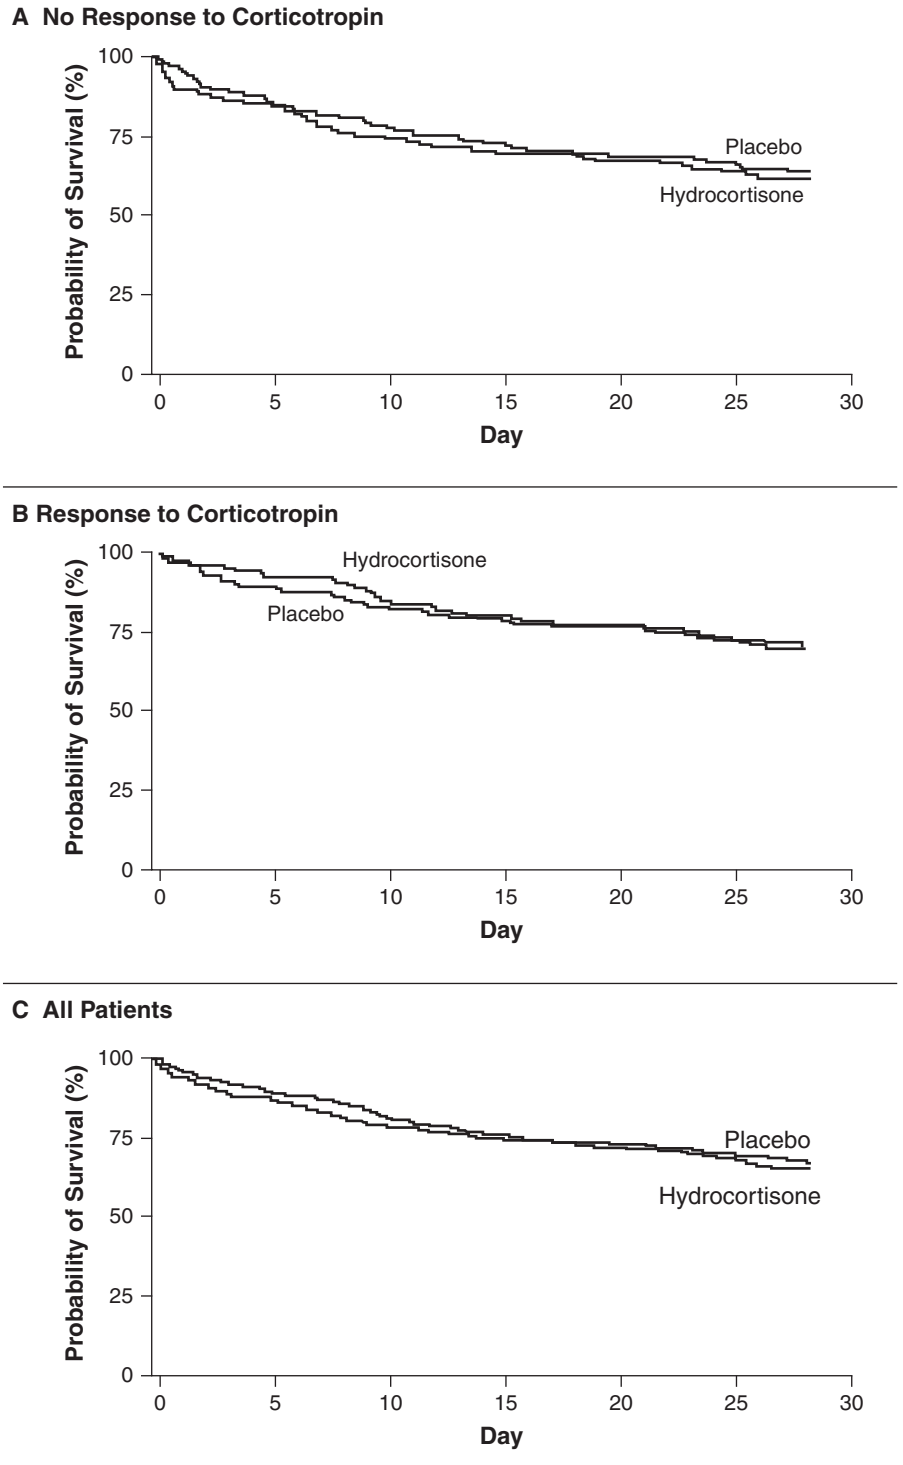

FIGURE 32.5. Shown are Kaplan–Meier curves for survival at 28 days comparing patients with septic shock who received hydrocortisone versus placebo. There was no difference among patients who did not have a response to a corticotropin test (*Panel A*), those who had a response to corticotropin (*Panel B*) and all patients randomized (*Panel C*). CLINICAL USE OF VASOACTIVE DRUGS

In the volume-resuscitated patient with persistent hypotension, vasoactive medications are administered with the goal of improving arterial pressure while avoiding myocardial ischemia, arrhythmias, and excess vasoconstriction. Although a mean arterial blood pressure of greater than 60 mm Hg is usually adequate to maintain autoregulatory blood flow to vital organs [67], some patients may require considerably higher pressures. Therefore, it is essential to use other indicators of global and regional perfusion in addition to the mean arterial pressure to guide therapy. Altered mental status, oliguria, and cool skin are important clinical signs of poor perfusion, but are somewhat nonspecific. The clinical use of mixed venous oxygen saturation and serum lactate level, as well as intramucosal pH monitoring by gastric tonometry remains unproven [2]. Although some clinicians have advocated achieving "supranormal" levels of oxygen delivery in the treatment of critically ill patients, this approach is controversial [68], and adverse effects of hyperoxia have been demonstrated on coronary blood flow and myocardial function in patients with coronary artery disease [69] and heart failure [70], respectively. A meta-analysis in critically ill

patients found that various approaches to hemodynamic optimization reduced mortality when patients were treated early to achieve hemodynamic goals before the development of organ failure and when therapy produced differences in oxygen delivery [71].

Vasopressors and positive inotropes are powerful drugs with considerable potential for toxicity. Diligent monitoring and careful adjustment of medications based on changes in clinical status are essential. Patients should be treated in an intensive care setting with continuous monitoring of cardiac rhythm, urine output, and arterial oxygenation. Fluid resuscitation and careful attention to intravascular volume are paramount, as up to 50% of patients with hypotension related to sepsis may stabilize with fluids alone [2]. Moreover, the administration of vasopressors to intravascularly depleted patients can worsen end-organ perfusion. The routine use of pulmonary artery catheters in this setting remains unproven, as overaggressive treatment may increase the risk of adverse events [72]. However, a randomized trial demonstrated that early goal-directed therapy, using a central venous catheter capable of measuring oxygen saturation, improved outcomes in patients with septic shock [73]. In patients who do not respond adequately to initial fluid boluses and brief infusion of vasopressors, invasive hemodynamic monitoring may aid in optimizing filling pressures and selecting the appropriate vasoactive agent. Intra-arterial cannulation and direct monitoring of blood pressure is suggested during prolonged vasopressor use. Drugs should be administered through central venous catheters via volumetric infusion pumps that deliver precise flow rates. In the event of vasopressor extravasation, an α_1-adrenergic antagonist (e.g., phentolamine, 5 to 10 mg, diluted in 10 to 15 mL of saline) can be infiltrated into the area to limit local vasoconstriction and tissue necrosis.

With few exceptions, the drugs discussed in this chapter are short-acting agents with rapid onset and offset of action. They are generally initiated without a bolus and can be titrated frequently. Abrupt lowering or discontinuation of vasoactive drugs should be avoided to prevent rebound hypotension. Common dose ranges are provided in Table 32.1, but there may be considerable variation in the dose required to restore adequate hemodynamics. Furthermore, an individual patient's response to an agent may diminish with time owing to several mechanisms, including adrenergic receptor desensitization.

Critically ill patients in the intensive care unit are generally treated with multiple drugs in addition to vasoactive agents (e.g., other cardiovascular medications, antibiotics). Careful attention should be paid to potential drug–drug interactions, as they can significantly alter the response to a given sympathomimetic amine. For example, prior or current treatment with a β-adrenergic antagonist can cause resistance to the action of dobutamine or other β-adrenergic agonists. The administration of less-selective drugs (e.g., norepinephrine) to a patient receiving chronic beta-blockade can result in unopposed α-adrenergic stimulation. Another well-described interaction is the exaggerated response to some catecholamines in individuals taking monoamine oxidase inhibitors. The starting dose for these patients should be less than 10% of the usual dose [1]. Intensive care unit rounding with a dedicated pharmacist is recommended.

CHAPTER 33 ■ MANAGEMENT OF ADVANCED HEART FAILURE

G. WILLIAM DEC

Advanced heart failure accounts for a small minority (approximately 10%) of patients with chronic disease. It is generally defined as persistent New York Heart Association functional class IIIB or IV symptoms that limit daily activities and occur despite adequate pharmacologic treatment (see later) and is usually associated with a left ventricular ejection fraction below 30% [1]. Patients with advanced heart failure typically have experienced one or more hospitalizations for decompensated heart failure within the previous year.

PROGNOSTIC FEATURES

More than 50 variables have been examined in univariate and multivariate models and shown to predict prognosis in advanced heart failure populations. No single study has assessed all, or even most, of these predictors simultaneously and it is therefore impossible to rank prognostic features strictly based on their level of importance. Nonetheless, several features appear repeatedly in the published literature (Table 33.1). Eichhorn identified plasma norepinephrine level, B-type natriuretic peptide (BNP) level, left ventricular ejection fraction, peak oxygen uptake on cardiopulmonary exercise testing, advanced age, and a history of symptomatic ventricular arrhythmias or sudden cardiac death as the most important predictors of outcome [2].

Functional capacity, as assessed by the New York Heart classification remains among the most useful outcome predictors in advanced heart failure. One year mortality rates range from <5% for Class I, 10% to 15% for Class II, 20% to 30% for Class III, with Class IV patients experiencing rates of 30% to 70% depending on their response to therapy [2]. Although left ventricular ejection fraction (LVEF) is a consistent predictor of outcome in a heterogeneous population of patients whose left ventricular ejection fractions range from 10% to 50% [2], this parameter correlates very poorly with symptoms or day-to-day functional capacity and loses much of its predictive accuracy among patients with advanced symptoms [3]. In advanced heart failure, small variations in markedly depressed LVEF (i.e., between 10% and 20%) have little bearing on symptoms or prognosis [2,3].

Findings on physical examination also predict prognosis and should influence treatment during hospitalization. The presence of a chronic third heart sound or elevation in jugular venous pressure establishes more advanced disease and predict increased long-term mortality [4]. Both moderate-to-severe mitral or tricuspid regurgitation are also associated with increased symptoms, morbidity, and mortality [5].

Serum B-type natriuretic peptide (BNP) and N-terminal-pro-BNP are increasingly measured in patients with suspected heart failure. Recent data suggest that serial assessment of BNP during hospitalization is useful in predicting postdischarge prognosis and suggests that this approach may soon help guide heart failure inpatient management [6]. However, it should be recognized that a variety of etiologies including pulmonary embolism, acute coronary syndromes, and sepsis may also lead to markedly elevated BNP [7].

Renal dysfunction has recently been recognized as an extremely powerful predictor of heart failure outcome. Deterioration in renal function may result from diminished cardiac output and a corresponding reduction in glomerular filtration rate, alterations in the distribution of cardiac output, intrarenal vasoregulation, alterations in circulatory volume, more intense neurohormonal activation, and/or the nephrotoxic effects of medications administered during hospitalization [8]. The presence of chronic renal insufficiency, defined as a serum creatinine >1.4 mg/dL for women and >1.5 mg/dL for men, predicts an increased risk of death (risk ratio = 1.43) [8]. Unfortunately, approximately 25% of hospitalized patients with decompensated heart failure will exhibit deterioration in renal function despite appropriate medical therapy [9]. In these hospitalized patients, a rise in serum creatinine of only 0.1 to 0.5 mg/dL is associated with a longer length of hospital stay and increased in-hospital mortality [9]. This constellation of poorly understood physiologic mechanisms has been termed the "cardiorenal syndrome" and its optimal management remains to be defined.

Thus, a variety of demographic, clinical, hemodynamic and laboratory findings help to accurately characterize patients with advanced heart failure at increased risk of adverse events during hospitalization. Proper identification of these patients should lead to improved management strategies. Hernandez, et al. have reported that patients with heart failure undergoing major noncardiac surgical procedures experience substantially increased morbidity compared to patients with ischemic heart disease or an age-matched population [10]. After adjusting for demographic characteristics, type of surgery,

TABLE 33.1

PREDICTORS OF PROGNOSIS IN CHRONIC HEART FAILURE

Demographic	Advanced age, sex, ischemic etiology
Symptoms	NYHA class IV, syncope
Signs	Chronic S3, right heart failure
Laboratory	Na^+, creatinine, anemia, CTR, LVEDD
ECG	QRS or QTc prolongation, NSVT, VT
Hemodynamic	LVEF, PCW, CI
Exercise	6-min walk distance, peak VO_2
Neurohormonal	PNE, ANP, BNP

ANP, atrial natriuretic peptide; BNP, B-type natriuretic peptide; CI, cardiac index; CTR, cardiothoracic ratio on chest film; LVEDD, left ventricular end-diastolic dimension on echocardiogram; LVEF, left ventricular ejection fraction; NSVT, nonsustained ventricular tachycardia; PCW, pulmonary capillary wedge pressure; PNE, plasma norepinephrine; VO_2, oxygen consumption on cardiopulmonary exercise testing; VT, ventricular tachycardia.

and comorbid conditions, the risk-adjusted operative mortality (death before discharge or within 30 days of surgery) was 11.7% for heart failure patients, 6.6% for ischemic heart disease patients, and 6.2% for controls. Further, the risk-adjusted 30-day re-admission rates were 20% for the heart failure cohort compared with 14% for the ischemic population and 11% for age-match controls. The presence of a third heart sound or signs of overt heart failure clearly identifies patients at increased risk for adverse outcome during noncardiac surgical procedures [11]. Every effort must be made to detect unsuspected heart failure by careful evaluation and to optimize therapy before embarking on nonemergent procedures.

Fonarow et al., using the ADHERE registry data on over 33,000 hospitalizations has performed the most detailed risk stratification of in-hospital mortality in acute decompensated heart failure [12]. The best single predictor for morality was high admission level of blood urea nitrogen (>43 mg/dL), followed by an admission systolic blood pressure below 115 mm Hg, and a serum creatinine level >2.75 mg/dL. Using these three variables, patients could be readily stratified into groups at low, intermediate, and high risk for in-hospital mortality with rates ranging from 2.1% to 21.9% [12]. Additional predictive variables in other studies include troponin release, markedly elevated natriuretic peptide levels, and hyponatremia [13].

PHARMACOLOGICAL MANAGEMENT OF ADVANCED HEART FAILURE

Heart failure that persists after correction of potentially reversible causes (i.e., anemia, hyperthyroidism, valvular heart disease, myocardial ischemia) should be treated with dietary sodium restriction, diuretics for volume overload, vasodilator therapy (particularly angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor antagonists),and a beta-adrenergic blocker (Fig. 33.1). Sodium restriction (<4 g per day) is generally indicated for patients with advanced symptoms [14]. Likewise, most patients with advanced heart failure require a 1.5 to 2 L per day fluid restriction.

Diuretics

Diuretics remain the mainstay for "congestive symptoms" but have not been shown to improve survival. Neurohormonal activation (as measured by circulating renin, angiotensin, endothelin, and BNP) has been shown to acutely decrease during short-term diuretic therapy administered to lower markedly elevated filling pressures [15]. Two pharmacologic classes of agents are relevant to acute heart failure management: loop diuretics and distal tubular agents (Table 33.2). The loop diuretics (e.g., furosemide, torsemide, bumetanide, and ethacrynic acid) are the most potent. Some data suggest that torsemide and bumetanide may be more effective than furosemide in advanced heart failure, perhaps due to superior absorption from the gastrointestinal tract in the setting of elevated right-sided filling pressures [15]. Although once daily dosing of loop diuretic is usually effective for outpatient therapy, patients with persistent symptoms or those with marked hemodynamic instability during hospitalization often require dosing two or three times a day to adequately manage volume overload.

Thiazide diuretics such as hydrochlorothiazide and metolazone act mainly by inhibiting reabsorption of sodium and chloride in the distal convoluted tubule of the kidney. Used alone, thiazides produce a fairly modest diuresis; these agents are ineffective when glomerular filtration rate (GFR) falls below 40 ml per minute [15].

Diuretic tolerance is often encountered in patients with advanced heart failure. Lack of response to diuretic therapy may be caused by excessive sodium intake, use of agents that antagonize their effects (particularly nonsteroidal anti-inflammatory drugs), worsening renal dysfunction, addition of potentially nephrotoxic agents during hospitalization or compromised renal blood flow due to worsening cardiac function. Combined intravenous loop diuretic plus thiazide creates a synergistic response and should be considered for patients who fail to diurese despite optimal doses of an intravenous loop diuretic alone. Metolazone is particularly effective when administered with a loop diuretic. High-dose furosemide when administered as a continuous infusion (1 to 10 mg per hour) may also be more effective than bolus administration for hospitalized patients [16].

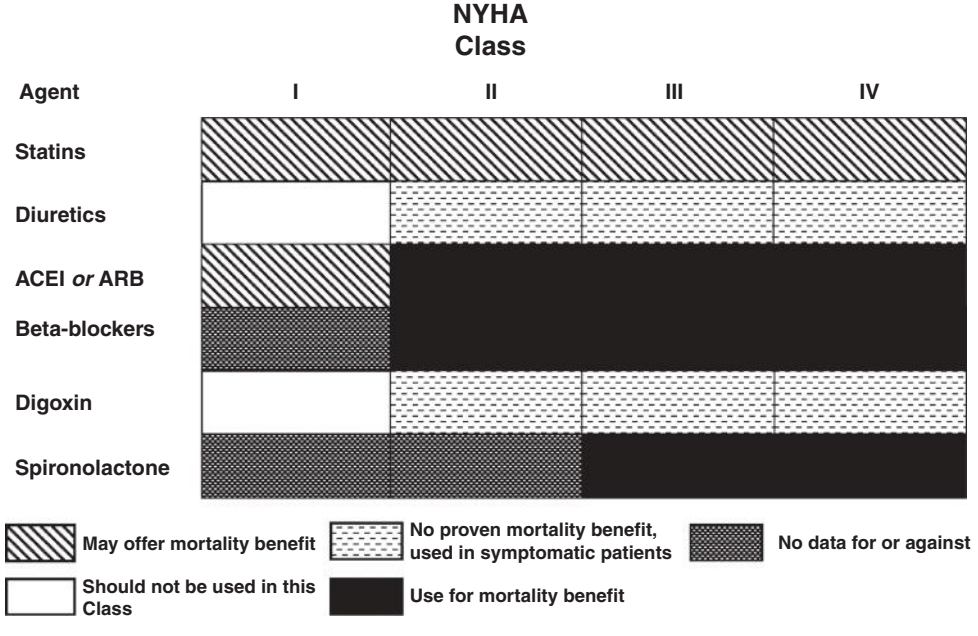

FIGURE 33.1. Standard pharmacological approach to heart failure based upon agent and severity of clinical heart failure symptoms [From Eichhorn E: Current pharmacologic treatment of heart failure. *Clin Cardiol* 22:V21–V29 (Figure 1), 1999, with permission.]

TABLE 33.2

INTRAVENOUS DIURETIC REGIMENS FOR TREATING DECOMPENSATED HEART FAILURE

Drug	Initial dose	Maximal single dose
Loop diuretics		
Furosemide	40 mg	200 mg
Bumetanide	1 mg	4–8 mg
Torsemide	10 mg	100–200 mg
Thiazide diuretics		
Chlorothiazide	500 mg	1,000 mg
Synergistic nephron blockade		
Chlorothiazide	500–1,000 mg + loop diuretics 1–4 × per day	
Metolazone	2.5–10 mg PO + loop diuretic 1–2 × per day	
Intravenous infusions		
Furosemide	40 mg IV loading dose; then 5–40 mg/hour infusion	
Bumetanide	1–2 mg IV loading dose; then 0.5–2 mg/hour infusion	
Torsemide	20 mg IV loading dose; then 5–20 mg/hour infusion	

IV, intravenous; PO, by mouth.

Elevated vasopressin levels play an important role in mediating fluid retention and contributing to hyponatremia. Short-term treatment with the V2-receptor antagonist, tolvaptan, has been shown to lower filling pressures, enhance diuresis, correct hyponatremia, and improve renal function [17]. However, tolvaptan had no effect on long-term mortality or heart-failure–related morbidity in a study of over 500 hospitalized with acute decompensated failure [17]. Thus, the role of this class of agents remains uncertain.

Ultrafiltration using a venovenous access approach is now feasible and potentially useful for acutely lowering elevated ventricular filling pressures when conventional high-dose combination diuretic therapy fails to produce adequate diuresis. Small, short-term observational studies suggest improvements in weight loss during hospitalization but have not demonstrated decreased length of stay or better preservation of renal function [18]. The UNLOAD trial randomized 200 patients with acute decompensated heart failure to standard intravenous diuretics versus ultrafiltration and demonstrated greater weight loss at 48 hours in the ultrafiltration cohort [19]. Readmissions for heart failure were also lower at 90 days (32% vs. 18%) for the ultrafiltration group. However, no comment was made on overall rehospitalization rates. No difference in in-hospital or outpatient renal function was observed between treatment groups [19]. Importantly, hemodynamic instability has been an exclusion criterion in all published studies. The latest ACC/AHA practice guidelines recommend ultrafiltration as a class IIA therapeutic option for heart failure that remains refractory to conventional diuretic therapy [14]. Additional prospective controlled trials are needed to establish the exact role of this new treat modality.

Vasodilator Therapy

Vasodilators remain a cornerstone of acute and chronic heart failure management [14]. Mechanisms of action vary and include a direct effect on venous capacitance vessels (e.g., nitrates), arterioles (e.g., hydralazine), or balanced effects (sodium nitroprusside, ACE inhibitors, and angiotensin II receptor blockers [ARBs]). Drugs that produce balanced venous and arteriolar dilatation should generally be chosen as first-line therapy since both preload and afterload are elevated in decompensated heart failure. However, in the ICU setting, it may sometimes be useful to use nitrates to reduce markedly elevated preload or hydralazine to treat elevated afterload for short periods of time. ACE inhibitors play a crucial role by altering the vicious cycle of hemodynamic abnormalities and neurohormonal activation that characterize advanced heart failure. Randomized, controlled clinical trials have demonstrated the beneficial effects of ACE inhibitors on functional capacity, neurohormonal activation, quality of life, and long-term survival in patients with chronic heart failure due to left ventricular systolic dysfunction (Table 33.3). There is compelling evidence that ACE inhibitor therapy should be prescribed whenever feasible in all symptomatic heart failure patients. Despite their unequivocal benefits, only 60% to 75% of all heart failure patients currently receive these agents [20]. The elderly and patients with advanced heart failure symptoms are least likely to receive this therapy [20]. It is especially important to recognize in patients with advanced heart failure that even low doses of vasodilator treatment confer benefit. Low-dose treatment should be considered for patients with marginal blood pressure (i.e., systolic pressure >80 to 90 mm Hg) to permit the subsequent introduction of beta-blockers. An ACE inhibitor should be initiated for any patient who experiences a transmural myocardial infarction during hospitalization as postinfarction trials have shown 10% to 27% reduction in all-cause mortality and 20% to 50% reduction in the subsequent risk of developing overt heart failure when these agents are begun following acute infarction [21].

Alternative therapy with combination hydralazine and nitrates should be considered for patients with marginal renal function (creatinine >2.5 mg per dL) and those with previously documented intolerance to ACE inhibitors or ARBs. Similar hemodynamic goals can be achieved with these agents among patients with advanced NYHA Class III or IV heart failure [22]. Women appear somewhat less responsive to ACE inhibitor therapy than do men [23]. Important racial differences may also exist in pharmacologic responsiveness to different vasodilator regimens. Two retrospective analyses from large trials confirmed ACE inhibitor therapy to be less effective in blacks than whites with heart failure of comparable severity [24]. The African-American Heart Failure trial (A-HeFT) confirmed the

TABLE 33.3

INHIBITORS OF THE RENIN–ANGIOTENSIN–ALDOSTERONE SYSTEM AND BETA-BLOCKERS USED FOR ADVANCED HEART FAILURE DUE TO SYSTOLIC DYSFUNCTION

Drug	Initial dose	Maximal dose
ACE inhibitors		
Captopril	6.25 mg three times daily	50 mg three times daily
Enalapril	2.5 mg twice daily	20 mg twice daily
Lisinopril	2.5 mg daily	40 mg daily
Fosinopril	5 mg daily	40 mg daily
Ramipril	1.25 mg daily	10 mg daily
Quinapril	5 mg twice daily	20 mg twice daily
Trandolapril	1 mg daily	4 mg daily
Angiotensin receptor blockers		
Losartan	25 mg daily	100 mg daily
Valsartan	20 mg twice daily	160 mg twice daily
Candesartan	4 mg daily	32 mg daily
Aldosterone antagonists		
Spironolactone	12.5 mg every other day	25 mg twice daily
Eplerenone	25 mg daily	50 mg daily
Beta-adrenergic blockers		
Metoprolol XL/CR[a]	12.5 mg daily	200 mg daily
Carvedilol	3.125 mg twice daily	50 mg twice daily
Bisoprolol	1.25 mg daily	10 mg daily

[a] Metoprolol succinate, extended release.

benefit of hydralazine and isosorbide dinitrate in this population; this combination should be considered when initiating therapy for hospitalized black patients [25].

ARBs are now also considered suitable first-line therapy for heart failure patients [14]. These drugs should be selected for ACE-inhibitor intolerant, non–African-American patients who experience rash or cough with an ACE inhibitor. They cannot be used for patients who experience ACE-inhibitor–related deterioration in renal function, hypotension, or hypokalemia [25]. Symptomatic and mortality benefits appear comparable between ACE inhibitors and ARBs [14]. For patients with advanced heart failure, the addition of a low-dose ARB to standard therapy with ACE inhibitor and beta-blocker provides significant morbidity benefit with reduction in recurrent hospitalizations but no mortality benefit [26]. A modest reduction in maintenance ACE inhibitor dose may be necessary to introduce an ARB in this population.

Digitalis

Digoxin continues to have an important role in the management of patients with advanced NYHA class III–IV symptoms [14]. The drug has mild positive inotropic effect on cardiac muscle, reduces activation of the sympathetic and renin angiotensin systems, and partially restores the favorable inhibitory effects of cardiac baroreceptor function. Short- and long-term controlled trials have provided unequivocal evidence that chronic digoxin administration increases left ventricular ejection fraction, improves exercise capacity, decreases advanced heart failure symptoms, and reduces heart failure associated hospitalizations [27]. Post hoc analysis has shown that patients most likely to demonstrate a favorable response had severe symptoms, greater degrees of left ventricular dysfunction, lower ejection fractions, and the presence of a third heart sound [27]. A prespecified subgroup analysis of patients enrolled in the Digitalis Investigation Group (DIG) trial provide confirmatory evidence that patients with severe heart failure (LVEF <25% or CT ratio >0.55) showed the greatest benefit [27]. The drug has neutral effects on all-cause and cardiovascular mortality [27]. As renal function may fluctuate considerably during hospitalization, measurement of serum digoxin levels is important [28]. Retrospective subgroup analysis has suggested an increased risk of all-cause mortality among both women and men who have digoxin levels >1.0 ng/dL [28]. Poor renal function, small lean body mass, and elderly patients are at greatest risk for developing digoxin toxicity during standard maintenance dosing. In addition, a number of commonly used drugs including verapamil, flecainide, spironolactone, and amiodarone will significantly increase serum digoxin levels. For adult patients with normal renal function, a dosage of 0.25 mg per day is appropriate. For patients at increased risk of toxicity, the initial starting dose should be 0.125 mg daily and up-titrated as necessary to achieve a trough level of 0.5 to 0.9 ng per dL.

Beta-Adrenergic Blockers

Three distinct classes of beta-blockers are now available for clinical use. Propranolol and other "first-generation" compounds such as timolol are nonselective agents with equal affinity for β_1 and β_2 receptors [29]. Metoprolol and bisoprolol are "cardioselective" second-generation compounds that block the β_1 receptor to a greater extent than the β_2 receptor. Metoprolol is approximately 75-fold more selective for β_1 than β_2 receptors while bisoprolol is 120-fold more selective [29]. Labetalol, carvedilol, and bucindolol are third-generation compounds that block β_1 and β_2 receptors with almost equal affinity. These agents also have ancillary properties including

α_1-blockade (labetalol and carvedilol), antioxidant properties (carvedilol), and intrinsic sympathomimetic activity (ISA) (bucindolol). Specific beta-blockers have been shown to lower all-cause mortality and decrease heart failure hospitalizations in a variety of randomized controlled trials in patients with NYHA class II–IV symptoms (Table 33.3) [30,31]. The mortality benefits of beta-blocker therapy in patients with advanced (NYHA class IV) heart failure symptoms have been established. The Carvedilol Perspective Randomized Cumulative Survival (COPERNICUS) trial evaluated patients with severe symptoms and LVEF <25% [32]. Carvedilol reduced all-cause mortality by 35%, the combined risk of death or cardiovascular hospitalization by 27%, and the risk of death or heart failure hospitalization by 31% [32]. Importantly, carvedilol-treated patients spent 40% fewer days in the hospital for acute heart failure decompensation [32]. It is appears that not all beta-blockers have equivalent benefits in heart failure. For example, bucindolol, a third-generation nonselective beta-blocker with ISA properties, was not associated with statistically significant reductions in overall mortality amongst patients with advanced heart failure. As such, unlike ACE inhibitors or ARBs, the specific beta-blockers validated in clinical trials should be prescribed. The effectiveness of these agents appears equal among men and women with advanced heart failure [33]. Clinicians should consider initiating carvedilol as first-line therapy, given its broader antiadrenergic effects whenever possible. However, for patients with marginal blood pressure in whom alpha blockade may be deleterious, metoprolol or bisoprolol may be suitable first-line agents.

A small minority of patients with advanced heart failure (<10%) are unable to tolerate even the lowest doses during initial attempts at drug introduction. Some investigators are now combining a phosphodiesterase inhibitor (enoximone or milrinone) with a beta-blocker [34]. Phosphodiesterase-III inhibitors improve hemodynamics and exercise performance but increase the risk of exacerbating myocardial ischemia and promoting ventricular arrhythmias. Theoretically, beta-blockers should counteract the ischemic and arrhythmic properties of these agents and provide synergistic benefits. Small uncontrolled short-term studies suggest that this approach may be beneficial in hospitalized patients with refractory heart failure [34]. Several randomized clinical trials are now evaluating the safety and efficacy of combination therapy.

Beta-blocker treatment should be attempted in all patients including those with advanced heart failure. For patients entering the intensive care unit who have not received such therapy, treatment should be initiated at very low doses and gradually up-titrated every few days or within 1 week. The usual starting doses are carvedilol 3.125 mg twice daily or metoprolol succinate 6.25 mg twice daily. Beta-blockers should not be initiated until optimal volume status and hemodynamic stability have been achieved.

The majority of chronic heart failure patients requiring hospitalization are already beta-blocker treated. In general, beta-blockers should not be withdrawn unless bradycardia or hemodynamic instability develops, due to the risk of rebound hypertension and tachycardia. Where necessary to facilitate management of acute decompensated heart failure, a 50% reduction in the ambulatory dose is often preferable to drug cessation. In a retrospective observational study of more than 2,300 patients eligible to receive beta-blocker during hospitalization, Fonarow et al. demonstrated that continuation of beta-blocker was associated with a significantly lower risk in propensity-adjusted postdischarge death and rehospitalization rates compared with the absence of beta-blocker [35]. Further, beta-blocker withdrawal was associated with a substantially higher adjusted risk for mortality (hazard ratio: 2:3) compared to continuation of beta-blockade.

Aldosterone Antagonists

Circulating aldosterone levels are elevated in relationship to heart failure severity, affect prognosis, and contribute to left ventricular remodeling following acute myocardial infarction. Potential deleterious effects include endothelial dysfunction, increased oxidative stress, enhanced platelet aggregation, activation of matrix metalloproteinase, and increased sympathetic activation. The mineralocorticoid receptor antagonist (MRA) spironolactone has been shown to reduce mortality in patients with severe heart failure by 30% [36]. Results of the EPHESUS trial confirm that eplerenone, a more selective MRA, can also reduce morbidity and mortality amongst patients with evidence of systolic dysfunction and heart failure following acute myocardial infarction [37]. The beneficial effects of MRAs appear to be independent of their diuretic actions, and likely relate to interruption of the downstream effects of aldosterone activation.

Spironolactone and eplerenone should not be initiated in the ICU setting. Both can be associated with serious hyperkalemia, particularly in the presence of impaired renal function or other medications which impair potassium excretion. They should be considered for addition to the patient's medical regimen prior to discharge following optimization of other heart failure therapies. Patients who have been receiving these agents should continue taking them during hospitalization unless marked hemodynamic instability, electrolyte disturbances, or worsening renal function ensue.

INTENSIVE CARE MANAGEMENT OF ADVANCED HEART FAILURE PATIENTS

Compensated Heart Failure States

A significant number of patients with advanced heart failure are hospitalized each year for management of noncardiac illnesses. Several principles apply to the in-hospital management of patients with compensated disease. Every attempt should be made to maintain the patient on the medical regimen that has provided optimal outpatient stability. Daily weights as well as a fluid restriction should be instituted for patients with advanced disease. Establishing a baseline weight and maintaining it through diuretic dosing adjustments is critical to prevent an acute decompensation. Diuretics should be switched to intravenous administration whenever questionable oral absorption (i.e., postoperative state) is expected. Once daily ACE inhibitor or ARB therapy is ideal for outpatient management to enhance compliance; however, if hemodynamic instability is anticipated during hospitalization, a temporary switch to a short-acting agent (e.g., captopril in place of lisinopril) should be considered. Among patients with deteriorating renal function, it may be necessary to withhold the ACE-inhibitor or ARB and transiently substitute hydralazine and nitrates, particularly when creatinine exceeds 3.0 mg per dL. Beta-blocker dosing should remain unchanged and may require a modest increase if atrial tachyarrhythmias are encountered in the postoperative state (see later). Serum electrolytes should be followed frequently, given the potential for electrolyte disarray (e.g., hypokalemia or hypomagnesemia) to potentiate atrial and ventricular arrhythmias in vulnerable patients. Despite marked reduction in LVEF, the majority of patients who require hospitalization for noncardiovascular illness will remain compensated with regard to their heart failure symptoms employing a continued maintenance regimen.

Decompensated Heart Failure States

Heart failure decompensation is the most common cause for hospitalization for patients over 65 years of age. Stevenson has popularized a 2-minute clinical assessment to ascertain the hemodynamic profiles for heart failure patients (Fig. 33.2) [23,38]. Patients are characterized in 2 × 2 fashion according to the presence or absence of congestion and low perfusion on physical examination [23]. The clinical profiles thus defined have been shown to correlate reasonably well with direct hemodynamic measurements of filling pressure and cardiac output and are correlated with prognosis following hospital discharge [23]. "Warm and dry" patients have normal resting hemodynamics and are well compensated. For these patients, other potential etiologies for dyspnea or fatigue should be considered. The majority (70% to 80%) of patients admitted with worsening symptoms fit the "warm and wet" profile. These individuals are volume overloaded but have adequate end-organ perfusion. The primary treatment goal is thus relief of "congestive" symptoms using intravenous loop diuretics alone or in combination with a thiazide. Those who fail to respond to escalating doses of intravenous loop diuretics may benefit from a continuous intravenous loop diuretic infusion. The small minority of patients with refractory volume overload may benefit from continuous venovenous hemofiltration (CVVH) or ultrafiltration [14,38]. Although neurohormonal antagonists including ACE-inhibitors, ARBs, and beta-blockers should ideally be maintained during periods of acute heart failure decompensation, for patients that are difficult to diurese or hypotensive, downward dose adjustment or temporary suspension (particularly of beta-blockers) should be considered. A very small minority of patients (<5%) fall into the "cold and dry" profile. These individuals have impaired cardiac output but do not adequately use the Starling mechanism to increase preload. Judicious hydration should be attempted. Patients who fail to demonstrate improvement in end-organ perfusion may require a short-term infusion of a positive inotropic agent such as dobutamine or milrinone.

Hemodynamically Guided Therapy

Approximately 10% to 15% of patients with advanced heart failure will demonstrate marked hemodynamic deterioration on admission ("cold and wet" profile). These patients have impending cardiogenic shock. Potential causes for acute decompensation such as recent myocardial infarction, rhythm change, worsening valvular disease, or medical/dietary nondiscretion should be sought. The ESCAPE trial randomized patients with acute decompensation without hemodynamic compromise to conventional medical management based on physical findings and symptoms versus tailored hemodynamic monitoring following insertion of a pulmonary artery catheter. Somewhat surprisingly, outcomes did not differ between the two management strategies [39]. Certain high-risk subgroups may, nonetheless, benefit from short-term hemodynamic monitoring for management of acute decompensated heart failure. Principal indications for hemodynamic monitoring with a pulmonary artery catheter include evidence of worsening end-organ dysfunction, need for withholding vasoactive medications due to hypotension, heart failure associated with other comorbidities (i.e., unstable angina or valvular heart disease) or inability to wean positive inotropic support (Table 33.4). "Tailored" hemodynamic treatment for refractory heart failure is outlined in Table 33.5. Following initial assessment of baseline hemodynamics, intravenous diuretics, vasodilators, or positive inotropes are administered to achieve desired hemodynamic

TABLE 33.4

INDICATIONS FOR HEMODYNAMIC MONITORING IN DECOMPENSATED HEART FAILURE

- Ongoing congestive symptoms and suspected end-organ hypoperfusion
  - Narrow pulse pressure
  - Declining renal function
  - Mental confusion
  - Cool extremities
  - Hypotension on ACE or ARB
  - Progressive hyponatremia
- Heart failure and other medical comorbidities
  - Cardiac: unstable angina pectoris; stenotic valvular lesions, hypertrophic cardiomyopathy
  - Noncardiac: severe obstructive or restrictive pulmonary disease, advanced renal disease, sepsis
- Other situations
  - Perioperative monitoring to optimize status for high-risk procedure
  - Symptoms disproportionate to clinical assessment of degree of compensation
  - Uncertain volume status
  - Inability to wean inotropic support

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker.

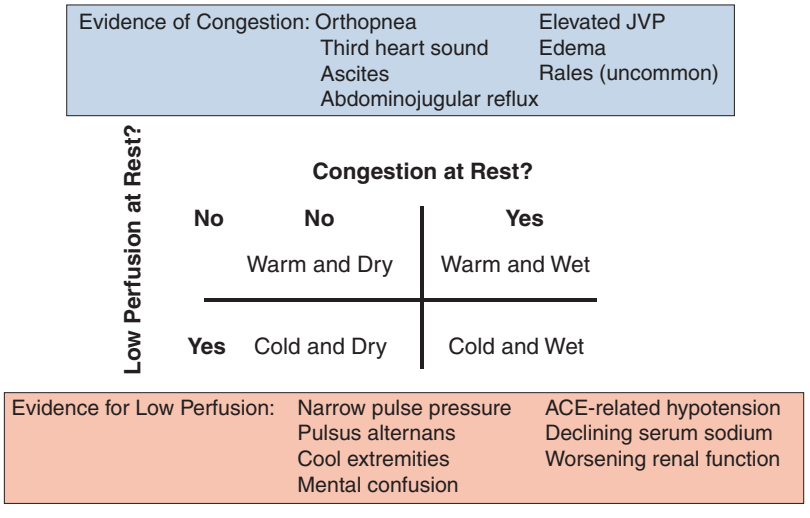

FIGURE 33.2. Diagram of hemodynamic profiles for patients presenting with heart failure symptoms. Most patients with advanced heart failure can be classified accurately in a 2-minute assessment of their physical findings and symptoms. [From Nohria J, Lewis E, Stevenson LW: Medical management of advanced heart failure. *JAMA* 287:639 (Figure 1), 2002, used with permission.]

TABLE 33.5

PRINCIPLES OF HEMODYNAMIC TAILORED HEART FAILURE THERAPY

- Measure baseline resting hemodynamics (CVP, PAP, PCW, CI, SVR)
- Administer intravenous diuretics, vasodilator (nitroprusside, nitroglycerin, or nesiritide) or inotropic agent (milrinone or dobutamine) dosed to achieve specific hemodynamic goals:
  - Pulmonary capillary wedge pressure <16 mm Hg
  - Right atrial pressure <8 mm Hg
  - Cardiac index >2.2 L/min/m^2
  - Systemic vascular resistance <1,000–1,200 dynes/sec/cm^5
  - Systolic blood pressure >80 mm Hg
- Maintain optimal hemodynamics for 24–48 hours
- Up-titration of oral vasodilators as intravenous vasodilators are weaned
- Adjust oral diuretics to keep optimal volume status

CI, cardiac index; CVP, central venous pressure; PAP, pulmonary artery pressure; PCW, pulmonary capillary wedge pressure; SVR, systemic vascular resistance.
Adapted from Stevenson LW: Tailored therapy to hemodynamic goals for advanced heart failure. *Eur J Heart Fail* 1:251–257, 1999 (Table 2, page 254), used with permission.

goals which generally include a pulmonary capillary wedge pressure below 15 mm Hg and a cardiac index above 2.2 L per minute per m^2. This intravenous program is maintained for 24 to 48 hours to effect desired diuresis and improve end-organ perfusion. Following this stage, oral vasodilators are up-titrated as intravenous agents are weaned. Further adjustment in diuretic dose and ambulation should be completed during the final 24 to 48 hours of hospitalization. This "tailored approach" produces sustained improvement in filling pressures, forward cardiac output, decreased mitral regurgitation, and decreased neurohormonal activation [23]. Oral vasodilator therapy and beta-blockers should be withheld during treatment with intravenous vasoactive agents.

Considerable controversy continues to exist regarding the relative roles of intravenous vasodilator drugs (i.e., nitroglycerin, nitroprusside, or nesiritide) versus positive inotropic agents (dobutamine, dopamine, or milrinone) in this population. Previously, inotropic infusions have been used for patients with moderate heart failure to promote brisk diuresis. These agents, however, are associated with an increased risk of ischemic events and tachyarrhythmias [40]. A second major limitation of short-term inotropic support is the additional complexity needed to readjust oral regimens as the infusions are weaned [23]. Although positive inotropes should not be routinely used for "warm and wet" patients, these agents can be life saving for patients with rapidly progressive hemodynamic collapse [38]. Patients who present or develop obtundation, anuria, persistent hypotension, or lactic acidosis may only respond to inotropic support, which should be continued until the cause of cardiac deterioration is determined and definitive therapy implemented. Brief inotropic treatment may also be appropriate for patients who develop the cardiorenal syndrome. It should be emphasized, however, that many patients with low cardiac output have high systemic vascular resistance that predictably improves with vasodilator therapy alone, obviating the need for inotropic support [23,38]. In-hospital mortality has also been shown to be lower for nonhemodynamically compromised patients treated with intravenous vasodilators compared to positive inotropes [41]. Intravenous nitroprusside, a direct nitrovasodilator, rapidly lowers filling pressures and improves cardiac output, which in turn, improves response to diuretic therapy. Hemodynamically monitored nitroprusside infusions rarely cause systematic hypotension but may be complicated by thiocyanate toxicity, particularly when high doses are required for prolonged periods of time in patients with preexisting hepatic or renal dysfunction. Intravenous nitroglycerin also produces arterial and venous dilatation but is less effective than nitroprusside. Nesiritide, a human recombinant form of endogenous BNP, rapidly improves symptoms. It has largely been used for patients demonstrating the "warm and wet" hemodynamic profile rather than those with more advanced "cool and wet" profiles. A small study suggested that short-term in-hospital nesiritide administration resulted in fewer rehospitalizations for heart failure and lower 6-month mortality following discharge compared with dobutamine [42]. However, the safety of nesiritide has been questioned and the hope that this agent would attenuate renal dysfunction during heart failure treatment has not been realized [43]. Two retrospective post hoc analyses have suggested short-term nesiritide treatment may be associated with worsening renal function and may increase short-term mortality risk. Further, it has not been studied extensively in patients with hypotension or hypoperfusion. The ongoing ASCEND-HF trial of 4,500 patients will address the safety and efficacy of short-term nesiritide therapy in acute decompensated heart failure. Table 33.6 summarizes vasaactive agents used to manage of acute decompensated heart failure.

Biomarker-Guided Therapy

The use of serial BNP or NT-pro-BNP to guide therapy remains controversial. Small, controlled trials in ambulatory patients

TABLE 33.6

INTRAVENOUS VASOACTIVE AGENTS FOR DECOMPENSATED HEART FAILURE

Drug	Initial dose	Maximal dose
Vasodilator		
Nitroprusside	0.20 μg/kg/min	10 μg/kg/min
Nitroglycerin	10 μg/kg/min	1,000 μg/kg/min
Nesiritide	Loading dose: 2 μg/kg/min Maintenance dose: 0.01 μg/kg/min	0.030 μg/kg/min
Positive inotropic agents		
Dobutamine	2.5 μg/kg/min	20 μg/kg/min
Milrinone	Loading dose: 50 μg/kg Maintenance dose: 0.375 μg/kg/min	0.75 μg/kg/min
Dopamine	2.5 μg/kg/min	20 μg/kg/min

with chronic heart failure demonstrated fewer heart failure rehospitalizations using BNP to adjust pharmacologic therapy. However, this approach recently failed to improve survival free of repeat hospitalizations or quality of life in a large cohort of patients [44]. A reasonable approach for inpatients with acute decompensated heart failure should include the measurement of BNP or NT-pro-BNP on admission and prior to discharge when the patient is euvolemic, both for prognostic purposes as well as to aid in tailoring postdischarge treatment [45]. Daily biomarker measurement does not add significant prognostic value. A fall of 30% or greater in BNP or NT-pro-BNP identifies patients at low risk at discharge. Conversely, a rise in either biomarker suggests worsening disease or inadequate therapy and should prompt a review of the patient's heart failure regimen.

PERIOPERATIVE MANAGEMENT OF ADVANCED HEART FAILURE PATIENTS

Nonemergent surgical procedures should be delayed until heart failure status has been optimized. Volume overload should be corrected and adequate oxygenation insured. Maintenance pharmacologic therapy including vasodilators, beta-blockers, and digitalis should be continued. A trough digoxin level should be checked and maintained below 1 ng per dL to minimize potential toxicity. Spironolactone should be withheld until stable hemodynamics and renal function have been achieved. Patients with refractory symptoms or deteriorating end-organ function should have a pulmonary catheter inserted to optimize their hemodynamics. Current evidence does not support the routine use of a pulmonary artery catheter for perioperative monitoring [11]. A single large-scale randomized clinical trial of pulmonary artery catheterization in high-risk surgical patients demonstrated no improvement in survival [46]. However, only 16% of patients enrolled in this trial had heart failure. Ejection fraction alone is insufficient to recommend the use of continuous hemodynamic monitoring. Many patients with markedly impaired ventricular function (LVEF <20%) may be well compensated on optimized pharmacologic therapy and undergo surgery without invasive monitoring. Conversely, some patients with only moderate impairment in LVEF may benefit from pulmonary artery monitoring when hemodynamic instability is anticipated. Practice guidelines for intraoperative hemodynamic monitoring published by the American Society of Anesthesiologists consider the severity of the patient's underlying cardiovascular disease, the type of surgical procedure, and the likelihood of major hemodynamic lability [47]. The extent of anticipated intraoperative and perioperative fluid shifts is another key factor. Current ACC/AHA guidelines recommend intraoperative pulmonary artery monitoring as a Class 2B indication as indicated for patients at risk for major hemodynamic disturbances that are easily detected by pulmonary artery catheter who are scheduled to undergo a procedure that is likely to cause these hemodynamic changes [11].

MANAGEMENT OF ARRHYTHMIAS

Atrial and ventricular arrhythmias are nearly ubiquitous in advanced heart failure patients and often contribute to clinical decompensation. Atrial fibrillation and flutter are the most commonly encountered supraventricular arrhythmias. The likelihood of atrial fibrillation increases with heart failure severity and approaches 40% for NYHA class III and IV patients. The potential adverse effects of atrial fibrillation include loss of atrioventricular synchrony, rapid or inappropriately slow ventricular response rates, variable diastolic filling times, and thromboembolic complications. Atrial fibrillation has been associated with increased mortality and more frequent hospitalizations in some, but not all, series [48]. Patients with a known history of chronic atrial fibrillation should have adequate heart rate control and anticoagulation whenever feasible (see later). Uncontrolled, sustained, rapid (>120 beats per minute) atrial fibrillation can result in a reversible dilated cardiomyopathy or, more typically, can worsen preexisting left ventricular systolic dysfunction. A heart rate below 100 beats per minute during modest ambulation is a reasonable goal. Beta-adrenergic blockers and digoxin remain first-line rate-controlled treatment options [4]. Calcium channel blockers (e.g., diltiazem and verapamil) should be avoided with advanced heart failure due to their negative inotropic effects. Amiodarone is a highly effective drug for rate control and is frequently useful for controlling persistent atrial arrhythmias in ICU patients [49].

Atrial fibrillation commonly occurs during hospitalization due to enhanced sympathetic stimulation. In all patients, thyroid function should be assessed to exclude hyperthyroidism as a contributor. For stable heart failure patients with atrial fibrillation initial therapy should focus on adequate rate control (HR <100 per minute) using digoxin or beta-blockers, with pharmacologic or electrical cardioversion reserved for those patients who in whom symptoms are refractory or those who are intolerant of conservative medical management. Patients who experience active angina pectoris or hemodynamic instability during new onset atrial fibrillation should undergo urgent synchronized cardioversion with initiation of an atrial-stabilizing agent to prevent recurrence. For heart failure patients in whom restoration or maintenance of sinus rhythm is desirable, amiodarone, dofetilide, and sotalol remain the most useful antiarrhythmic drugs [49]. In compensated heart failure, amiodarone is well tolerated from a hemodynamic standpoint. For patients with advanced heart failure symptoms or recent decompensation, the loading dose of amiodarone should be kept below 1,000 mg per day to prevent exacerbation of heart failure. Dronedarone, a new noniodinated derivative of amiodarone, has been shown to be effective for maintenance of sinus rhythm and rate-control in rapid atrial fibrillation [50]. However, increased mortality due to worsening heart failure has been reported in one recent controlled trial [1,49]. Until additional data are available, this agent should not be used for patients with severe systolic dysfunction or hemodynamic instability.

Dofetilide is a class III antiarrhythmic drug that blocks the repolarizing potassium current. It is highly effective in restoring sinus rhythm but is associated with torsades de pointes in up to 3% of patients [49]. Continuous ECG monitoring for the first 48 hours after initiation in the hospitalized patient is essential. Sotalol, an additional class III antiarrhythmic drug, may occasionally be substituted for other beta-blockers in heart failure patients, but carries with it a similar risk of torsades, and is generally less effective than amiodarone.

Asymptomatic nonsustained ventricular tachycardia (NSVT) occurs in over 50% of patients with NYHA class III/IV heart failure. Pharmacologic suppression of NSVT does not lower the risk of sudden death. Asymptomatic ventricular ectopy should be viewed as a marker of disease severity rather than a specific marker for sudden cardiac death risk [51]. Heart failure patients often develop frequent ventricular premature beats or short runs of NSVT during their ICU stay. Precipitating causes such as electrolyte disturbances (hypokalemia or hypomagnesemia), enhanced sympathetic tone, a decrease in beta-blocker dose, or withholding of prior antiarrhythmic therapy should be considered. The majority of patients have no symptoms and do not require pharmacologic

TABLE 33.7

RESULTS OF RANDOMIZED TRIALS OF PHARMACOLOGIC TREATMENT AND ULTRAFILTRATION IN ACUTE DECOMPENSATED HEART FAILURE

Intervention	Trial	Year	Study	No. of patients	Findings	Reference
Hydralazine-Nitrates	A-HeFT	2004	RCT	1,050	43% reduction in all-cause mortality in blacks	25
Carvedilol	COPERNICUS	2002	RCT	2,289	31% reduction in death or HF hospitalizations in NYHA class III/IV patients	32
Milrinone	OPTIME-CHF	2002	RCT	951	No reduction in hospitalizations for cardiac causes within 60 days of treatment with milrinone for ADHF	40
Ultrafiltration	UNLOAD	2007	RCT	200	UF resulted in greater weight loss and fewer rehospitalizations for heart failure	19
Pulmonary artery catheter (PAC) placement	ESCAPE	2005	RCT	433	PAC for tailoring of therapy did not lower mortality or rehospitalizations	39
Nesiritide vs. dobutamine	—	2002	Open label randomized	261	Nesiritide resulted in fewer readmissions and lower 6-month mortality than dobutamine	42
Nesiritide	NAPA	2007	RCT	279	Nesiritide improved renal function after CABG	

ADHF, acute decompensated heart failure; A-HeFT, African American Heart Failure Trial; CABG, coronary artery bypass grafting; COPERNICUS, Carvedilol Prospective Randomized Cumulative Survival Study; ESCAPE, Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness; NAPA, nesiritide-administered perianesthesia in patients undergoing cardiac surgery; RCT, randomized controlled trial; OPTIME-CHF, Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbation of Chronic Heart Failure.

suppression. Frequent runs of ventricular tachycardia or sustained monomorphic VT require antiarrhythmic treatment. Amiodarone (intravenous 0.50 to 1.0 mg/min) or lidocaine (0.5 to 2 mg per min) is generally most effective for acute management. Beta-blockers, sotalol, and amiodarone are effective long-term oral treatment options.

A growing percentage of advanced heart failure patients have implantable cardioverter defibrillators (ICDs) to treat symptomatic ventricular tachyarrhythmias or for primary prevention of sudden cardiac death. The ICD should be interrogated for any recent atrial or ventricular arrhythmias prior to admission and the device temporarily inactivated prior to surgical procedures that involve electrocautery. It should be reactivated and its function checked by an electrophysiologist in the early perioperative period.

Anticoagulation

Systemic anticoagulation is often a part of a heart failure patient's outpatient management. Studies have suggested that the risk of thromboembolic complications is lower than previously expected, averaging 1.5 to 3 episodes per 100 patient years when normal sinus rhythm is present. Current indications for systemic anticoagulation include paroxysmal or chronic atrial fibrillation, a history of thromboembolism, or echocardiographically documented left ventricular thrombus. Relative indications include a markedly dilated left ventricle (>75 mm) with severe systolic dysfunction and spontaneous echocardiographic contrast ("smoke") indicating sluggish intracavitary blood flow. The presence of a low ejection fraction alone is *insufficient* to warrant systemic anticoagulation. Warfarin should be continued with an INR goal of 2.0 to 3.0 if invasive procedures are not planned. If surgery or central venous catheter placement is required, warfarin can be reversed with vitamin K or fresh frozen plasma and transiently substituted with intravenous heparin or subcutaneous low-molecular weight heparin as feasible. For those patients who require anticoagulation but are unable to receive heparin (e.g., due to heparin-induced thrombocytopenia), alternative anticoagulants including the direct thrombin inhibitors argatroban and hirudin, or the pentasaccharide fondaparinux can be considered.

CONCLUSION

The patient with advanced heart failure requires special considerations. Meticulous attention to volume status and maintenance of appropriate vasodilator therapy and beta-adrenergic blockade form the cornerstones of acute management (Table 33.7). Negative inotropic drugs and agents that might further impair renal function should be avoided. Patients with refractory symptoms or recent decompensation may require hemodynamic monitoring via a pulmonary artery catheter and initiation of short-term vasoactive therapy including nitroprusside, nitroglycerin, nesiritide, milrinone, or dobutamine. Maintenance of sinus rhythm and suppression of recurrent ventricular tachyarrhythmias is mandatory. With careful management, hospital morbidity and mortality can be minimized despite the presence of severe ventricular systolic or diastolic dysfunction.

CHAPTER 34 ■ VALVULAR HEART DISEASE

GARRICK C. STEWART AND PATRICK T. O'GARA

The incidence of valvular heart disease continues to rise due to the increasing longevity of the population and remains a source of significant morbidity and mortality [1]. More than 5 million Americans are living with valvular heart disease and nearly 100,000 undergo valve surgery each year [2]. Patients with native or prosthetic valve disease constitute a significant proportion of intensive care unit (ICU) admissions. Many patients come to medical attention during an acute illness that triggers an abrupt change in cardiovascular physiology. While stabilization with medical management is possible for most patients with mild or moderate disease, surgery may be urgently required if severe disease is present. Prompt diagnosis often requires a high index of suspicion [3]. Timely cardiac imaging with transthoracic echocardiography (TTE) can define valve anatomy and lesion severity. Transesophageal echocardiography (TEE) may be required in select circumstances for better visualization and characterization. The need for an invasive hemodynamic assessment may follow. Early collaboration among intensivists, cardiologists, and cardiac surgeons is critical for optimizing patient outcome. This chapter will highlight an integrated approach to the diagnosis and treatment of the native and prosthetic valve diseases most commonly encountered in an ICU setting.

AORTIC STENOSIS

Aortic stenosis (AS) is a progressive disease for which there is no medical treatment. The ICU management of patients with AS may be quite challenging, particularly in the setting of concomitant medical illness. Characterizing the severity of stenosis is critical for determining the timing of surgical intervention and requires a careful history, physical examination, and initial imaging with TTE.

Etiology

AS accounts for one-quarter of all chronic valvular heart disease, with approximately 80% of symptomatic cases occurring in adult males (Fig. 34.1). Common etiologies of valvular AS include age-related calcific degeneration, stenosis of a congenitally bicuspid valve, and rheumatic heart disease. Age-related, degenerative calcific AS is the most common cause of AS among adults in the United States. More than 30% of adults older than 65 years exhibit aortic valve sclerosis, whereas only 2% have more significant valvular stenosis. The valve cusps are focally thickened or calcified in aortic sclerosis, with production of a systolic ejection murmur, but without significant outflow obstruction (peak jet velocity of <2.5 m per second). Recent studies suggest calcific AS is the end result of an active disease process rather than the inevitable consequence of aging [4]. There may also be a genetic predisposition to calcific degeneration of trileaflet valves [5]. The histologic appearance of a sclerotic valve is similar to atherosclerosis, with inflammation, calcification, and thickening. Both calcific AS and aortic sclerosis appear to be a marker for coronary heart disease events [6]. Older age, male sex, smoking, diabetes mellitus, hypertension, chronic kidney disease, and hypercholesterolemia are risk factors for calcific AS. Despite the compelling connection between atherosclerosis and calcific valve degeneration, high-dose lipid lowering therapy has thus far not been shown to retard the progression of AS in randomized trials [7,8].

Congenitally bicuspid aortic valves are present in 1% to 2% of the population, with a 4 to 1 male predominance, and seldom result in serious narrowing of the aortic orifice during childhood [9]. Abnormal valve architecture makes the two cusps susceptible to hemodynamic stresses, ultimately leading to thickening, calcification, and fusion of leaflets, and narrowing of the orifice. AS develops earlier in bicuspid valves, usually in the fifth or sixth decades, compared with trileaflet aortic valves, which usually do not exhibit calcific AS until the sixth or seventh decade of life [10]. Bicuspid aortic valves are also associated with aortic regurgitation (AR) and aortic root/ascending aortic dilatation and coarctation (Fig. 34.2). Up to 25% to 40% of patients with bicuspid aortic valve will have an ascending aortic aneurysm unrelated to the severity of the valve lesion. Patients with bicuspid aortic valves are susceptible to aortic dissection [11]. Medial degeneration similar to that seen in Marfan syndrome is responsible for aneurysm development in patients with a bicuspid aortic valve [12].

Rheumatic disease may affect the aortic leaflets leading to commissural fusion, fibrosis, and calcification, with narrowing of the valve orifice. Rheumatic AS is almost always accompanied by involvement of the mitral valve and concomitant AR. Radiation-induced AS as a sequela of cancer radiotherapy often occurs in conjunction with proximal coronary artery disease (CAD). Rare causes of valvular AS include Paget's disease of bone, rheumatoid arthritis, and ochronosis. By the time AS becomes severe, superimposed calcification may make it difficult to determine underlying valve architecture and the precise etiology.

In addition to valvular AS, other causes of left ventricular (LV) outflow obstruction include hypertrophic obstructive cardiomyopathy (HOCM), a congenitally unicuspid aortic valve, discrete congenital subvalvular AS resulting from a fibromuscular membrane, and supravalvular AS. The various causes of LV outflow obstruction can be differentiated by careful physical examination and TTE.

Pathophysiology

Obstruction to LV outflow produces a pressure gradient between the LV and the aorta (Fig. 34.3). The ventricle responds to this pressure overload with concentric hypertrophy, which is initially adaptive because it reduces wall stress and preserves ejection performance. The law of Laplace states that wall stress is directly proportional to the product of LV pressure and radius and inversely proportional to LV wall thickness. Compensatory hypertrophy may accommodate a large pressure gradient for years before it becomes maladaptive and LV function declines, with chamber dilatation and reduced cardiac output [13]. In the setting of AS with preserved ejection fraction (EF),

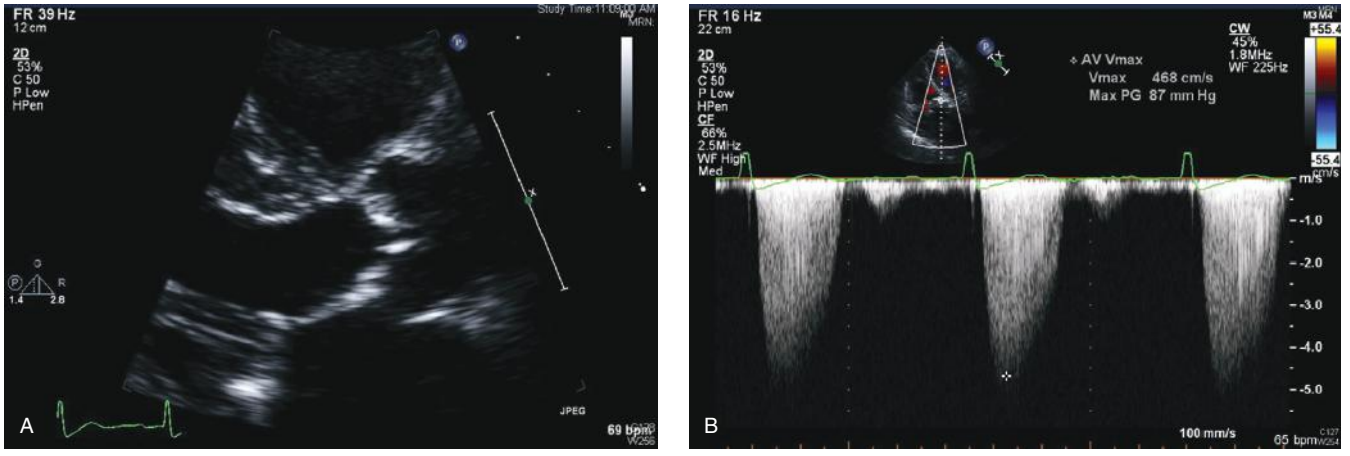

FIGURE 34.1. Transthoracic echocardiography of severe valvular aortic stenosis. **A:** Transthoracic echocardiogram parasternal long axis view of the aortic valve during systole. Aortic valve leaflets are thickened with severely restricted motion consistent with severe aortic stenosis. **B:** Transaortic continuous wave Doppler jet from the apical five-chamber view. Peak transaortic velocity is 4.68 m/sec, producing an estimated peak transaortic gradient of 87 mm Hg.

cardiac output may be normal at rest but fail to rise appropriately with exercise. Coronary flow reserve may be reduced because of the increased oxygen demand of the hypertrophied LV and increased transmural pressure gradient, and the longer distance blood must travel to reach the subendocardial layer. Taken together, these factors can contribute to subendocardial ischemia even in the absence of epicardial CAD [14]. The loss of appropriately timed atrial contraction, such as occurs with atrial fibrillation (AF), may cause rapid progression of symptoms because of the reliance on atrial systole to fill the stiff, hypertrophied LV.

No single parameter of valve structure or function is sufficient to define the severity of AS. Integration of the clinical history, physical examination, and TTE is required to place the lesion in context [15]. The physical examination of AS in the ICU may be particularly challenging, contributing to the greater importance of timely TTE. Echocardiographic criteria for severe AS in patients with normal underlying LV function include

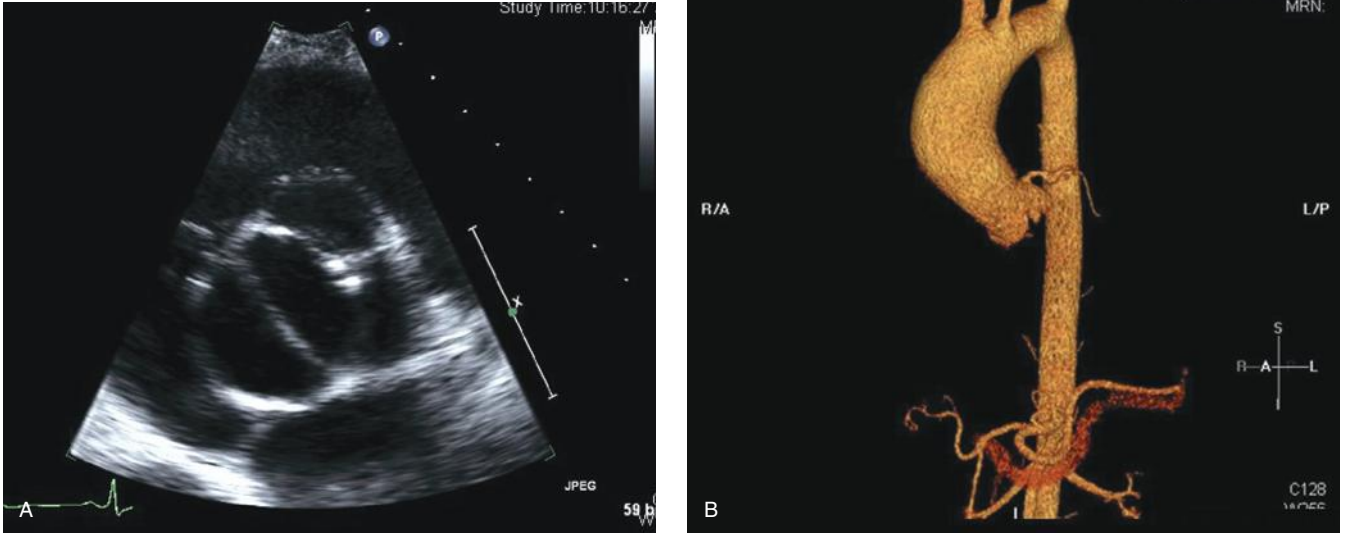

FIGURE 34.2. Bicuspid aortic valve and aortic root aneurysm. **A:** Transthoracic echocardiogram with parasternal short axis view at the level of the aortic valve reveals a bicuspid aortic valve with fusion of the left and noncoronary cusps. **B:** A 5.1-cm ascending aortic aneurysm in a 37-year-old man with bicuspid aortic valve disease and only moderate aortic stenosis (valve area, 1.2 cm^2). Patients with bicuspid disease frequently develop aneurysms of the ascending aorta independent of the severity of hemodynamic valvular impairment and are at risk for aortic dissection. Resection is indicated for maximal aneurysm size larger than 5.0 cm, an increase in aneurysm size of more than 0.5 cm/y, or at the time of aortic valve replacement if the aneurysm size exceeds 4.5 cm. [From Libby P (ed): *Essential Atlas of Cardiovascular Disease*. New York, NY, Springer, 2009, p 216, Figure 9–6, with permission.]

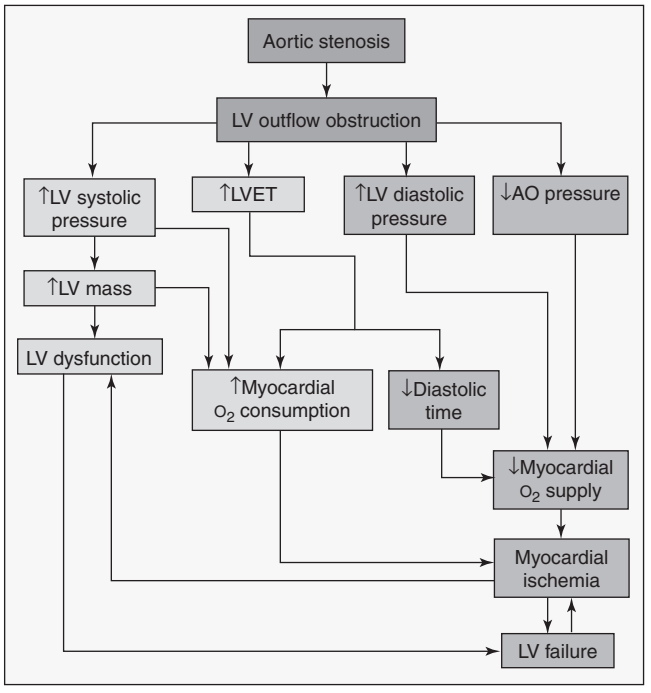

FIGURE 34.3. Pathophysiology of aortic stenosis. Left ventricular (LV) outflow obstruction results in a gradual increase in LV systolic pressure, an increase in LV ejection time (LVET), an increase in LV diastolic pressure, and a decrease in mean aortic (Ao) pressure. Increased LV systolic pressure results in compensatory LV hypertrophy (LVH), which may lead to LV dysfunction and failure. Increased LV systolic pressure, LVH, and prolonged LVET increase myocardial oxygen (O_2) consumption. Increased LVET results in a decrease in LV diastolic time (myocardial perfusion time). Increased LV diastolic pressure and decreased Ao diastolic pressure decrease coronary perfusion pressure, thereby decreasing myocardial supply. Increased myocardial O_2 consumption and decreased myocardial O_2 supply produce myocardial ischemia, which further compromises LV function. [Adapted from Bonow R, Braunwald E: Valvular heart disease, in Zipes D, et al. (eds): *Braunwald's Heart Disease*. Philadelphia, Elsevier, 2005, p 1585, with permission.]

calcified leaflets with reduced excursion, maximal transaortic jet velocity of more than 4 m per second, mean transaortic gradient of more than 40 mm Hg, or an effective aortic valve orifice of less than 1 cm^2 (Table 34.1). When there is underlying LV systolic dysfunction, severe AS may be present despite low transaortic velocity and mean gradient. Such patients are at particularly high risk for complications and require further evaluation to determine if true valvular AS is present or whether the reduced valve area relates to an underlying cardiomyopathy (pseudo-severe AS) [16].

Clinical Presentation

History

The cardinal symptoms of AS are dyspnea, angina, and syncope [17]. Exertional dyspnea is typically the first reported symptom and reflects an elevation in LV end-diastolic pressure transmitted to the pulmonary venous circulation. Some patients, particularly the elderly, may report generalized fatigue and weakness rather than dyspnea. Angina occurs in two thirds of patients with AS and is similar to that reported by patients with flow-limiting coronary atherosclerosis [18]. Syncope is effort related and due to cerebral hypoperfusion from a decrease in mean arterial pressure produced by the combination of peripheral vasodilatation in the presence of a fixed cardiac output or an inappropriate baroreceptor reflex. Severe AS is also rarely associated with acquired von Willebrand's disease related to sheering of von Willebrand multimers passing through the stenotic orifice [19]. As a result, gastrointestinal bleeding, epistaxis, or ecchymoses may be present in some patients.

TABLE 34.1

SEVERITY OF AORTIC STENOSIS

Severity of stenosis	Valve area (cm^2)	Mean gradient (mm Hg)	Jet velocity (msec)
Mild	>1.5	<25	<3.0
Moderate	1.0–1.5	25–40	3.0–4.0
Severe	<1.0	>40	>4.0

Most patients with AS have gradually increasing LV obstruction over many years, producing a long latent phase. During this clinically silent period, there is a very low risk of sudden death (<1% per year) [20]. The rate of AS progression is variable, with an average increase in mean gradient of 7 mm Hg and reduction in valve area of 0.1 cm^2 per year [21]. Symptoms from valvular AS are rare until the valve orifice has narrowed to approximately less than 1 cm^2. The onset of symptoms is a critical turning point in the natural history of the disease, usually indicates severe AS, and heralds the need for surgical evaluation and treatment because of the markedly reduced survival [17] (Fig. 34.4). An abrupt change in the natural history of AS may occur with AF, endocarditis, or myocardial infarction (MI), each of which may trigger acute decompensation [22].

Physical Examination

The hallmark of AS is a carotid arterial pulse that rises slowly to a delayed peak, known as *pulsus parvus et tardus*. In the elderly, stiffened carotid arteries may mask this finding. Similarly, patients with AS and concomitant AR may have preservation of the arterial upstroke due to an elevated stroke volume. The LV apical impulse may be displaced laterally with a sustained contour due to LV hypertrophy (LVH) and prolonged systolic ejection.

The murmur of AS is a systolic ejection murmur commencing shortly after S1, rising in intensity with a peak in mid ejection, then ending just before aortic valve closure. It is

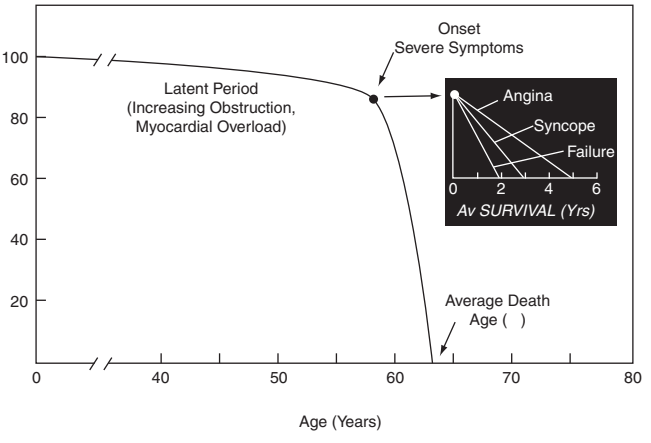

FIGURE 34.4. The onset of symptoms in patients with aortic stenosis initiates a rapid rise in the risk of mortality. Patients with angina have a better prognosis than those with syncope. [From Ross J Jr, Braunwald E: Aortic stenosis. *Circulation* 38(1S5):61–67, 1968, with permission.]

characteristically low-pitched, harsh, or rasping in character and best heard at the base of the heart in the second right intercostal space. The AS murmur radiates along the carotid arteries, though may sometimes be transmitted downward to the apex where it may be confused with the murmur of mitral regurgitation (MR) (Gallavardin effect). The murmur of AS is diminished with Valsalva maneuver and standing, in contrast to the murmur of hypertrophic cardiomyopathy which gets louder with these maneuvers. Often S2 becomes paradoxically split in severe AS because of prolonged LV ejection. An S4 is audible at the apex and reflects LVH with an elevated LV end-diastolic pressure. An S3 gallop generally occurs late in the course of AS when LV dilatation is present. Murmur intensity does not necessarily correspond to AS severity. The best predictors of AS severity on physical examination are a late peaking systolic murmur, a single S2 (absent aortic valve closure sound), and *pulsus parvus et tardus*. In patients with heart failure and a low cardiac output, the findings related to AS are less impressive.

Investigations

Electrocardiography

Most patients with severe AS will have evidence of LVH on electrocardiogram (ECG). Left atrial (LA) enlargement is common. Nonspecific ST and T wave abnormalities may be seen or evidence of LV strain may be apparent. Rarely, atrioventricular conduction defects may develop due to extension of perivalvular calcium into the adjacent conduction system. This finding is more common after aortic valve replacement (AVR). There is poor correlation between ECG findings and AS severity.

Chest Radiography

The chest radiograph may be normal in severe AS. There may be "poststenotic" dilation of the ascending aorta or a widened mediastinum if aortic aneurysmal dilatation is present in patients with a bicuspid aortic valve. LV chamber size is usually normal, though aortic valve calcification may be seen, especially on the lateral film. Valvular calcium deposits can be visualized using fluoroscopy during cardiac catheterization, chest computed tomography (CT), or TTE. A normal radiograph does not exclude severe AS. In the later stages of AS, the LV dilates leading to a widened cardiac silhouette, often accompanied by pulmonary congestion.

Echocardiography

TTE with Doppler is indicated for assessing the severity of AS. TTE visualizes aortic valve structure, including the number of cusps, degree of calcification, leaflet excursion, annular size, and supravalvular anatomy. Eccentric valve cusps are characteristic of congenitally bicuspid aortic valves, often accompanied by aneurysmal enlargement of the root or ascending aorta. TTE is also useful for identifying coexisting valvular disease, differentiating valvular AS from other forms of LV outflow tract obstruction, assessing pulmonary artery systolic pressure, and evaluating underlying biventricular function. The peak transvalvular jet velocity on continuous wave Doppler is critical for assessing AS severity. Peak and mean transvalvular gradients are derived from the jet velocity using the modified Bernoulli equation and the aortic valve area is estimated from the continuity equation. The dimensionless index, which is the ratio of LV outflow tract velocity to peak aortic velocity, can also be used to estimate AS severity when measurement of LV outflow tract diameter is difficult due to extensive calcification. A dimensionless index less than 0.25 is consistent with severe AS [15].

Cardiac Catheterization

Noninvasive assessment with TTE is now standard, but catheterization may be helpful if there is a discrepancy between the clinical and echocardiographic findings. Calculation of aortic valve area by invasive hemodynamic assessment requires accurate assessment of the transvalvular flow and mean transvalvular pressure gradient to calculate effective orifice area using the Gorlin formula [23]. Concerns have been raised about the risk of cerebral embolization during attempts to cross the aortic valve and directly measure the transaortic gradient. Angiography is indicated to detect CAD in patients older than 45 years who are being considered for operative treatment of severe AS [24]. Coronary CT angiography is likely to be performed more often for this indication in patients with a low pretest likelihood of CAD.

Special Case: Low-Output/Low-Gradient Aortic Stenosis

The evaluation and management of patients with AS and a depressed EF can be vexing. Patients with anatomically severe AS and reduced EF (<40%) often have a relatively low-pressure gradient (<30 mm Hg) due to a weakened ventricle and afterload mismatch. The true severity of AS can be difficult to determine when the cardiac output and transaortic gradient are low. If the ventricle itself is diseased and unable to generate sufficient systolic force to open the leaflets adequately, a reduced aortic valve area may be present at rest, overestimating AS severity. This condition is known as pseudo-severe AS [25]. In such cases, LV dysfunction is the predominant pathology and may be caused by prior MI or a primary cardiomyopathy. Patients either with true severe AS with reduced EF or pseudo-severe AS have a low-flow state with low transaortic gradients contributing to calculated aortic valve areas less than 1 cm^2. Pseudo-severe AS patients must be distinguished from those with true severe AS and poor LV function, since patients with true severe AS and contractile reserve will usually benefit from valve surgery, whereas patients with pseudo-severe AS are not operative candidates [26–28].

Dobutamine stress echocardiography has a well-defined diagnostic role in this setting [29] (Fig. 34.5). The inotropic effects of low-dose dobutamine will increase transvalvular flow in patients with a contractile reserve [30]. Contractile reserve is defined as an increase in stroke volume with inotropic infusion of more than 20%. Dobutamine infusion, particularly at doses $\leq$20 μg per kg per minute, is generally well tolerated but should only be performed in experienced centers with a cardiologist in attendance. In patients with true severe AS and LV dysfunction, dobutamine will increase cardiac output and mean transvalvular gradient, but the calculated aortic valve area will remain low (<1 cm^2). Patients with pseudo-severe AS will have an increase in aortic valve area into a range no longer considered severe (>1.2 cm^2) with little change in transvalvular gradient. Some patients will not show contractile reserve to dobutamine, signaling a poor prognosis [31]. Surgery is indicated in true severe AS with contractile reserve after dobutamine challenge, and generally contraindicated for patients with pseudo-severe AS or those without contractile reserve [32]. Patients with low-gradient AS undergoing AVR have a significantly higher perioperative and long-term mortality if multivessel CAD is present [27,33].

Intensive Care Unit Management

Surgery with AVR is the preferred treatment strategy for patients with symptomatic severe AS and for asymptomatic patients with severe AS who have a reduced EF (<50%). In

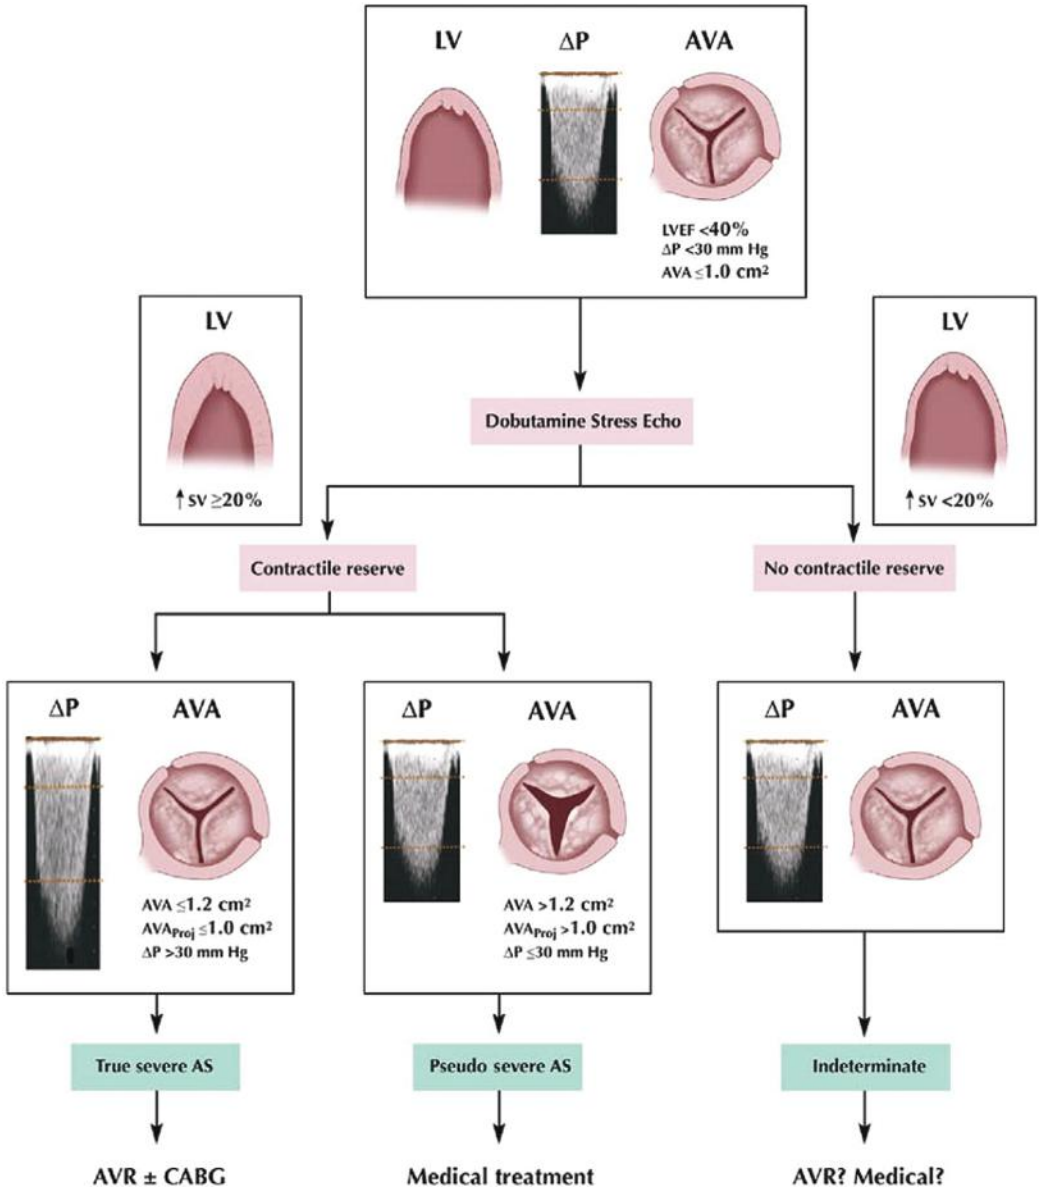

FIGURE 34.5. Decision making in low-flow, low-gradient aortic stenosis (AS). Dobutamine stress echocardiography aids decision making in low-flow AS. Contractile reserve is defined as an increase in stroke volume of >20%. When contractile reserve is elicited, patients with true severe AS have an increase in transvalvular gradient (ΔP) with a persistently low calculated valve area (AVA). One can also determine the projected AVA at a standardized normal flow rate (AVA_{proj}), with an $AVA_{proj} \leq 1$ cm^2 consistent with true severe AS. Management decisions are more challenging if contractile reserve is absent. AVR, aortic valve replacement; CABG, coronary artery bypass grafting; LV, left ventricle. [From Picano E, Pibarot P, et al: The emerging role of exercise testing and stress echocardiography in valvular heart disease. *J Am Coll Cardiol* 54:2251–2260, 2009, with permission.]

contrast, surgery may be postponed in patients with severe, asymptomatic AS and normal LV function, as these patients may do well for years [34]. AVR is also indicated for patients with moderate AS who require other cardiac surgery, such as coronary artery bypass grafting (CABG) or aortic aneurysm repair. Patients with severe AS and cardiogenic shock may be considered for percutaneous aortic balloon valvuloplasty (PABV) as a bridge to AVR. Transcatheter aortic valve implantation (TAVI) has been performed in more than 5,000 patients worldwide and promises to be a viable treatment alternative for patients with severe AS who are considered too high risk for conventional surgery.

Medical Management

Medical interventions in severe AS are largely supportive until surgery is feasible. In patients with severe AS with heart failure or cardiogenic shock, management should be guided by invasive hemodynamic monitoring with a pulmonary artery catheter. Gentle diuresis may relieve pulmonary congestion, but patients with severe AS have a preload-dependent state, so overdiuresis can cause a severe drop in blood pressure. For patients in cardiogenic shock, arterial pressure should be supported with inotropes and/or vasopressors until valve surgery can be performed. Vasodilators are generally contraindicated, except in select patients with depressed EF [35]. In these

select patients with EF less than 35%, severe AS and cardiogenic shock accompanied by high systemic vascular resistance, sodium nitroprusside infusion has been shown to modestly improve hemodynamics and can serve as a bridge to the operating room [36].

Surgical Treatment

AVR is the preferred treatment for severe symptomatic AS [32,37]. Choice of valve prosthesis depends on patient age, anticipated lifespan, and preference for and tolerance of anticoagulation [38]. The perioperative mortality for isolated AVR ranges from less than 1% in healthy, younger patients with normal LV systolic function to 10% or more in elderly patients with coexisting CAD and reduced EF. Age alone is not a contraindication to AVR. Other factors associated with reduced survival after AVR include chronic kidney disease, obstructive lung disease, reoperation, emergency operation, and age older than 65 years. The overall 10-year survival for patients with AVR is approximately 60%. Surgical risk for valve replacement can be estimated using one of several online calculators (Society for Thoracic Surgeons, EuroSCORE, or others) [39–41].

Percutaneous Aortic Balloon Valvuloplasty and Percutaneous Valve Replacement

PABV is often used instead of an operation in children and young adults with congenital, noncalcific AS. During the procedure in adults, a balloon is placed across the stenotic aortic valve and inflated to high pressure to fracture adherent calcium and increase effective orifice area [42]. A technically successful procedure can reduce the transaortic valve gradient to a mild degree but rarely increase valve area to more than 1 cm^2. Valvuloplasty is not widely used in adults with severe calcific AS because of high restenosis rates, frequent embolic complications (particularly stroke), and the development of AR [43]. In adults with acutely decompensated AS, PABV is particularly high risk and has no proven long-term benefits [44]. Given these risks, PABV is seldom used even in a palliative setting. In rare cases, it may be used as a bridge to AVR in patients with severe LV dysfunction and shock who are too ill to tolerate surgery without a period of metabolic recovery. PABV should not be considered as a substitute for AVR.

TAVI has generated considerable enthusiasm because it can eliminate the incremental risks conferred by sternotomy, cardiopulmonary bypass, and general anesthesia. TAVI can now be achieved in select patients and is undergoing active clinical investigation [45–48]. The procedure involve preparatory PABV followed by deployment of a balloon or self-expanding stented valve across the stenotic orifice. An antegrade, retrograde or LV transapical approach may be used. The retrograde approach is preferred but depends critically on whether relatively large diameter catheters can be successfully manipulated through the arterial system. Lower profile devices are under active development. There are several potential complications, though results with TAVI have been improving steadily and are quite promising [49]. TAVI will likely to have a major impact on management of AS in elderly, high-risk patients [50,51].

AORTIC REGURGITATION

Acute severe AR may occur in previously normal or only mildly diseased valves and often results in abrupt hemodynamic decompensation and respiratory compromise requiring ICU admission. Acute valvular regurgitation is a surgical emergency, but accurate diagnosis may be a challenge because examination findings may be subtle and the clinical presentation nonspecific [52]. Patients with acute AR appear gravely ill and have tachycardia, significant dyspnea, and often hypotension. The presentation of acute AR may even be mistaken for other acute conditions like sepsis, pneumonia, or nonvalvular heart failure. In marked contrast, chronic severe AR may be asymptomatic or minimally symptomatic and is rarely encountered in the ICU setting. In cases of acute valvular regurgitation, a high index of suspicion is required, along with timely TTE, and prompt surgical consultation.

Etiology

Most cases of acute severe AR are caused by infective endocarditis (IE), but other causes include aortic dissection and blunt chest trauma. Staphylococcus has emerged as the most important causative organism of native valve endocarditis [53,54]. Patients with antecedent aortic valve disease or a congenital bicuspid valve are at increased risk for IE, though organisms like *Staphylococcus aureus* can infect a normal trileaflet valve. IE is a particular problem among injection drug users, patients with indwelling catheters, and those on hemodialysis. Acute severe AR from IE is the consequence of tissue destruction, leaflet perforation, or bulky vegetations impairing leaflet coaptation [55].

AR is present in up to 65% of patients with Stanford Type A aortic dissection [56]. Ascending aortic dissection may be seen in Marfan syndrome, bicuspid aortic valve, or following CABG or AVR surgery. Retrograde extension of the dissection flap into the annulus may cause prolapse or eversion of the aortic valve leaflets. Type A aortic dissection with AR is a surgical emergency requiring prompt diagnosis and intervention [57]. Aneurysmal enlargement of the aortic root without dissection may also lead to AR. Although AR is usually chronic when produced by aortic root dilatation, an acute-on-chronic decompensation may occur if there is superimposed dissection or abrupt aneurysm enlargement [58]. Important causes of aortic root pathology producing AR include connective tissue disorders (Marfan syndrome and Ehlers-Danlos syndrome) and vasculitis (syphilis aortitis, giant cell arteritis, or Takayasu's arteritis). Aortic leaflets tears, perforation, or detachment producing AR may also follow blunt chest trauma or occur as a complication of PABV for AS [59].

Pathophysiology

Unlike in chronic AR, the LV in acute AR has not had time to develop compensatory eccentric hypertrophy in response to elevated afterload and preload (Fig. 34.6). The nondilated, noncompliant left ventricle receives a significant diastolic volume load from the regurgitant flow, resulting in an abrupt rise in LV end-diastolic pressure. This pressure may in turn be transmitted to the pulmonary bed resulting in pulmonary edema. Since the LV cannot dilate acutely in response to the volume load, forward stroke volume is decreased and tachycardia develops to maintain cardiac output. Impaired forward stroke volume leads to decreased systolic pressure and relatively narrow pulse pressure. Patients may present with signs of impending cardiogenic shock. LV diastolic pressure may equilibrate with aortic pressure during the latter half of diastole (diastasis), resulting in attenuation of the AR murmur in the acute setting. The elevation in end-diastolic pressure and tachycardia can increase myocardial oxygen demand and, when coupled with decreased diastolic coronary blood flow, can reduce myocardial perfusion and result in coronary ischemia. Ischemia from AR can be compounded by impairment in coronary flow from

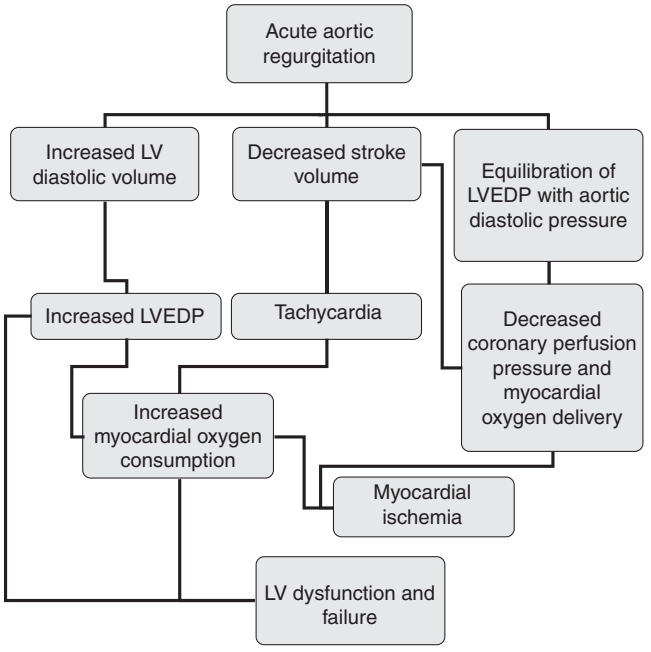

FIGURE 34.6. Pathophysiology of acute aortic regurgitation. LV, left ventricle; LVEDP, left ventricular end diastolic pressure. [Adapted from Bonow R, Braunwald E: Valvular heart disease, in Zipes D, et al. (eds): *Braunwald's Heart Disease*. Philadelphia, Elsevier, 2005, with permission.]

preexisting atherosclerosis or an aortic dissection flap. In acute severe AR, LV failure and cardiogenic shock develop if surgery is not promptly performed.

Clinical Presentation

History

Acute AR may present with little or no warning. Symptoms of weakness, profound dyspnea, angina, and presyncope are common. Antecedent valve disease, fever, and skin findings may suggest IE. Severe, ripping chest or back pain with hypertension may indicate aortic dissection. Signs of blunt chest trauma may be disarmingly subtle. The natural history of acute severe AR is one of LV failure and death in the absence of rapid intervention. Patients with chronic AR may present acutely with a sudden worsening of their underlying pathology.

Physical Examination

The classic eponymous signs observed in chronic AR are attenuated or absent in acute AR. Patients are often tachycardic with low or low-normal blood pressure. Pulse pressure may underestimate AR severity in the acute setting. Tachypnea, accessory muscle use, and hypoxemia are worrisome findings and pulmonary rales are common. LV apical impulse is not displaced unless prior LV dysfunction was present. The first heart sound (S1) is often soft due to premature closure of the mitral valve from the rapid LV diastolic pressure rise. There is often a low-pitched systolic ejection murmur from increased flow across the aortic valve, whereas the diastolic regurgitant murmur is of grade 1 or 2 intensity and of short duration. A pulse deficit or relative decrease may be appreciated in the setting of AR from aortic dissection.

Investigations

Electrocardiography

Sinus tachycardia is often present, though the ECG may be entirely normal in acute severe AR. In contrast, LVH is a feature of chronic AR. Nonspecific ST-segment and T-wave abnormalities or signs of LV strain are common. In IE, if there is paravalvular extension of the infection in the region of the atrioventricular node, heart block of varying degree may be present. In the setting of acute heart failure, supraventricular and ventricular tachycardias may occur.

Chest Radiography

The cardiac silhouette may be normal unless AR is chronic or there was preexisting heart disease. Pulmonary edema is common and characterized by cephalization of interstitial markings and Kerley B lines. A widened mediastinum may signify aortic dissection or thoracic aortic aneurysm.

Echocardiography

Urgent TTE is mandated whenever acute AR is suspected. Echocardiography can determine etiology and hemodynamic severity of AR while providing information on underlying LV function, aortic size, and coexisting valvular heart disease (Fig. 34.7). Severe AR is characterized by a wide regurgitant jet (vena contracta >6 mm) and holodiastolic flow reversal in the descending thoracic aorta [60]. The rapid rise in LV diastolic pressure with acute severe AR produces short pressure half time (<250 milliseconds) and premature mitral valve closure [61]. CT angiography has become the preferred imaging test to assess for acute dissection, but TEE may be indicated if the study is nondiagnostic and can be crucial for surgical planning [62,63].

Cardiac Catheterization

Establishing the hemodynamic severity of AR seldom requires catheterization, which can delay surgery [64]. Younger patients without coronary risk factors may proceed directly to emergency valve replacement without angiography. Patients with Type A dissection should proceed directly to surgical repair.

Intensive Care Unit Management

Medical Management

Acute severe AR has a high mortality rate. Medical management should not delay urgent or emergent surgery. Congestive heart failure and cardiogenic shock are the principle targets of acute medical therapies. Use of vasodilators, particularly sodium nitroprusside, and diuretics are the mainstays of medical therapy, if the systemic blood pressure allows [65]. Inotropes such as dopamine or dobutamine may be used to augment cardiac output. Pulmonary edema from acute AR frequently requires intubation and mechanical ventilation. Intra-aortic balloon counterpulsation (IABP) is strictly contraindicated. Beta-blockers should only be considered in cases of acute aortic dissection. Antibiotics are indicated for IE, but surgery must not be delayed once heart failure intervenes [24].

Surgical Treatment

Surgery is indicated for acute severe AR unless overwhelming patient comorbidities dictate otherwise. AVR is most commonly performed, but valve repair may be possible in

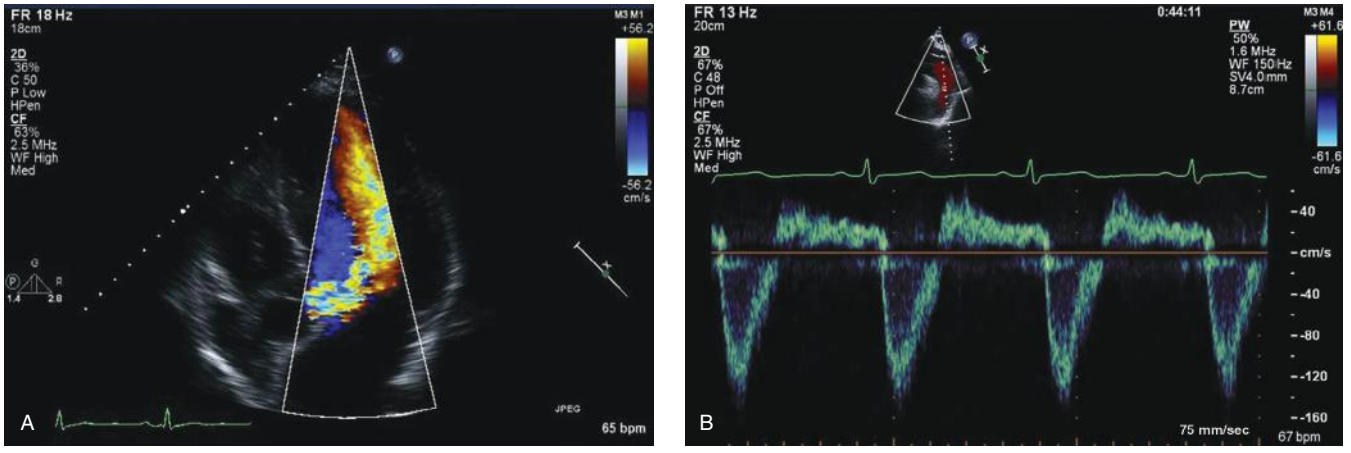

FIGURE 34.7. Echocardiographic appearance of severe aortic regurgitation. **A:** Transthoracic echocardiogram apical four-chamber view with severe aortic regurgitation from infective endocarditis. Color Doppler shows ventricular filling from the aorta during diastole. **B:** Pulse wave Doppler of the descending thoracic aortic reveals holodiastolic flow reversal consistent with severe aortic regurgitation.

cases of leaflet perforation. Most surgeons favor the use of homograft material for management of aortic valve/root IE given the low reinfection rates with cadaveric tissue. A composite valve-graft conduit may be used when disease dictates replacement of both the aortic root and valve [66]. Perioperative risk depends on age, preoperative LV function, etiology, and urgency of the surgery. Debridement of periaortic abscess or aortic root replacement compounds operative risk.

MITRAL STENOSIS

Widespread use of programs to detect and treat Group A streptococcal pharyngitis have reduced the incidence of rheumatic fever in the developed world, the leading cause of MS [67]. The burden of rheumatic valve disease in the developing world remains considerable and is a significant cause of premature death. Most cases of rheumatic MS in the United States are seen in patients who have recently emigrated from endemic areas [1]. Symptomatic MS requires mechanical relief of LV inflow obstruction. ICU management goals include treatment of heart failure, rate control of AF, and preparation for valvotomy or valve replacement surgery.

Etiology

Rheumatic fever produces valvular inflammation and scarring, though nearly half of patients may not recall history of acute rheumatic fever or chorea. Two thirds of patients with rheumatic MS are female and 40% of patients with rheumatic valvular disease will have isolated MS [68]. Screening TTE in endemic areas may detect up to 10 times as many cases of rheumatic valve disease compared with clinical screening alone [69]. By contrast, in developed countries, MS is more commonly produced by calcific degeneration of the annulus and mitral leaflets, congenital abnormalities, or collagen vascular diseases such as lupus or rheumatoid arthritis [70]. Atrial myxoma may mimic MS by causing obstruction to LV inflow. The natural history of MS is often dependent on the patient's nationality: in developing countries, patients tend to be younger with a more pliable valve, whereas in developed countries, patients are older with comorbid conditions [71].

Pathophysiology

Rheumatic fever leads to inflammation and scarring of the mitral valve, with fusion of the commissures and subvalvular apparatus [67]. Although the initial insult is rheumatic, altered flow patterns may lead to calcification and valve deformity, leading to a narrow funnel-shaped valve. Calcific degeneration of acquired mitral valve thickening may also produce MS. The mitral orifice is normally 4 to 6 cm^2. MS develops when the area is reduced to less than 2 cm^2 so that an elevated left atrioventricular pressure gradient is required to propel blood across the mitral valve. Severe MS is present when the valve area is less than 1 cm^2 and a mean transmitral gradient of more than 10 mm Hg is present (Table 34.2). An elevated LA pressure leads to pulmonary hypertension, exercise intolerance, and eventually right-sided heart failure. Adequate transit time is required to allow blood to flow across the stenotic mitral valve during diastole.

Clinical Manifestations

History

MS is a slowly progressive disease with a latent period of up to two decades between the episode of rheumatic carditis and symptom onset. Progression of MS in developing countries is more rapid and may be associated with recurrent episodes of rheumatic fever. The typical patient will have an asymptomatic period with an abnormal physical examination. As MS progresses, lesser stresses precipitate symptoms and the patient becomes limited in daily activities; orthopnea and paroxysmal

TABLE 34.2

SEVERITY OF MITRAL STENOSIS

Severity of stenosis	Valve area (cm^2)	Mean gradient (mm Hg)	PA systolic pressure (mm Hg)
Mild	>1.5	<5	<30
Moderate	1.0–1.5	5–10	30–50
Severe	<1.0	>10	>50

nocturnal dyspnea develop. Pulmonary edema in previously asymptomatic individuals may be triggered by tachyarrhythmias (AF), volume overload, fever, anemia, hyperthyroidism, or pregnancy [72]. Each of these circumstances shortens the diastolic filling period and elevates the LA–LV transvalvular gradient. Development of persistent AF marks a turning point in the patient's course, with an accelerated rate of symptom progression. Systemic embolization may be the first clue to the presence of MS, irrespective of underlying rhythm [73]. Patients may also suffer from hemoptysis due to shunting between the pulmonary and bronchial veins, leading to rupture. Underappreciated calcific MS may also be identified after failure to wean from mechanical ventilation.

The overall 10-year survival with untreated MS is 50% to 60% [74]. Asymptomatic patients have a survival of more than 80% at 10 years, whereas symptomatic MS led to death within 2 to 5 years in the era before the development of mitral valvotomy [75]. Once pulmonary hypertension develops, mean survival is less than 3 years. Common causes of death associated with MS are heart failure, systemic embolism, and infections, including endocarditis.

Physical Examination

MS produces signs of heart failure, including pulmonary rales, peripheral edema, ascites, an elevated jugular venous pressure, and congestive hepatomegaly. Patients with severe MS may also have a malar flush with pinched and blue facies. The first heart sound (S1) is usually accentuated in the early phases of the disease. The opening snap (OS) of MS is best appreciated in early diastole during expiration near the cardiac apex. The time interval between aortic valve closure (A2) and OS varies inversely with the severity of MS and the height of LA pressures. The OS is followed by a low-pitched rumbling diastolic murmur best heard at the apex with the patient in the left lateral decubitus position. Presystolic accentuation of the murmur may be present in sinus rhythm. In general, the duration of the murmur corresponds to the severity of stenosis. If the valve is heavily calcified and immobile, with low cardiac output or AF, it may be relatively "silent" with a soft S1, absent presystolic accentuation, and an inaudible diastolic rumble. Associated valvular lesions, including the murmurs of AR, pulmonic regurgitation (PR), and tricuspid regurgitation (TR), may be present, along with a loud P2 from pulmonary hypertension or a parasternal lift from right ventricle (RV) pressure or volume overload.

Investigations

Electrocardiogram

The ECG in sinus rhythm may reveal LA enlargement but AF can be present at any stage in the natural history. A vertical QRS axis may be present along with nonspecific ST-segment and T-wave abnormalities. Signs of RV hypertrophy signify advanced disease.

Chest Radiograph

Radiographic changes with MS include LA enlargement, dilation of the main pulmonary artery and its central branches, RV enlargement, and signs of pulmonary vascular congestion. Interstitial or alveolar edema signifies a marked and often acute elevation of pulmonary capillary wedge (PCW) pressure.

Echocardiography

Rheumatic MS is characterized by thickened mitral leaflet tips, immobility of the posterior leaflet, and restricted anterior leaflet motion. Calcific MS is marked by dense echogenic deposits throughout the mitral apparatus and turbulent LV diastolic inflow. Direct planimetry to measure valve area may be difficult in heavily calcified valves [76]. Continuous wave Doppler can be used to estimate the LA–LV pressure gradient. Estimates of mitral valve area can be made by the pressure half-time technique or the continuity equation [77]. Careful assessment of the degree and location of valvular calcification, thickening of the leaflet and subvalvular apparatus, and leaflet mobility can determine suitability for percutaneous mitral balloon valvuloplasty (PMBV) [78]. Routine assessment of chamber dimension and ventricular function should be performed. TEE is required to exclude LA thrombus in patients being considered for PMBV.

Cardiac Catheterization

Catheterization may be necessary to determine stenosis severity when noninvasive and clinical data are discordant or as a prelude to PMBV (Fig. 34.8). Cardiac output and mean transvalvular gradient measurements are used to calculate mitral valve area using the Gorlin formula [23].

Intensive Care Unit Management

Medical Therapy

Acute MS typically manifests as pulmonary edema. Reversible precipitants must be identified, such as rapid AF, anemia, sepsis, volume overload, or thyrotoxicosis. Medical therapy is directed at rate control of AF and alleviation of pulmonary and systemic congestion by loop diuretics. Nodal blocking agents such as beta-blockers or calcium-channel blockers are the preferred rate controlling agents and may be administered intravenously [79]. Cardioversion may be required in the acute setting to restore hemodynamic stability, though most patients respond to rate control. Anticoagulation should be initiated promptly. In patients with only mild-to-moderate MS, addressing one or more underlying precipitants will suffice without the need for mechanical intervention. Patients with severe MS have a poor prognosis without intervention, which may consist of PMBV, surgical commissurotomy, or mitral valve replacement (MVR) (Fig. 34.9).

Percutaneous Mitral Balloon Valvuloplasty

PMBV is the preferred treatment for symptomatic (NYHA Class II–IV) patients with isolated severe MS (valve area is $<1\ cm^2$) and favorable valve morphology. Unlike PABV, PMBV has achieved durable results. Ideal patients for PMBV are younger (age <45 years), have better NYHA functional class, and have pliable mitral leaflets [80]. PMBV is performed by transseptal puncture, passing a guidewire across the mitral valve, and inflating a balloon (Inoue balloon) across the mitral orifice to split the commissures and widen the stenotic valve [43,81].

Successful PMBV doubles the mitral valve area, reduces mean transmitral gradient by half, and improves symptoms without development of significant MR [82]. Acute complications of PMBV include severe MR; residual atrial septal defect after transseptal puncture; and, less commonly, LV perforation, cardiac tamponade, and systemic emboli. Overall procedural morality is between 0.4% and 3.0% [83]. Patients have excellent event-free survival after PMBV with rates of 80% to 90% over 3 to 7 years when performed by a skilled operator in a high-volume center [84]. Short- and intermediate-term outcomes after PMBV are comparable with those after open surgical commissurotomy, but with reduced morbidity and at lower cost [85]. There is a significant rate of restenosis after both percutaneous and surgical commissurotomy with most patients requiring a repeat procedure within 10 to 15 years.

Surgical Treatment

If the anatomy is unfavorable for PMBV or the procedure is unsuccessful, open surgical valvotomy may be performed, which requires cardiopulmonary bypass [86]. MVR is necessary in patients with MS and significant MR and those in whom valve anatomy is too distorted to respond to commissurotomy alone. MVR is often performed with preservation of the chordal attachments to facilitate LV recovery. A surgical MAZE procedure or isolation of the pulmonary veins may also be performed to treat concomitant AF, though success rates are relatively lower in rheumatic MS patients. The average operative risk for MVR is 5%, with an overall 10-year survival in surgical survivors of 70%. Long-term prognosis is influenced by patient age, comorbid conditions, and the presence of concomitant pulmonary hypertension and RV dysfunction.

MITRAL REGURGITATION

Acute, severe MR presents with pulmonary edema and hemodynamic compromise because of the lack of time for the cardiopulmonary circuit to adapt to the additional volume load. Examination findings may be subtle and presentation may be mistaken for other acute conditions such as pneumonia or nonvalvular decompensated heart failure. A high clinical index of suspicion, timely evaluation by TTE, and prompt referral for surgical consultation are of critical value in the management of this condition [52]. Many patients in the ICU will have MR accompanied by reduced LV systolic function, from either MI or chronic cardiomyopathy. The management of patients with MR and advanced systolic heart failure remains controversial.

Etiology

MR may be caused by abnormalities of any component of the mitral apparatus: annulus, valve leaflets, chordae tendineae, papillary muscles, and adjacent LV free wall [87] (Table 34.3). Common causes of acute MR include chordal rupture from myxomatous degeneration, blunt trauma, or endocarditis; leaflet perforation from endocarditis or leaflet avulsion from trauma; papillary muscle infarction with rupture or displacement from acute or chronic ischemia and LV remodeling; acute rheumatic carditis or other acute condition like stress cardiomyopathy; and mitral prosthetic paravalvular leak [88–90]. Often, the causes of MR are divided into "organic" disorders involving the mitral valve leaflets and "functional" disorders due to tethering of the mitral apparatus from ventricular remodeling, LV dilatation, and increased sphericity. This classification emphasizes when attention should be directed toward mitral valve surgery (organic causes) or to addressing an underlying cardiomyopathy (functional causes).

Ischemic MR refers to MR produced after acute MI and, more commonly, in chronic ischemic cardiomyopathy. The most important mechanism of ischemic MR is mitral valve leaflet tethering due to chronic postinfarction remodeling, resulting in apical and lateral displacement of the papillary muscles. This shape change occurs after an inferior or posterior transmural MI leads to displacement of the posteromedial papillary muscle [91]. After MI, the presence of MR can augment postinfarction remodeling, further exacerbating the degree of functional MR [92]. Papillary rupture is a rare complication of acute MI (1% to 3%) with a bimodal peak at 1 day, then 3 to 5 days post-MI. The posteromedial papillary muscle has a single blood supply from the right coronary or left circumflex artery, and thus is 6 to 10 times more likely to rupture than the anterolateral papillary, which has a dual blood supply. Dynamic MR can occur during episodes of transient ischemia involving the papillary muscles but is not usually severe [93]. Dynamic MR is also a feature of HOCM and has been described in some patients with stress cardiomyopathy.

Pathophysiology

In acute MR, the LV ejects blood into a small, noncompliant LA leading to a rapid rise in LA pressure during systole. The difference in LA compliance explains why chronic MR

(increased compliance) can be well tolerated and why acute MR (reduced compliance) is not. The rise in LA pressure is transmitted to the pulmonary venous bed and leads to pulmonary edema, which may be asymmetric if there is an eccentric jet of MR directed to a particular pulmonary vein. The severity of pulmonary edema may be relatively less in patients whose LA has been conditioned by some degree of chronic MR. Large V waves are typically inscribed in the LA and PCW tracings during ventricular systole in acute MR [94]. Such V waves may also be seen in other conditions, including LV failure and acute ventricular septal rupture. During acute MR, LV systolic function may be normal, hyperdynamic, or reduced depending on the etiology of MR. Tachycardia may temporarily preserve forward cardiac output, but hypotension, organ failure, and cardiogenic shock may evolve.

Clinical Manifestations

History

In acute severe MR, symptoms of left heart failure predominate, including dyspnea, orthopnea, and cough. Patients with post-MI papillary muscle rupture or ischemic MR may have concurrent angina, dyspnea, and abrupt hemodynamic compromise. Spontaneous chordal rupture in myxomatous degeneration may be accompanied by chest pain in nearly half of patients. Symptoms of fevers, chills, malaise, and anorexia may be present in patients with endocarditis. Trauma is usually self-evident (Table 34.4).

Physical Examination

Patients with acute severe MR are tachycardic and tachypneic. Blood pressure is variable, though pulse pressure is often narrow due to reduced forward stroke volume. Jugular venous pressure may be normal or elevated. Rales or wheezes may be

TABLE 34.4

CLINICAL FINDINGS IN ACUTE SEVERE MITRAL REGURGITATION

	Acute organic MR	Papillary muscle rupture	Functional MR with CHF
Etiology	Ruptured chordae, endocarditis, trauma	1 or 3–5 d post-MI	Ischemic heart disease, dilated cardiomyopathy
Presentation	Acute pulmonary edema	Sudden onset pulmonary edema and cardiogenic shock	CHF and pulmonary edema
Clinical Examination			
Point of maximum impulse/apex beat	Normal or displaced thrill	Usually normal if no prior LV dysfunction	Displaced
Murmur	Holosystolic loud	May be very soft or absent	Early systolic, rarely holosystolic soft
Sounds	Third heart sound, second heart sound split	Decreased sounds	Third heart sound
Investigations			
Electrocardiogram	Normal	Acute MI	Left bundle branch block
Chest radiograph	Normal heart size	Usually normal	Cardiomegaly
Echocardiogram			
Two-dimensional	LV and LA size normal Ruptured chord	Normal LV Ruptured head of papillary muscle	LV and LA dilated Annular dilatation Tenting of mitral valve leaflets
Doppler	Pulmonary venous flow reversal	Unimpressive color	Restrictive filling
Quantitation	Large regurgitation volume Large effective regurgitation orifice	Free-flow MR	Variable regurgitation volume Dynamic effective regurgitation orifice

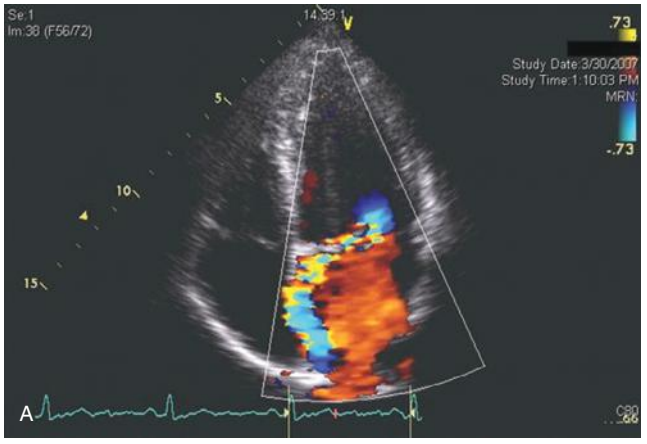
audible over the lung fields and may be asymmetric. The precordium is often hyperdynamic with a palpable apical thrill. S1 is normal or decreased in intensity, whereas S2 may be widely split due to early closure of the aortic valve. A diastolic filling complex may be appreciated and consists of a third heart sound (S3) and a short mid-diastolic rumble from increased transmitral diastolic flow. The systolic murmur of acute MR may be highly variable, and even absent in up to half of cases of post-MI papillary muscle rupture. The murmur of acute MR is usually not holosystolic but rather early to mid-systolic in timing, with a crescendo–decrescendo configuration, and is coarse rather than high pitched. These features reflect the rapid LA pressure rise and diminution of the LV–LA pressure gradient throughout systole. The murmur of chronic MR, in contrast, is holosystolic (plateau) due to the persistent LV–LA gradient during systole. The murmur of acute MR is usually loudest at the left sternal border or apex, and the direction of radiation may provide a clue as to etiology. Anterior leaflet prolapse or flail produces a posterior-lateral regurgitant jet, so the murmur typically radiates to the axilla and back. With posterior leaflet involvement, the jet is anterior-medial in direction, so the murmur is transmitted to the base, where it may be confused with AS.

Investigations

Electrocardiogram



ECG may show sinus tachycardia or an atrial arrhythmia, such as AF. LA abnormality may be discernible if P waves are present, though signs of LV chamber enlargement are rare in the acute phase. With post-MI papillary muscle rupture, evidence of an evolving inferior-posterior or lateral MI may be seen.

Chest Radiograph

In acute MR, the cardiac silhouette is normal in size despite the present of alveolar pulmonary edema. Asymmetric edema may be present in patients with a flail leaflet producing an eccentric MR jet, particularly in the right upper lobe [95]. Decompensated chronic MR may have associated cardiomegaly, LA enlargement, and prominent pulmonary arteries.

Echocardiography

Prompt TTE is the most important study for patients with suspected acute MR (Fig. 34.10). TTE can delineate mitral anatomy, characterize severity, and document underlying LV function and coexisting valvular pathology. Flail leaflet may be diagnosed by rapid movement of a portion of leaflet/chordal tissue posteriorly in to the LA during systole. Chordal rupture, leaflet vegetations, and periannular abscess may be identified in endocarditis. In patients with functional MR, LV remodeling may be evident along with annular dilatation, papillary muscle displacement, and leaflet tethering. Semiquantitative assessment of MR severity can be performed with color flow and continuous wave Doppler interrogation. MR severity correlates with LA jet width area, pulmonary vein systolic flow reversal, effective regurgitant orifice area, and regurgitant fraction and volume [96,97]. These semiquantitative measures are less important as guides for acute decision making but remain important for longitudinal management (Table 34.5). TEE can

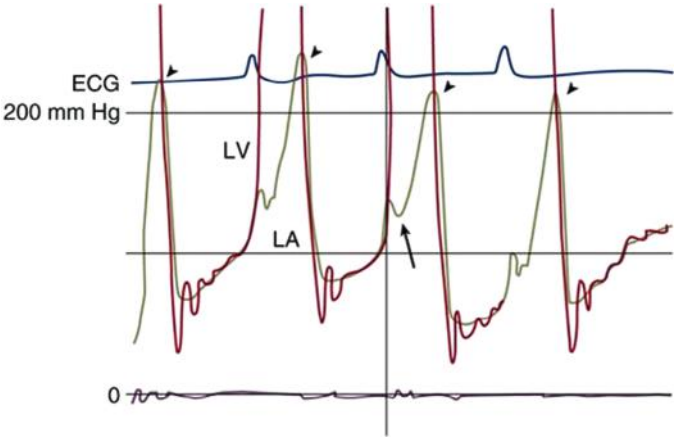


FIGURE 34.10. Mitral regurgitation. **A:** Color-flow Doppler image from the apical four-chamber view of a patient with myxomatous degeneration of the mitral valve with posterior leaflet prolapse producing an anteromedially directed jet of severe mitral regurgitation against the interatrial septum. Eccentric jets are common in prolapse and/or flail leaflet and are directed opposite the involved leaflet. **B:** The "V" wave of mitral regurgitation. This hemodynamic tracing shows a large left atrial "V" wave (arrowheads) occurring during ventricular systole in a patient with atrial fibrillation ("A" wave absent). Following the "V" wave, there is a rapid fall in left atrial (LA) pressure, along the course of the declining left ventricular (LV) pressure. In diastole, LA and LV pressures are equalized. The arrow indicated the "C" wave deflection. Giant "V" waves are defined by an increase in >10 mm Hg above mean pressure and are consistent with mitral regurgitation, but may be blunted in patients with large and compliant left atria. ECG, electrocardiogram. [From O'Gara PT: Valvular heart disease, in Libby P (ed): *Essential Atlas of Cardiovascular Disease*. New York, NY, Springer, 2009, p 216, Figures 9–20 and 9–22.]

further characterized mitral anatomy and MR severity if TTE images are suboptimal or complicated IE is suspected.

Cardiac Catheterization

Catheterization is rarely required to define MR etiology or severity. If there is a discrepancy between clinical findings and noninvasive imaging or when estimated pulmonary artery pressures are out of proportion to the degree of MR, then invasive hemodynamic assessment is indicated. MR severity may be qualitatively assessed by contrast ventriculography. Coronary angiography typically precedes surgery for patients with coronary risk factors and in those with suspected post-MI papillary rupture or dynamic, ischemic MR.

TABLE 34.5

ECHOCARDIOGRAPHIC FINDINGS CONSISTENT WITH SEVERE MITRAL REGURGITATION

Qualitative
Vena contracta width >0.7 cm with large central MR jet (area >40% left atrial area) or with a wall-impinging jet of any size, swirling in left atrium (Echo, Doppler)
Pulmonary vein systolic flow reversal (Doppler)
Dense contrast in left atrium (angiography)
Quantitative
Regurgitant volume ≥60 mL per beat
Regurgitant fraction ≥50%
Effective regurgitant orifice ≥0.40 cm^2

Intensive Care Unit Management

Medical Therapy

The goal of medical therapy for acute severe MR is to stabilize the patient in anticipation of surgery for definitive treatment. Afterload reduction with intravenous vasodilators is the mainstay of acute medical therapy, as systolic blood pressure tolerates. Sodium nitroprusside infusion is preferred, though extended use requires monitoring of thiocyanate levels [65]. Inotropes such as dobutamine or dopamine may occasionally be required to support cardiac output and arterial pressure. IABP for mechanical afterload reduction may be particularly helpful in reducing regurgitant volume and decreasing LV end-diastolic pressure. If end-organ hypoperfusion or hypotension indicates that cardiogenic shock is present, IABP should be promptly initiated as a bridge to the operating room. Loop diuretics may help ameliorate pulmonary edema.

Adjunctive medical therapy is driven in part by suspected etiology. Antibiotics are indicated for IE and anti-ischemic therapy is required for post-MI papillary muscle rupture [98]. With medical therapy alone, the mortality after papillary rupture is 80% [99]. Although percutaneous coronary intervention (PCI) may help relieve MR in the setting of acute MI, severe MR will most often require surgical correction despite successful coronary reperfusion. Despite recent advances in percutaneous valve repair techniques, none has yet been tested in the setting of acute MR [100,101]. Similarly, cardiac resynchronization therapy (CRT) may help reduce chronic, functional MR related to contractile dyssynchrony but has no role in the acute setting [102]. Surgical planning should not be delayed, but an operation may have to await improvement in organ function after the measures described above are instituted.

Surgical Therapy

Surgery is indicated for the treatment of acute severe MR. In contrast to acute severe AR, many patients with acute severe

MR may be stabilized over the course of several days with IABP or inodilators to allow operation under less urgent circumstances [24]. Also unlike acute AR, acute severe MR may be treated with either repair or replacement. Valve repair is the preferred surgical therapy when possible [103]. Mitral repair involves valve reconstruction using a variety of valvuloplasty techniques and insertion of an annuloplasty ring. In addition to reducing the need for anticoagulation and the risk of late prosthetic valve failure, valve repair preserves the integrity of the subvalvular apparatus, which maintains LV function to a greater degree. Valve repair using an undersized annuloplasty ring is more likely to be used for ischemic MR [52]. Valve replacement with chordal sparing is needed when there is destruction, distortion, or infection of the native tissue that makes repair impossible. Surgical strategy is often guided by intraoperative TEE and direct visual inspection after the patients is placed on cardiopulmonary bypass.

Surgical outcome depends on age, underlying LV function, the presence of concomitant coronary disease, patient comorbidities, and the etiology of MR [104]. IE has a high mortality rate even with medical and surgical therapy, though mortality has decreased with improvements in operative technique and more widespread use of mitral repair [105,106]. With the addition of bypass grafting to mitral valve repair, operative mortality in patients with ischemic MR is now less than 10% [99,107].

The surgical approaches to patients with MR accompanied by advanced systolic heart failure continue to evolve and remain controversial [108]. There is broad consensus that patients with chronic MR and heart failure should be optimized on medical therapy, evaluated for revascularization if coronary disease is present, and provided with CRT if the EF is less than 35% and a wide QRS, left bundle branch block complex (>120 milliseconds) is present. After these steps, reconfirmation of MR severity is required before considering MV surgery. If severe MR is present, a careful integrated assessment of LV reverse remodeling viability (usually with cardiac magnetic resonance imaging), mitral apparatus geometry, and patient comorbidities must be made in consultation with cardiology and cardiac surgery colleagues [108]. As percutaneous and less invasive approaches to mitral valve disease in patients with heart failure continue to evolve, ongoing clinical trials will help refine the selection of candidates for mitral surgery and determine outcomes of mitral repair versus chord-sparing replacement.

TRICUSPID REGURGITATION

Most ICU patients with TR have functional regurgitation rather than a primary valvular abnormality. Functional TR is produced when the tricuspid annulus is dilated due to RV infarction, congenital heart disease, or pulmonary hypertension with RV dilatation, often secondary to chronic left heart failure. TR is often present in patients with chronic left-sided valve disorders that produce secondary pulmonary hypertension or with pathologic processes affecting multiple valves, such as rheumatic disease, endocarditis, or myxomatous degeneration [109]. The most important causes of primary valvular TR are trauma and IE, particularly in patients who abuse intravenous drugs. When severe, TR may contribute to symptoms of right heart failure, including fatigue, edema, and ascites. The murmur of TR usually increases in intensity with inspiration (Carvallo's sign). Examination of the neck veins reveals large V-waves. A pulsatile liver edge may also be felt in the right upper quadrant.

Despite the significant volume load imposed by severe TR, the RV tolerates TR remarkably well and operation is rarely indicated in the absence of other valve disease [32]. Therapy for TR is targeted at the underlying disease process and reversing secondary causes of pulmonary hypertension [110]. For example, with LV failure, appropriate management with diuresis and afterload reduction with vasodilators may reduce the degree of functional TR. When caused by left-sided heart disease, worsening TR can be a marker of underlying RV compromise and heralds a poor prognosis [111]. Secondary TR caused by mitral valve disease is increasingly addressed with annuloplasty repair at the time of mitral valve surgery, since functional TR occurring late after a left-sided valve operation is associated with high morbidity and mortality [112]. Tricuspid annuloplasty or valve replacement surgery may also be required for severe primary TR causing worsening RV systolic function or refractory right heart failure.

PROSTHETIC VALVE DYSFUNCTION

Valve replacement surgery has been a major breakthrough allowing patients with severe valvular heart disease to have better quality and length of life. Prosthetic valves may be either mechanical or bioprosthetic (Fig. 34.11). The choice of prosthesis is informed by patient age, the need for anticoagulation, hemodynamic profile, durability, and patient preference [113]. Mechanical valves have excellent durability and hemodynamic performance but require life-long anticoagulation to prevent thromboembolic complications [114]. In contrast, the principal advantage of bioprosthetic valves is the virtual absence of thromboembolic complication after 3 months, except when there are risk factors such as a hypercoagulable state or chronic AF with atrial enlargement [115]. Bioprosthetic valves are usually xenografts (porcine or cryopreserved, mounted bovine pericardium); homografts from human cadavers are used to treat aortic valve and root endocarditis. All bioprostheses are at risk for structural valve deterioration (SVD), which is mostly a function of age at implant. SVD occurs more rapidly among patients younger than 40 years compared with those older than 65 years. Rates of SVD may not differ between homograft and xenograft valves. Over the past 10 years, there has been a trend toward using bioprosthetic valves in relatively younger patients (ages 50 to 65 years) despite the inherent risk of SVD and need for reoperation, given the increased durability of the current generation xenograft valves, decreased risk at reoperation, aggregate risks of long-term anticoagulation, and patient lifestyle preferences.

All prosthetic valves are subject to dysfunction that can lead to significant hemodynamic compromise. Common prosthetic valve abnormalities include mechanical valve thrombosis, prosthetic valve endocarditis (PVE), structural deterioration and failure, and paravalvular regurgitation with or without hemolysis. For patients with a prosthetic valve admitted to the ICU, management focuses on appropriately excluding prosthetic valve dysfunction using TTE and TEE when required and maintaining optimal prosthetic valve function [116].

Prosthetic Valve Thrombosis

Prosthetic valve thrombosis (PVT) is any valve thrombus attached to or near an operated valve that occludes part of the blood flow path or interferes with the function of the valve [32]. PVT is a rare but life-threatening condition (Fig. 34.12). It is more common with older generation mechanical valves, particularly in the setting of inadequate anticoagulation. The incidence is estimated to be between 0.3% and 1.3% per year in patients with mechanical valves [117,118].

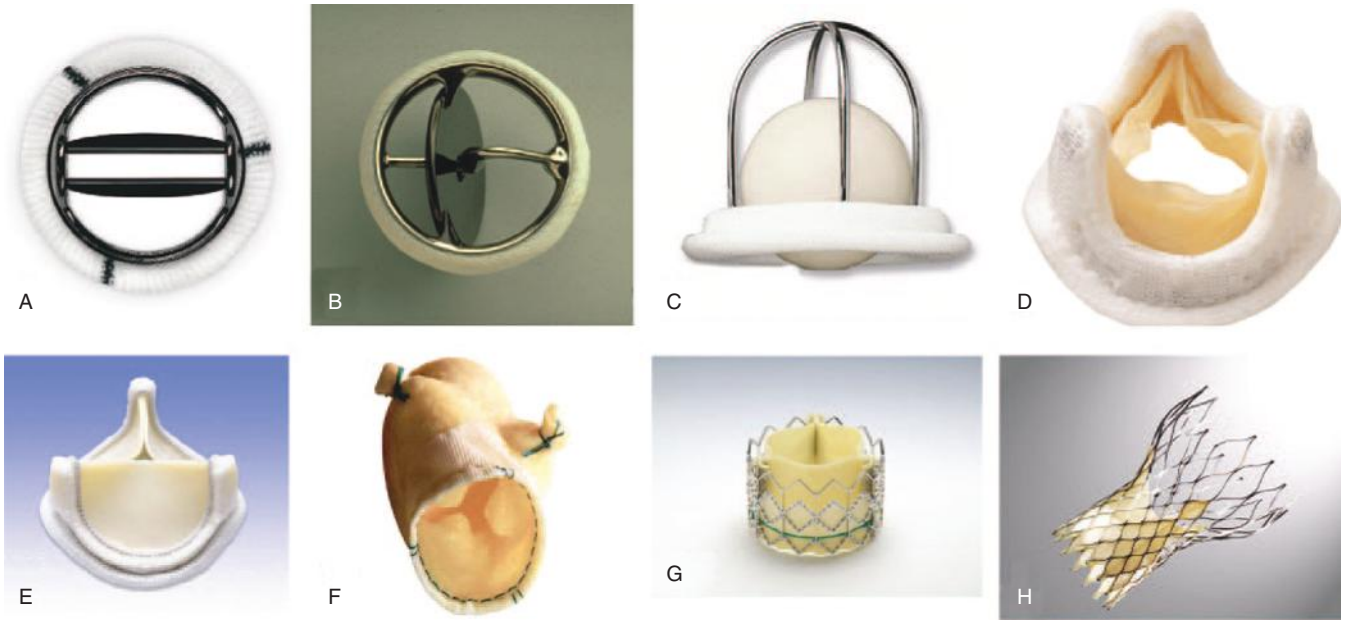

FIGURE 34.11. Different types of prosthetic heart valves. **A:** Bileaflet mechanical valve (St. Jude's); **B:** monoleaflet, tilting disk mechanical valve (Medtronic Hall); **C:** caged ball valve (Starr-Edwards); **D:** stented porcine bioprosthesis (Medtronic Mosaic); **E:** stented pericardial bioprosthesis (Carpentier-Edwards Magna); **F:** stentless porcine bioprosthesis (Medtronic Freestyle); **G:** percutaneous bioprosthesis expanded over a balloon (Edwards Sapien); **H:** self-expandable percutaneous bioprosthesis (CoreValve). [From Pibarot P, Dumesnil JG: Prosthetic heart valves: selection of the optimal prosthesis and long-term management. *Circulation* 119:1034–1048, 2009, with permission.]

Clinical Presentation and Investigations

PVT follows a rapid clinical course, unlike the in-growth of fibrous/pannus tissue within a prosthetic valve ring, which slowly gives rise to valve dysfunction and stenosis [119]. PVT manifests as abrupt onset of systemic embolization, congestive heart failure, or cardiogenic shock. The degree of hemodynamic compromise is determined by valve position and degree of resulting dysfunction. In general, the time course may be more insidious with caged-ball valves and more abrupt with tilting disk valves [120]. The physical examination may be unrevealing, though soft mechanical valve closure sounds or a pathologic murmur may be present.

A subtherapeutic international normalized ratio (INR) in a patient with a mechanical valve is a red flag for PVT [121]. Rapid diagnosis depends on prompt TTE or fluoroscopy, though both modalities may be complementary [122]. TTE can diagnose the presence of valve thrombus, its composition, and associated functional stenosis or regurgitation. TEE usually provides further risk stratification, particularly in cases of suspected mitral PVT and when TTE windows are inadequate [123]. Fluoroscopy can be useful to characterize caged-ball, tilting-disc, or bileaflet mobility. Excursion of tilting-disc mechanical valves is much better appreciated with fluoroscopy than with TTE.

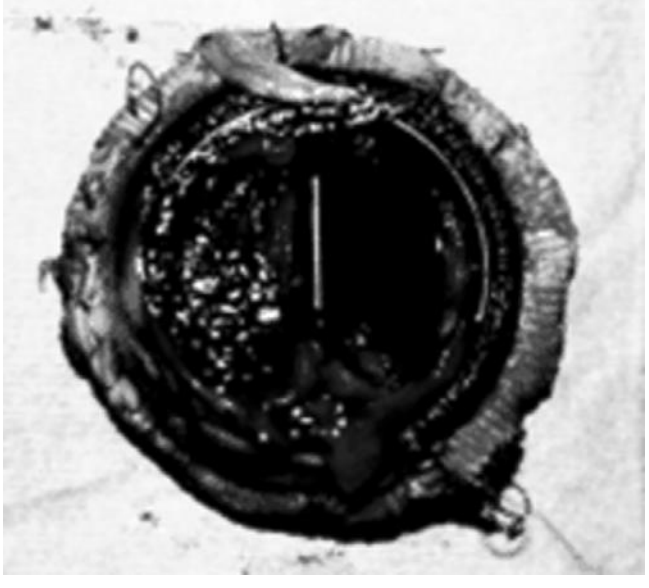

FIGURE 34.12. Prosthetic valve thrombosis in a bileaflet mitral valve. [From Goldsmith I, Turpie AGG, Lip GYH: ABC of antithrombotic therapy: valvar heart disease and prosthetic heart valves. *BMJ* 325(7374):1228–1231, 2002, with permission.]

Intensive Care Unit Management

Initial management should focus on systemic anticoagulation with intravenous heparin to prevent thrombus extension. Small thrombi without hemodynamic compromise are often treated with anticoagulation alone, whereas larger thrombi require either fibrinolytic therapy or surgery [24,37]. Fibrinolytic therapy is associated with risks of life-threatening hemorrhage and systemic embolization and thus is often delivered in the ICU for purposes of monitoring. The latter risk is low with right-sided PVT and higher with left-sided PVT, with a risk of cerebral embolism of 12% to 15% [124,125]. Fibrinolysis is considered first-line therapy for patients with right-sided PVT and for those with left-sided PVT, a small thrombus burden or NYHA Class I–II symptoms [32]. Fibrinolysis is less useful and potentially more harmful if LA thrombus is present, if the valve thrombus is older than 2 weeks, or if PVT is accompanied by shock. TTE after fibrinolysis can monitor for thrombus resolution and dictate the need for additional fibrinolysis for residual

thrombus [126]. Alteplase is the most commonly used fibrinolytic for PVT, though urokinase and streptokinase have also been used. After successful fibrinolysis, unfractionated heparin should be initiated along with warfarin until an INR of 3.0 to 4.0 is achieved in patients with a prosthetic aortic valve or an INR of 3.5 to 4.5 for a prosthesis in the mitral position [24].

Emergency operation is recommended for patients with hemodynamic instability, NYHA Class III–IV symptoms, or a large clot burden as defined by TEE (>0.8 cm^2) [32,37]. Perioperative mortality rates approach 15% and are highest for PVT in the mitral position. A bioprosthesis is recommended after PVT to reduce future risk of valve thrombosis.

Prosthetic Valve Endocarditis

The incidence of PVE is 0.5% per year even with appropriate antibiotic prophylaxis and accounts for 7% to 25% of all cases of endocarditis in the developed world [54]. Endocarditis of a prosthetic valve is a devastating disease that carries a mortality rate of 30% to 50%. This high mortality reflects not only more serious infection but also the difficulty eradicating infection with antibiotics alone [127]. Infection may involve any part of the valve prosthesis, but the sewing ring may be particularly vulnerable. Sewing ring infection may result in abscess formation, paravalvular regurgitation, and further penetration into adjacent cardiac structures. The risk of PVE may be higher with mechanical valves in the first few months after implantation, but long-term risk is similar for mechanical and bioprosthetic valves [53]. Infection with coagulase-negative staphylococci is common within the first postoperative year; *S. aureus* and streptococci species dominate in later years [128–130].

Fever is the most common symptom and may be associated with other signs of prosthetic valve dysfunction including congestive heart failure, a new murmur, or embolic phenomena. Blood cultures are crucial and should be drawn prior to antibiotic therapy in any patient with a fever and a prosthetic valve. TEE is essential because of its greater sensitivity in detecting signs of PVE including vegetations, paraprosthetic abscess, or new paravalvular regurgitation [131].

Eradication of the infecting pathogen with antimicrobial therapy alone is often impossible and depends on the virulence of the organism and extent of infection. Medical therapy is more likely to be successful with late PVE or in nonstaphylococcal bacterial infections [132]. Surgical consultation should be sought early in the course of PVE. Indications for surgical therapy include failure of medical treatment marked by persistent bacteremia, hemodynamically significant prosthesis regurgitation with LV dysfunction, large vegetations, paravalvular extension with abscess or conduction defects, or development of intracardiac fistulas [32]. Surgery is almost always required in cases of *S. aureus* PVE. Infection with *S. aureus* is a marker for hospital mortality.

Structural Valve Deterioration

Failure of mechanical valves in the absence of infection is rare. Mechanical failure from strut fracture often presents with dyspnea, acute heart failure, and hemodynamic collapse with a physical examination marked by absent valve clicks. Death from mechanical valve strut fracture ensues rapidly if the valve is in the aortic position; patients with mitral valve failure can often be stabilized prior to surgery.

With conventional stented bioprostheses, freedom from SVD is 70% to 90% by 10 years, and 50% to 80% at 15 years [133,134]. SVD of bioprostheses is often related to tearing or rupture of one prosthetic valve cusp or progressive calcification and immobility [135]. Risk factors for SVD include younger age at implant, mitral valve position, renal insufficiency, and hyperparathyroidism [136]. Evaluation for SVD requires TTE and often TEE with care to exclude endocarditis as a complicating feature. SVD is the most common cause of reoperative valve replacement in patients with a bioprosthesis. Indications for reoperation are similar for those with native valve disease and are dominated by the development of heart failure.

TABLE 34.6

ADVANCES IN VALVULAR HEART DISEASE

- Transcatheter aortic valve implantation for advanced calcific AS has been safely performed in select centers and is being studied in multiple clinical trials [47–49]. It will likely become available for clinical use in high-risk AVR patients with severe AS.
- Given the incremental risk conferred by coronary artery bypass grafting along with valve surgery, hybrid surgical approaches combining percutaneous coronary intervention with primary or reoperative valve repair/replacement are now being used for high-risk patients [143].
- The natural history of bicuspid aortic valve disease is influenced by age at diagnosis, degree of valvular dysfunction, and aortic morphology [10]. In patients with bicuspid aortic valves who require valve surgery, careful elucidation of thoracic aortic morphology by CT angiography or MRI is required for optimal planning [144].
- In patients with low-flow, low-gradient AS, significant predictors of poor outcome are impaired functional capacity on 6-minute walk, severity of AS at a normalized transvalvular flow rate, reduced peak stress LV ejection fraction during dobutamine echocardiography, multivessel coronary artery disease, and low mean gradient (<20 mm Hg) [26,27,33].
- Despite the association between atherosclerosis and calcific valve degeneration, intensive lipid lower therapy has failed to halt the progression of calcific AS in multiple randomized clinical trials [7,8].
- In developing countries, systematic screening with echocardiography reveals a higher prevalence of rheumatic heart disease (approximately 10 times as great) compared with clinical screening, raising important public health implications [69].
- Endovascular edge-to-edge mitral valve clipping can reduce mitral regurgitation and stimulate reverse remodeling, offering an alternative to surgical repair for functional mitral valve disease [145].
- Novel oral anticoagulants have been developed (e.g., dabigatran, a direct thrombin inhibitor) for use in AF and are being studied for anticoagulation of mechanical valve prostheses [146].
- Transcatheter closure of prosthetic paravalvular leak is being used in select centers [141].
- Updated guidelines now recommend that routine antibiotic prophylaxis for infective endocarditis is no longer necessary except in patients at greatest risk for complications from endocarditis, including those with prosthetic valves or previous endocarditis [132,147].

AF, atrial fibrillation; AS, aortic stenosis; AVR, aortic valve replacement; CT, computerized tomography; LV, left ventricle; MRI, magnetic resonance imaging.

Development of percutaneous valve-in-valve bioprosthesis implantation is underway and may offer an alternative to reoperation in select high-risk patients [137].

Paravalvular Regurgitation

Paravalvular regurgitation is most often due to infection, suture dehiscence or fibrosis, and calcification of the native annulus leading to inadequate contact between the sewing ring and annulus. Mild paravalvular regurgitation on perioperative echocardiography has a benign course with reoperation required in less than 1% of patients at 2 years [138]. In patients with more severe paravalvular leak, close follow-up is required and surgical intervention is warranted for those who develop symptoms, progressive LV dysfunction, or hemolysis. A large proportion (>50%) of mechanical valve patients have some degree of mild intravascular hemolysis marked by anemia and an elevated lactate dehydrogenase. Paravalvular leaks, particularly small leaks, can lead to more severe anemia due to shearing of red blood cells. Severe, refractory anemia not responsive to iron, folate, and erythropoietin is an indication for repeat valve operation or closure of the paravalvular leak [139]. In high-risk patients not suitable for reoperation, percutaneous occlusion of the paravalvular leak may be achieved in select cases with the use of a septal or ductal occluder device [140,141].

PREVENTING INFECTIVE ENDOCARDITIS

Emerging data on the lifetime risk of IE, as well as trends in antibiotic resistance and antibiotic-associated adverse events, have led to changes in guideline recommendations for antibiotic prophylaxis [142]. IE is much more likely to occur from frequent exposure to random bacteremias associated with daily activities than from medical or dental procedures. Antibiotic prophylaxis for IE should only be provided to patients at greatest risk for complications from endocarditis, including patients with prosthetic valves, previous IE, complex congenital heart disease, or cardiac transplantation. Routine antibiotic prophylaxis for mitral valve prolapse is no longer recommended. In the ICU, antibiotic prophylaxis may be reasonable for procedures involving an infected respiratory, gastrointestinal, or genitourinary tract [32,132].

Advances in valvular heart disease are summarized in Table 34.6.

CHAPTER 35 ■ CRITICAL CARE OF PERICARDIAL DISEASE

AKSHAY S. DESAI AND KENNETH L. BAUGHMAN†

PERICARDIAL ANATOMY

The pericardium consists of two layers: the inner layer (*visceral* pericardium) is a thin, elastic monolayer of mesothelial cells that is tightly adherent to the epicardial surface of the heart, whereas the outer layer (*parietal* pericardium) is a largely acellular network of collagen and elastin fibers that make up a thick, stiff fibrous envelope. The visceral pericardium reflects back near the origins of the great vessels and the junctions of the caval vessels with the right atrium, becoming continuous with the parietal pericardium and generating a potential space (pericardial *sac*) that is normally lubricated by up to 50 mL of serous fluid. Most of the heart (excepting a portion of the left atrium) and portions of the aorta, pulmonary trunk, pulmonary veins, and venae cavae are contained within this sac, which has ligamentous attachments to the diaphragm, sternum, and other structures in the anterior mediastinum. The main arterial blood supply of the pericardium is provided by the pericardiophrenic artery, a branch of the internal thoracic artery, whereas venous drainage occurs via pericardiophrenic veins that are tributaries of the brachiocephalic veins. Sensory enervation is provided by the phrenic nerves with vasomotor innervation from the sympathetic trunks [1,2].

NORMAL PHYSIOLOGY OF THE PERICARDIUM

Although an intact pericardium is not critical to the maintenance of cardiovascular function, the pericardium does have several physiologically relevant functions. First, it provides important structural support for the heart, limiting excessive cardiac motion within the thoracic cavity during respiration and changes in body position. In addition, it acts as a lubricant (minimizing friction between the cardiac chambers and the surrounding structures) and as an anatomic barrier to infection. Perhaps the best-characterized mechanical function of the normal pericardium, however, is as a restraint on cardiac filling and rapid chamber dilation [3]. At low applied stresses, approximating those at physiologic cardiac volumes, pericardial tissue is quite compliant. As the distending pressure increases, however, it abruptly becomes quite stiff and resistant to further stress. As a result, the pericardium passively restrains intracardiac volume and limits ventricular filling, with a component of intracavitary filling pressure reflecting transmitted pericardial pressure. In addition, this pericardial restraint defines a total compliance for the system, enhancing ventricular interdependence by accentuating the consequences of septum-mediated ventricular interactions during diastolic filling [4].

The pericardium itself has a small capacitance reserve (150 to 250 mL) that admits initial increments in intrapericardial volume with trivial increases in intrapericardial pressures. Once this capacitance is exceeded, rapid increases in intrapericardial volume result in steep increments in intrapericardial pressures, with potentially deleterious consequences for cardiac filling and ventricular performance [5,6]. By contrast, gradual changes in myocardial or pericardial volume (well in excess of the normal pericardial reserve) may be accommodated without invoking dramatic consequences of pericardial restraint. In experimental models of chronic volume overload, the pericardium exhibits the ability to undergo gradual stretch and hypertrophy, enhancing its compliance and diminishing its impact on the ventricular pressure–volume relationship [7]. Such chronic stretch is the primary mechanism permitting the accommodation of chronic cardiac dilation (as in dilated cardiomyopathy) or large, slowly accumulating pericardial effusions (as in malignant lymphoma), without hemodynamic embarrassment (Fig. 35.1).

PERICARDIAL PATHOPHYSIOLOGY

Pericardial manifestations are seen in a wide spectrum of medical and surgical conditions, including a host of infectious, immune/inflammatory, and neoplastic disorders (Table 35.1). Broadly speaking, from the vantage point of critical care, there are three conditions to be considered: (i) acute pericarditis, (ii) pericardial effusion and tamponade, and (iii) constrictive pericarditis. We consider the diagnosis, pathophysiology, and management of each of these in turn in the discussion to follow.

Acute Pericarditis

Pericardial inflammation presents in many clinical settings and has a wide range of causes. Although pericarditis is classically identified by the clinical triad of acute chest pain, pericardial friction rub, and characteristic electrocardiographic changes, subacute and chronic presentations are also possible. It may occur as an isolated entity or as the result of systemic disease; though most often a strictly inflammatory fibrinous lesion without clinically recognizable fluid, sequelae including pericardial effusion (occasionally progressing to tamponade), pericardial constriction, or recurrent (relapsing) pericarditis are often seen. A prevalence of around 1% in autopsy studies suggests that pericarditis may frequently be subclinical [8]. Pericarditis is thought to account for around 5% of presentations to emergency departments for nonischemic chest pain [9].

Causes

Despite an ever-expanding array of diagnostic techniques, the vast majority of cases of pericarditis remain idiopathic in etiology [10–12]. Even when pericardial fluid or tissue samples are obtained, the cause is undefined in up to 30% of patients.

†Deceased

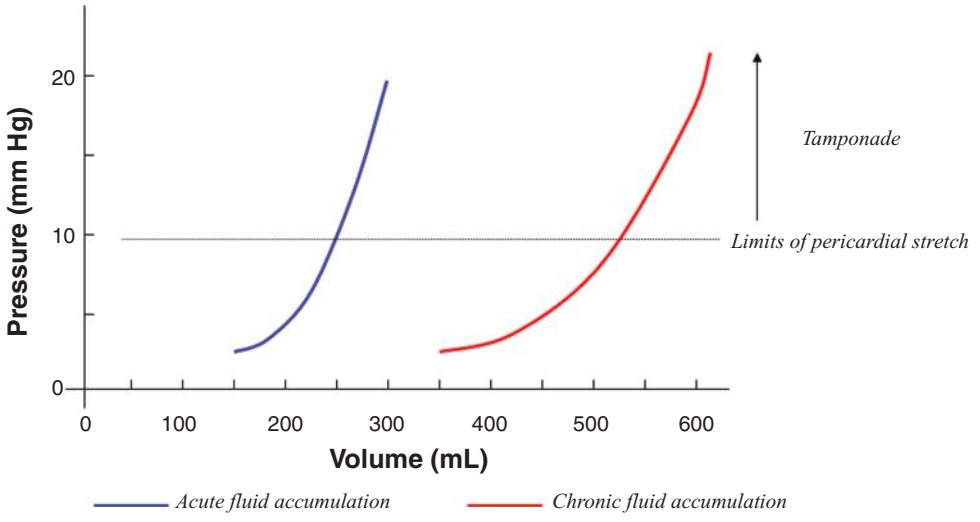

FIGURE 35.1. Pericardial pressure–volume relationship and relationship to development of pericardial tamponade. The ability of the pericardium to accommodate pericardial fluid without hemodynamic embarrassment depends heavily on the rate of fluid accumulation. Note the steepness of the relationship in normal pericardium and the marked flattening and shift to the right with chronic volume overload. [Adapted from Freeman G, LeWinter MM: Pericardial adaptations during chronic cardiac dilation in dogs. *Circ Res* 54:294–300, 1984.]

Broadly speaking, pericarditis is either infectious (two-thirds of cases) or noninfectious (one-third of cases) in etiology, with noninfectious cases attributable to one of a number of immune, neoplastic, traumatic, and metabolic conditions (see Table 35.1). A wide range of organisms cause infectious pericarditis, but viral infection remains the most common probable or identifiable cause. Organisms responsible for myocarditis are commonly implicated, particularly enteroviruses, adenoviruses, and influenza; herpes simplex and cytomegalovirus may also be important in immunocompromised individuals. Myopericarditis has also been reported after smallpox vaccination in US military personnel not previously exposed to vaccinia [13]. Although pericardial abnormalities are seen in up to 20% of patients with human immunodeficiency virus (HIV) infection, symptomatic pericarditis in these patients is commonly due to secondary infection (e.g., mycobacterial) or neoplasia (particularly lymphoma or Kaposi's sarcoma), and the frequency decreases with effective antiretroviral therapy [14]. Bacterial pathogens typically cause purulent pericarditis, but are implicated infrequently in pericardial disease, typically as a consequence of hematogenous seeding or direct extension from adjacent infected tissues (lungs or pleural space) [15]. *Mycobacterium tuberculosis* causes up to 4% of acute pericarditis cases and 7% of tamponade presentations in developed countries, and remains an important causal factor in developing nations and immunocompromised hosts [16,17]. Tuberculosis-related pericarditis can require pericardial biopsy for diagnosis and is complicated by pericardial effusion or constriction in up to 50% of cases [18].

In the remainder of patients, pericarditis occurs in conjunction with a dissecting aortic aneurysm (in which blood leaks into the pericardial space), after blunt or sharp trauma to the chest, as a result of neoplastic invasion of the pericardium, after chest irradiation, in association with uremia or dialysis, after cardiac or other thoracic surgery, in association with an inflammatory or autoimmune disorder, or as a result of certain pharmacologic agents. Iatrogenic cases are increasingly common, with postpericardiotomy syndrome reported in up to 20% of patients at a median of 4 weeks following cardiac surgery [19] and symptomatic pericarditis in up to 2% of patients undergoing percutaneous coronary intervention, catheter ablation procedures, or implantation of active fixation pacemaker or defibrillator leads [10]. Pericarditis associated with acute transmural myocardial infarction and the delayed immune-mediated postinfarction pericarditis of Dressler's syndrome used to be common, but the incidence has declined with the broader utilization of early reperfusion strategies for acute coronary syndromes (thrombolysis and primary angioplasty).

Presentation and Diagnosis

Although patients with acute pericarditis may be asymptomatic, the typical presentation is with chest pain that is retrosternal in location, sudden in onset, and exacerbated by inspiration (pleuritic). The pain may be made worse by lying supine and improved by sitting upright and leaning forward. Precordial distress may closely mimic angina, including a predominant pressure sensation with radiation to the neck, arms, or left shoulder. However, radiation of chest pain to one or both trapezius muscle ridges favors the diagnosis of pericarditis because the phrenic nerve, which innervates these muscles, traverses the pericardium. A prodrome of low-grade fever, malaise, and myalgia is common, but fever may be absent in elderly patients. Associated symptoms can include dyspnea, cough, anorexia, anxiety, and occasionally, odynophagia or hiccups.

Nearly 85% of patients with pericarditis have an audible friction rub during the course of their disease [12]. Typically, the rub is a high-pitched scratchy or squeaky sound best heard at the lower left sternal border or apex at end expiration with the patient leaning forward. Classically, it consists of three components corresponding to ventricular systole, early diastolic filling, and atrial contraction, and has been likened to the sound made when walking on crunchy snow. It is distinct from a pleural rub in that it is present throughout the respiratory cycle, whereas the pleural rub disappears when respirations are suspended. The pericardial friction rub is often a dynamic sound that can disappear and reappear over short periods of time. Because of this variable quality, frequent auscultation in the upright, supine, and left lateral decubitus positions is important for patients in whom a diagnosis of pericarditis is suspected.

Electrocardiogram

The electrocardiogram (ECG) is a key diagnostic test in suspected pericarditis, though typical changes are not always seen. The classic finding is widespread, concave ST-segment elevation, often with associated PR-segment depression (Fig. 35.2). Although the changes may appear regional and therefore mimic myocardial ischemia, reciprocal ST-segment depressions are absent, as are pathologic Q-waves. In addition, the ECG in pericarditis exhibits a typical pattern of evolution that is

TABLE 35.1

ETIOLOGIES OF ACUTE PERICARDIAL DISEASE

Etiology	Examples	Incidence	Treatment
Idiopathic[a]	—	85%–90%	Aspirin, NSAIDs
Infectious	Echovirus, coxsackievirus, adenovirus, cytomegalovirus, hepatitis B, Epstein–Barr virus (infectious mononucleosis), HIV/AIDS *Pneumococcus*, *Staphylococcus*, *Streptococcus*, *Mycoplasma*, *Borrelia* spp. (Lyme disease), *Haemophilus influenzae*, *Neisseria meningitidis*, *Mycobacterium tuberculosis*, *M. avium-intracellulare, Histoplasma*, *Coccidioides*		
Viral[a]		1%–2%	Aspirin, NSAIDs
Bacterial[a]		1%–2%	Antibiotics, surgical drainage
Mycobacterial[a]		4%–5%	Antimycobacterial therapy and prednisone
Fungal		Rare (<1%)	Antifungal therapy, drainage
Immune/inflammatory	Connective tissue disease[a] (systemic lupus erythematosus, rheumatoid arthritis, scleroderma)	3%–5%	Aspirin, NSAIDs, glucocorticoids
	Arteritis (polyarteritis nodosa, temporal arteritis)	Rare (<1%)	Discontinue drug; aspirin, NSAIDs
	Drug induced[a] (e.g., procainamide, hydralazine, isoniazid, cyclosporine)		
Neoplastic	Primary: mesothelioma, sarcoma, etc.	5%–7%	NSAIDs, intrapericardial infusion of glucocorticoids
	Secondary[a]: breast carcinoma, lung carcinoma, lymphoma		
Myocardial infarction related	Early postmyocardial infarction (MI)	5%–6% of patients with transmural MI	Aspirin (avoid NSAIDs)
	Late postmyocardial infarction (Dressler's syndrome)[a]	Formerly 3%–4% of patients with MI, much less in the era of early reperfusion	
Aortic dissection related	Proximal aortic dissection	Rare (<1%)	Urgent surgery (do not drain)
Traumatic[a]	Blunt and penetrating trauma, postcardiopulmonary resuscitation	NA	NSAIDs (avoid aspirin)
Procedure and device related	Early postcardiac surgery	Common	Aspirin, NSAIDs
	Post-ICD/pacemaker,[a] postangioplasty,[a] late post cardiotomy or thoracotomy (Dressler's variant)[a]	Rare (<1%)	Aspirin, NSAIDs
Radiation induced[a]	Chest wall irradiation	Rare (<1%)	NSAIDs
Uremic or dialysis associated	—	~5% of patients with chronic kidney disease predialysis, ~13% after dialysis	Initiate or intensify dialysis, NSAIDs

[a] Conditions that manifest as acute pericarditis.

distinct from that of patients with evolving myocardial infarction. In patients with pericarditis, the ECG on presentation usually demonstrates diffuse ST-segment elevation and PR-segment depression (stage I) and evolves through three subsequent phases [20]. During the evolutionary phase (stage II), all ST-junctions return to baseline more or less "in phase," with little change in T-waves. (By contrast, in patients with ST-segment elevation due to acute myocardial injury, T-wave inversion begins to occur *before* the ST-segments return to baseline.) The T-waves subsequently flatten and invert (stage III) in all or most of the leads that showed ST-segment elevations. In stage IV, the T-waves return to their prepericarditic condition. The widespread T-wave inversions that appear in stage III are indistinguishable from those of diffuse myocardial injury, myocarditis, or biventricular injury. The entire ECG evolution occurs in a matter of days or weeks, but may not be seen in every patient. Often, the transition from stage III to stage IV is relatively slow, with some patients left with some degree of T-wave inversion for an indefinite period.

Although some 80% of patients with pericarditis exhibit a typical stage I ECG during their course [21], atypical variants (or even a normal ECG) may also be seen. An important ECG variant that can be quasidiagnostic is PR-segment (not PR-interval) depression in the absence of true ST-segment elevation, which though nonspecific, may be the only sign of pericarditis. This may occur as a consequence of superficial myocarditis affecting the atrium [22]. Although the ST-changes of pericarditis may occasionally resemble those of normal early

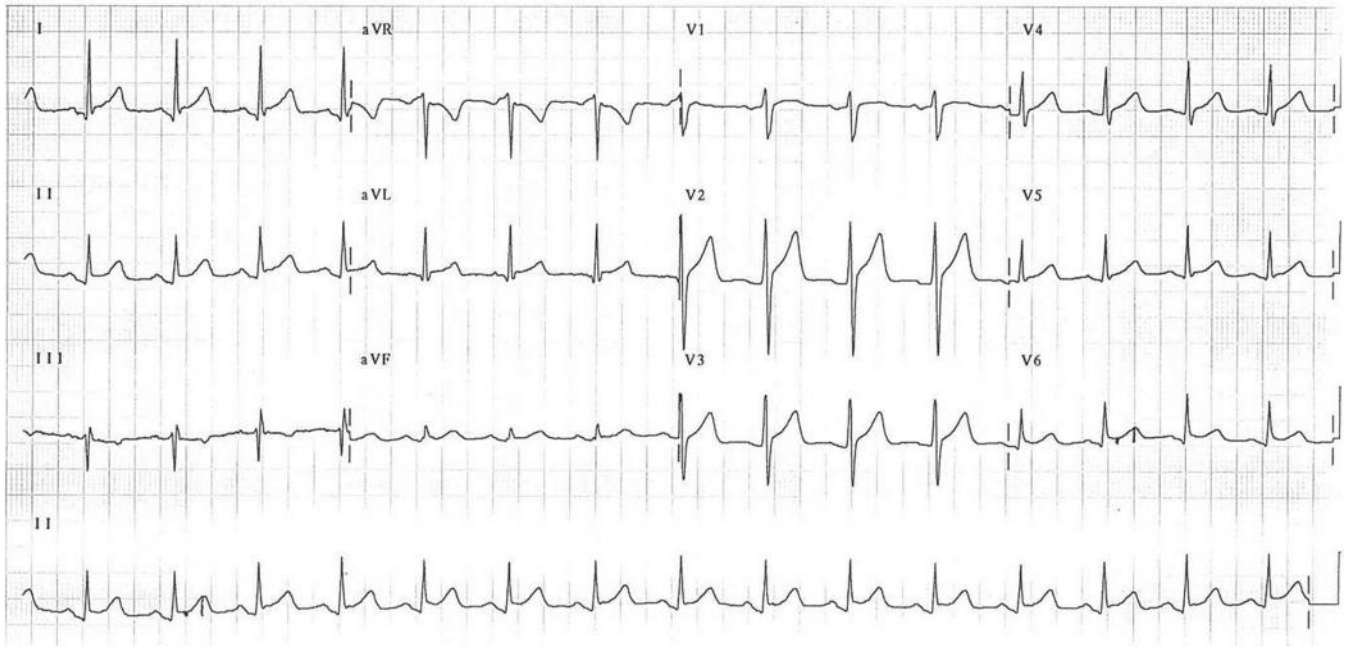

FIGURE 35.2. Electrocardiogram (ECG) in acute pericarditis. Note the diffuse, upward concave ST-segment elevation and PR-segment depression (lead II).

repolarization, a useful differentiating feature may be the ratio between the height of the ST-segment and the T-wave in lead V_6. A ratio exceeding 0.24 favors the diagnosis of pericarditis [23].

Imaging and Additional Laboratory Testing

Although laboratory findings in patients with suspected pericarditis are nonspecific, measurement of serum markers of inflammation (leukocyte count, erythrocyte sedimentation rate, C-reactive protein, and lactate dehydrogenase) and myocardial necrosis (creatine kinase, and troponins) may help to establish or confirm the diagnosis, define the extent of associated myocardial injury, and guide subsequent follow-up. The 2004 European Society of Cardiology guidelines on the management of pericardial diseases [24] therefore advise measurement of these parameters as part of the initial diagnostic evaluation in all patients, but this recommendation remains somewhat controversial. A markedly elevated white blood cell count, particularly in association with high fever, should raise suspicion for purulent pericarditis, and may prompt sampling of pericardial fluid (if present) for diagnosis. Cardiac enzymes including creatine kinase (creatine kinase, total and MB-fraction) and troponins are commonly elevated in patients with pericarditis due to associated epicardial inflammation or myocarditis [25]. Elevations in troponin I are seen more commonly than those in CK-MB and are frequently associated with male gender, ST-segment elevation, younger age at presentation, and pericardial effusion. The degree of troponin elevation is roughly related to the extent of myocardial inflammation and, distinct from acute coronary syndromes, does not appear to correlate with long-term prognosis [26]. Routine measurement of cardiac troponins in patients with suspected or definite pericarditis may therefore be unnecessary, unless there is suspicion for associated transmural myocardial infarction by ECG (due to the presence of pathologic Q-waves) [27]. Similarly, routine serologic testing for antinuclear antibodies or rheumatoid factor is rarely helpful, save in those patients in whom other clinical features suggest underlying connective tissue illness.

The chest radiograph is typically normal in acute pericarditis, but is often performed as a matter of course to assess for abnormalities in the mediastinum or lung fields, which may suggest an etiology, and to exclude cardiomegaly, which suggests the presence of a substantial pericardial effusion (>250 mL). Pericardial calcification is rarely seen, but may suggest constrictive pericarditis. Any suspicion for cardiomegaly should prompt a transthoracic echocardiogram to assess for hemodynamically significant pericardial effusion or tamponade. Routine echocardiography in patients with unequivocal evidence of pericarditis and normal hemodynamics by physical examination is probably unnecessary, though the detection of a pericardial effusion may help to support the diagnosis. In addition, detection of wall motion abnormalities or left ventricular dysfunction on echocardiography may be helpful in detecting associated myocardial infarction or in assessing the severity of associated myocarditis.

Natural History and Management

There are no large, randomized, controlled clinical trials to guide the therapy of patients with acute pericarditis. Initial management is directed at screening for specific etiologies and underlying conditions that may alter the treatment strategy (e.g., connective tissue disease, HIV infection, and tuberculosis) and control of symptoms. In the vast majority of patients, acute idiopathic pericarditis is a self-limited disease without significant complications or recurrence, and may be safely managed in the outpatient setting [28]. A subset of patients with high-risk features including fever greater than 38°C, subacute course (symptoms developing over days or weeks), large pericardial effusion (>20 mm in width in diastole by echocardiography), cardiac tamponade, or failure to respond to treatment with aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs) should be considered for hospital admission to permit additional observation and a more extensive etiologic work-up [29]. Immunosuppressed patients and those with blunt or penetrating chest trauma, serologic evidence of myocarditis (based on elevated cardiac biomarkers), or need for oral anticoagulant therapy may also be at risk for complications and warrant closer observation [30].

Treatment of pericarditis may vary on the basis of etiology. For the minority of cases in which a specific diagnosis is identified, therapy should be tailored appropriately, as outlined in

Table 35.1. (Details of treatment for specific conditions are beyond the scope of this discussion.) In uncomplicated cases of idiopathic pericarditis, treatment with NSAIDs is the cornerstone of therapy. Across the board, these agents are effective in reducing inflammation and symptoms of pain, fever, and malaise associated with pericarditis. Limited observational data suggest that the various available NSAIDs have comparable efficacy [31]. As a first-line agent, many favor treatment with ibuprofen, which is well tolerated and can easily be titrated over a range of doses. The typical dose is 600 mg every 6 hours, which sometimes relieves pain within 15 minutes to 2 hours of the first dose. Depending on patient tolerance and therapeutic response, the individual dose can be reduced to 400 mg or raised to 800 mg or greater with continued observation for side effects. Should this fail, aspirin 600 to 900 mg four times per day may be given. Indomethacin may be used, always given on a full stomach and in divided doses from 100 to 200 mg per day, beginning with 25 mg every 6 hours. In patients with myocardial infarction–related pericarditis, indomethacin should probably be avoided in light of experimental work showing that it reduces coronary flow, increases experimental infarction size, and raises blood pressure. Aspirin is the agent of choice in these cases because among the NSAIDs, it least retards scar formation in the infracted heart [32]. In all patients receiving high-dose NSAIDs, gastrointestinal protection with an antacid or proton–pump inhibitor should be considered to reduce the risk of drug-induced gastritis or bleeding.

Pain is typically relieved within hours to days of initiation of anti-inflammatory medications. Occasionally, chest pain persists beyond 2 weeks of therapy with an NSAID, but responds to therapy with a different NSAID or to the addition of colchicine 0.6 mg twice daily. Recurrent pericarditis may complicate 15% to 32% of cases, and can be a particularly troublesome problem [33]. Colchicine has long been known to be effective in preventing relapses of polyserositis in familial Mediterranean fever [34]. A wealth of observational data now support the notion that colchicine as an adjunct to therapy with NSAIDs or corticosteroids is well tolerated and effective in the treatment and prevention of relapsing pericarditis [35]. A small, randomized, controlled trial seems to confirm this impression. In the Colchicine for Recurrent Pericarditis (CORE) [36] trial, 84 patients with a first episode of recurrent pericarditis were randomized to conventional therapy with aspirin alone or conventional treatment plus colchicine (1.0 to 2.0 mg the first day and then 0.5 to 1.0 mg day for 6 months). Treatment with colchicine significantly decreased the recurrence rate at 18 months from 50.6% to 24.0% (p = 0.02, 95% confidence interval 2.5 to 7.1) and simultaneously reduced symptom persistence at 72 hours.

Efficacy in recurrent pericarditis has spurred interest in the utilization of colchicine in the first episode of acute pericarditis for the prevention of recurrent pericarditis. In the Colchicine for Acute Pericarditis (COPE) [37] trial, 120 patients experiencing their first episode of acute pericarditis (idiopathic, viral, postpericardiotomy, and connective tissue disease related) were randomly assigned to conventional treatment with aspirin or conventional treatment plus colchicine (1.0 to 2.0 mg for the first day and then 0.5 to 1.0 mg per day for 3 months). Corticosteroid therapy was permitted but restricted to patients with aspirin contraindications or intolerance. During the 2,873 patient-months of follow-up, colchicine significantly reduced both the symptom persistence at 72 hours and the recurrence rate relative to conventional therapy alone (recurrence rates 10.7% vs. 32.3%, respectively, at 18 months, p = 0.004). Overall, the COPE trial provides evidence to support the use of colchicine as an adjunct to NSAIDs during a first episode of pericarditis to prevent recurrence, though routine use of this agent for this indication is not recommended.

Intractably symptomatic pericarditis occasionally calls for adjunctive treatment with narcotics or more aggressive immunosuppression with corticosteroids, azathioprine, or even cyclophosphamide, though there is limited clinical experience with many of these agents [38]. Caution should be exercised in particular with initiation of steroid therapy, given that many patients experience extreme difficulty in weaning once they are begun. Importantly, in both the CORE and COPE trials, prednisone therapy was a strong predictor of pericarditis relapse, confirming the empiric observation that glucocorticoid therapy is a major factor in recurrence [39]. Steroid therapy should therefore be reserved as a therapy of last resort for nontuberculous, nonconnective tissue disease–related pericarditis. When necessary, steroids should be utilized in the lowest effective dose and rapidly weaned. Intrapericardial instillation of steroids may be an alternative in refractory cases and may help to avert some of the side effects of systemic therapy [40]. Of note, pericardiectomy has occasionally been employed for recurrent pericarditis, but appears to be effective in the minority of patients, perhaps because complete removal of the pericardium is not possible, and residual pericardial or pleural surfaces may remain inflamed [41].

Pericardial Effusion and Tamponade

Pericardial effusion may appear as a complication of acute pericarditis or as an isolated entity. In 60% of cases, the etiology is related to a known systemic disease [42]. Effusions are common following cardiac surgery; as many as 10% may progress to late tamponade [43]. Severe circulatory congestion due to heart failure may result in transudative effusion as a consequence of markedly elevated intracardiac filling pressures or obstructed pericardial drainage. Hemopericardium is a potentially lethal complication of chest wall trauma, myocardial rupture, or proximal aortic dissection. In some cases of pericardial effusion, despite a thorough diagnostic evaluation, there may be no identifiable cause even when the effusion has been present for years; such idiopathic effusions generally have benign course, though tamponade can develop without warning over time [44]. Because of the high prevalence of idiopathic pericarditis, this disorder accounts for the bulk of pericardial tamponade; as noted, however, this condition typically has a benign, uncomplicated course. By contrast, effusions associated with bacterial, fungal, and HIV infection, those associated with neoplasia, and those associated with bleeding into the pericardial space have a high likelihood of progressing to tamponade [45].

Pericardial effusions may have a spectrum of hemodynamic effects ranging from the inconsequential to complete circulatory collapse. As noted previously, the pericardium has a limited reserve volume such that the rapid accumulation of even modest amounts of pericardial fluid may have important hemodynamic consequences for ventricular filling and overall cardiac performance. Slowly accumulating effusions may be accommodated by pericardial stretch over time and may therefore escape clinical diagnosis until they are quite large. Although computed tomography (CT) and magnetic resonance imaging (MRI) may be more sensitive for the identification of small amounts of pericardial fluid, echocardiography is the primary modality for evaluation of the functional consequences of any pericardial effusion.

Cardiac Tamponade

Cardiac tamponade is defined as hemodynamically significant cardiac compression due to accumulating pericardial contents that evoke and defeat compensatory mechanisms, resulting in a decline in cardiac output (Fig. 35.3) [46]. The severity of cardiac compression may vary widely depending on the quantity and rate of accumulation of fluid, blood, pus, or gas

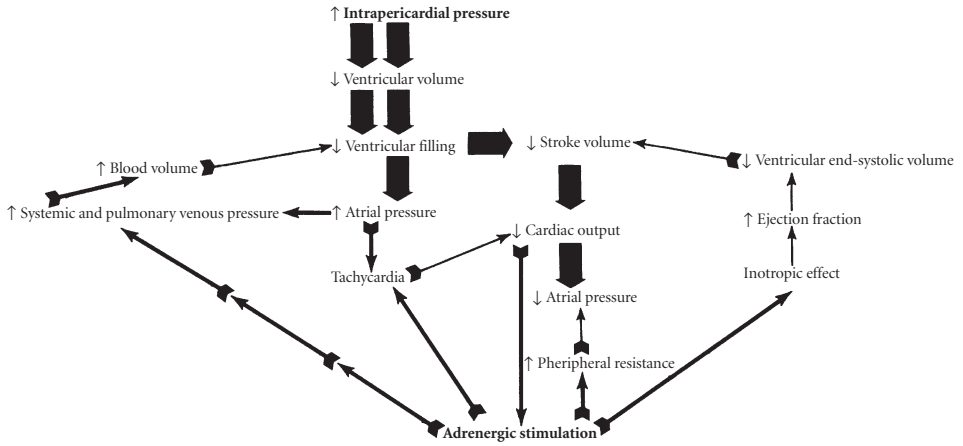

FIGURE 35.3. Cardiac tamponade (*heavy arrows without tails*) and compensatory mechanisms (*arrows with tails*). Thin-tailed arrows represent immediate mechanisms directed against tamponade changes; intermediate mechanisms are represented by heavier-tailed arrows. For example, decreased ventricular filling due to decreased ventricular volume is immediately supported by increased blood volume. Development of the latter is stimulated by the intermediate mechanism, increased venous pressures (see text).

(including air) in the pericardial space. Occasionally, pericardial effusion and tamponade are seen in combination with underlying constrictive physiology (constrictive–effusive pericarditis). Tamponade should be considered in the differential diagnosis of any patient with cardiogenic shock and systemic congestion.

Physiology

Understanding the physiology of cardiac tamponade is essential to diagnosis and treatment. The primary hemodynamic abnormality is an increase in pericardial pressure that affects the filling of one or more cardiac chambers; due to lower filling pressures in systole and diastole, right-heart performance is initially affected disproportionately to that of the left heart. For significant cardiac compression, the pericardial contents must increase at a rate exceeding the rate of stretch of the parietal pericardium (see Fig. 35.1) and, to some degree, the rate at which venous blood volume expands to maintain the small filling gradient to the right heart. As the chambers become progressively smaller and myocardial diastolic compliance is reduced, cardiac inflow becomes limited, ultimately equalizing mean diastolic pericardial and chamber pressures. Relentlessly increasing intrapericardial pressure progressively reduces ventricular volume to the point that even a high ejection fraction cannot avert critical reduction of stroke volume at any heart rate.

True filling pressure in the heart chambers is defined by the transmural pressure, which is equal to the difference between cavity pressure and pericardial pressure. Pericardial pressure is normally negative, and therefore augments transmural pressure (suction effect), facilitating cardiac filling. Increasing pericardial pressure due to accumulation of pericardial contents reduces and ultimately offsets transmural pressures, thereby compromising filling. In tamponade, both the ventricles fill against a common stiffness (pericardium plus fluid), evoking corresponding increases in left and right atrial pressures. Pericardial pressure quickly exceeds early diastolic pressure in the atria and right ventricle and rises further during ventricular diastolic expansion, causing early diastolic right ventricular collapse, which further impedes atrial emptying. Ultimately, there is elevation and near-complete equalization of pericardial and four-chamber pressures in diastole, abolishing the normal pressure gradient for filling; the ventricles may fill only during atrial systole, particularly at rapid heart rates. Because of reduced filling, ventricular systolic pressure ultimately falls, along with stroke volume, reducing cardiac output. As in heart failure, this fall in output triggers a cascade of compensatory neurohormonal mechanisms that generate tachycardia, increased contractility, enhanced circulating blood volume, and increased systemic vascular resistance in an attempt to defend end-organ perfusion (Fig. 35.3).

Presentation and Diagnosis

Cardiac tamponade may appear insidiously as the first sign of pericardial injury or intrapericardial bleeding, especially in conditions such as neoplasia, trauma, and connective tissue disorders. Commonly, however, it follows clinical acute pericarditis. The symptoms of tamponade are not specific, and may be similar to those of congestive heart failure (though frank pulmonary edema is uncommon). Dyspnea and fatigue are common presenting complaints, and patients may have other signs and symptoms of an associated systemic illness (e.g., malignancy or connective tissue disease). Those with advanced cardiac compression may exhibit signs of hypoperfusion, including pallor, cyanosis, confusion, diaphoresis, diminished urine output, and cold extremities. In patients with rapid tamponade due to hemorrhage, as in wounds and cardiac or aortic rupture, the dominant picture is one of shock, which if unchecked, can rapidly lead to electromechanical dissociation and death.

On physical examination, tachycardia and hypotension (relative or absolute) are the rule, though bradycardia may occasionally be seen in association with myxedema or uremia. Jugular venous distension is usually apparent, except in cases of rapid tamponade (e.g., acute hemopericardium), in which there has been insufficient time for the blood volume to increase. The venous contour typically exhibits an absent *y* descent due to loss of the gradient for passive ventricular filling in early diastole. The normal inspiratory fall in venous pressures is preserved in uncomplicated cardiac tamponade; a rise (or absence of fall) in the jugular venous pressure (Kussmaul's sign) is suggestive of associated constrictive physiology. When tamponade is due to inflammatory or neoplastic lesions, pericardial rubs frequently are present and can be quite loud, although the heart sounds may be distant due to insulating effects of the pericardial fluid and reduced ventricular function.

Excessive fluid in the pericardium often exaggerates the normal pericardial effects on ventricular interaction, heightening the normal inspiratory decrease in systemic blood pressure, leading to *pulsus paradoxus*. This is conventionally defined as a drop in systolic pressure of more than 10 mm Hg with normal inspiration, and may be palpable in muscular arteries (such as the femoral artery) [47]. The phenomenon occurs because in tamponade, increased right heart filling with inspiration can only be accommodated by bulging the atrial and ventricular septa toward the left atrium and ventricle (due to restraint by pericardial fluid). The decrease in left ventricular filling due to septal shift (enhanced by the normal decrease in left atrial filling on inspiration) diminishes left ventricular stroke volume and arterial pressure. Although pulsus paradoxus is the hallmark of tamponade, it may also be present in patients with obstructive lung disease (including severe asthma), pulmonary embolism, tense ascites, obesity, right heart failure due to mitral

stenosis or right ventricular infarction, and hypovolemic and cardiogenic shock. Because pulsus paradoxus occurs when respiratory changes alternately favor right and left heart filling, it may be absent in conditions that balance or blunt the effects of inspiratory venous return on ventricular filling (e.g., pericardial adhesions, atrial septal defect, severe aortic insufficiency, or diminished left ventricular compliance due to severe hypertrophy, infiltrative myopathy, myocardial infarction, or advanced heart failure) or in cases of severe hypotension where respiratory blood pressure variations may be imperceptible.

Additional Diagnostic Testing

The ECG in tamponade is rarely diagnostic. Clinical signs of pericarditis (ST-segment elevations and PR-depressions) may persist, and frequently, there is some decrease in voltage of the QRS and T-waves (typically sparing the P-wave), reflecting insulation of the heart by surrounding fluid and the effects of cardiac compression [48]. Although common, however, low voltage is not a sensitive or specific finding for tamponade. By contrast, electric alternation (beat-to-beat variation in P- or QRS amplitude reflecting a shifting electrical axis as the heart swings within a large effusion) is fairly specific for tamponade and virtually pathognomonic when it affects the both the P-waves and the QRS complex (simultaneous alternation) [49]. Although an enlarged cardiac silhouette on chest radiography may suggest a pericardial effusion, the chest radiograph alone is rarely diagnostic because cardiomegaly, large pericardial cysts, and pericardial effusions may be difficult to distinguish.

Echocardiography has a high degree of sensitivity and specificity for recognizing pericardial fluid and is the key diagnostic test for assessing the hemodynamic significance of a pericardial collection. CT, spin-echo, and cine MRI can also be used to assess the size and extent of simple and complex pericardial effusions (and indeed may be more sensitive for small amounts of pericardial fluid), but measurements by CT and MRI tend to be larger than those by echocardiography, and neither radiographic technique is typically useful in the acute management of patients with suspected tamponade [50]. By echocardiography, a pericardial effusion typically appears as a lucent separation between visceral and parietal pericardium in the region of the posterior left ventricular wall. With larger effusions, the fluid is also demonstrated anterior to the right ventricle. As pericardial effusion increases, movement of the parietal pericardium decreases. When the amount of pericardial effusion is massive, the heart may have a "swinging" motion in the pericardial cavity, the echocardiographic correlate of electrical alternans seen on the ECG.

Several echocardiographic findings indicate that a pericardial effusion is large enough to cause hemodynamic compromise (tamponade physiology). Early diastolic collapse of the right ventricle and late diastolic right atrial inversion are seen when pericardial pressure transiently exceeds the intracavitary pressure and are characteristic, though not entirely specific signs of tamponade [51]. The inferior vena cava is typically dilated with blunted respiratory variation indicating elevated right-sided filling pressures. Inspiratory shift of the ventricular septum toward the left and respiratory variation in ventricular chamber size may also be seen, reflecting right ventricular filling at the expense of the left due to essentially fixed intrapericardial volume. Corresponding changes can be seen on Doppler echocardiography, which permits the detection of exaggerated respiratory variation in transmitral and transtricuspid flow velocities during diastole. During inspiration, intrapericardial pressure (and therefore left ventricular end-diastolic pressure) and intrathoracic pressure normally fall to the same degree, whereas in tamponade, intrapericardial pressure falls substantially less than intrathoracic pressure. This leads to discordant changes in pulmonary venous pressure and left ventricular end-diastolic pressure on inspiration that diminish the pressure gradient for left ventricular filling. As a result, mitral valve opening is delayed, isovolumic relaxation time is prolonged, and peak transmitral filling velocity decreases. Reciprocal changes occur on the right side of the heart, with a resultant inspiratory increase in peak transtricuspid filling velocity [52]. Corresponding changes are visible on Doppler interrogation of the pulmonary and hepatic venous flows and may enhance the sensitivity and specificity of echocardiography for diagnosis of tamponade [53].

Cardiac catheterization in patients with tamponade is often performed as a prelude to pericardiocentesis, but can also be diagnostic. Typically, the hemodynamics at catheterization are notable for elevation and equalization of average diastolic pressures across all four cardiac chambers in the range of 15 to 30 mm Hg. As with the jugular venous waveform, the right atrial pressure tracing displays an absent *y* descent and preserved *x* descent, corresponding to diminished atrial emptying during ventricular diastole as a consequence of elevated end-diastolic pressures. As with echocardiography, discordant inspiratory changes in right- and left-sided pressures are often seen, with a fall in left-sided filling pressures and stroke volume with inspiration corresponding to the pulsus paradoxus noted on physical examination and the diminished transmitral flow seen by Doppler. For reasons that remain unclear, despite comparable filling pressures to patients with advanced heart failure, patients with cardiac tamponade do not typically develop pulmonary edema [54].

Special Cases

Because tamponade physiology is merely the result of a pericardial pressure that exceeds intracavitary pressure, it may occur at lower diastolic pressures (6 to 12 mm Hg) in patients who have a decrease in circulating blood volume and cardiac filling pressures due to hypovolemia or hemorrhage. In these conditions, even a relatively modest elevation in pericardial pressure may lower the transmural filling pressure sufficiently to compromise stroke volume. Such "low-pressure" tamponade may lack the typical hemodynamic or clinical signature, and is typically observed in patients with preexisting effusions who undergo aggressive diuresis or hemodialysis [55]. In addition, regional tamponade, affecting only limited portions of the heart (or even a single cardiac chamber), may occur in the setting of pericardial adhesions and loculated fluid collections, as can be seen after cardiac bypass surgery (even after the pericardium is left open). In this case, the typical hemodynamic features may not be present on conventional imaging, and diagnosis may require transesophageal echocardiography [56].

Management

Although pericardial effusions that are small or resolve rapidly with anti-inflammatory treatment may not require invasive therapy, those associated with hemodynamic compromise should be promptly drained using either a percutaneous or surgical approach. Transient medical stabilization of patients with tamponade physiology can often be achieved through aggressive volume resuscitation (particularly in volume-depleted patients) and pressor support with inotropic agents (e.g., norepinephrine, isoproterenol, and dobutamine), but medical therapy alone is usually insufficient. Positive-pressure ventilation may precipitate hemodynamic collapse due to excessive preload reduction, and should be avoided where possible until pericardial drainage can be accomplished. Percutaneous needle pericardiocentesis may be performed by trained personnel in the cardiac catheterization laboratory or at the bedside with echocardiographic (or CT) guidance. Echocardiography is helpful in demonstrating the most accessible window for passage of a needle; typically, the subxiphoid approach is most

effective, with insertion of a long needle underneath the xiphoid process at a 30-degree angle to the skin, directed gradually toward the left shoulder until pericardial fluid is aspirated. Attachment of an electrocardiographic lead to the needle may be useful for additional guidance in identifying the pericardial space because contact of the needle with myocardium generates an electrocardiographic current of injury. An apical approach (using a shorter needle inserted in the sixth or seventh rib space in the anterior axillary line) can also be considered if adequate fluid is visible in this region by echocardiography.

Once the pericardial space is reached, a soft-tipped guidewire is passed into the pericardial space and the needle removed. A multiholed catheter can then be introduced over the wire, sutured in place, and connected to a reservoir to allow complete drainage of the remaining pericardial fluid over the next several hours. Rapid reduction in intrapericardial pressures and associated hemodynamic improvement may be seen after the aspiration of only 100 to 200 mL of fluid. Fluid specimens should be sent for appropriate chemistry, cytology, and culture as appropriate for more definitive identification of etiology and direction of appropriate adjuvant therapy.

For patients with intrapericardial hemorrhage (e.g., due to proximal aortic dissection) or tamponade due to purulent pericarditis, surgical drainage may be optimal. A surgical approach may also be necessary in patients with rapid reaccumulation of pericardial fluid following pericardiocentesis (as is common in patients with malignant effusions), patients with loculated effusions causing regional tamponade (as following cardiac surgery), or in patients with large intrapericardial clots that are not amenable to catheter drainage. The two most commonly utilized surgical options are surgical subxiphoid incision and drainage and video-assisted thoracoscopic drainage [57] with creation of a pleuropericardial "window" to allow longer term egress of pericardial fluid into the pleural space. Thoracoscopic surgery provides the opportunity for concurrent performance of additional procedures such as biopsy of the lung, biopsy of pleural or mediastinal masses, or management of a concomitant pleural effusion, but requires single-lung ventilation and lateral decubitus positioning, which may preclude use of this approach in an emergency. Both the approaches may be accomplished with limited perioperative morbidity, and conversion to an open surgical approach (median sternotomy or anterolateral thoracotomy) is rarely necessary [58]. In patients who are poor candidates for surgical drainage, percutaneous balloon pericardiotomy may be an effective alternative [59].

Constrictive Pericarditis

Constrictive pericarditis is a rare, but severely disabling, consequence of chronic pericardial inflammation characterized by progressive fibrosis and dense adhesion of the pericardium that progressively impairs ventricular filling. Any patient with acute pericarditis may ultimately go on to develop constriction, but the syndrome appears particularly common in patients with pericardial disease due to tuberculosis, therapeutic chest irradiation, prior cardiac surgery, chest trauma, or uremia. The time course of development is variable, with constrictive physiology occasionally apparent acutely (constrictive–effusive pericarditis) but more commonly seen months to years following the initial inflammatory insult. The clinical presentation is that of marked venous congestion in the face of relatively preserved cardiac size and systolic function, and resembles that of right heart failure. Patients typically experience dyspnea, easy fatigability, and abdominal distension, and may exhibit dramatic physical findings including ascites, peripheral edema, and jugular venous distension with prominent *x* and *y* descents. The differential diagnosis is broad, and commonly includes restrictive cardiomyopathy, hepatic cirrhosis, or right heart failure due to any of a variety of causes including pulmonary embolism, right ventricular infarction, venous/valvular obstruction, or cor pulmonale.

Pathophysiology and Diagnosis

The fundamental physiologic abnormality in constrictive pericarditis is limited filling and enhanced interventricular dependence because of rigid encasement of the heart by thickened pericardium. Because the myocardium is intrinsically normal (unless there is a combined abnormality, as in patients with prior mediastinal irradiation), myocardial contractile function and relaxation may also be entirely normal (distinct from restrictive cardiomyopathy). Unlike cardiac tamponade, the heart is not compressed in early diastole and relaxes rapidly as filling proceeds until it reaches its pericardial limit (rubber-bulb effect). Early diastolic filling is rapid due to elevated right atrial pressures, but abruptly limited by the noncompliant pericardial shell, generating the classic "dip and plateau" or "square root" contour on intraventricular pressure recordings in diastole (Fig. 35.4). As the heart is effectively isolated from intrathoracic pressure variations by the stiff pericardial shell, jugular venous pressure increases during inspiration (Kussmaul's sign)

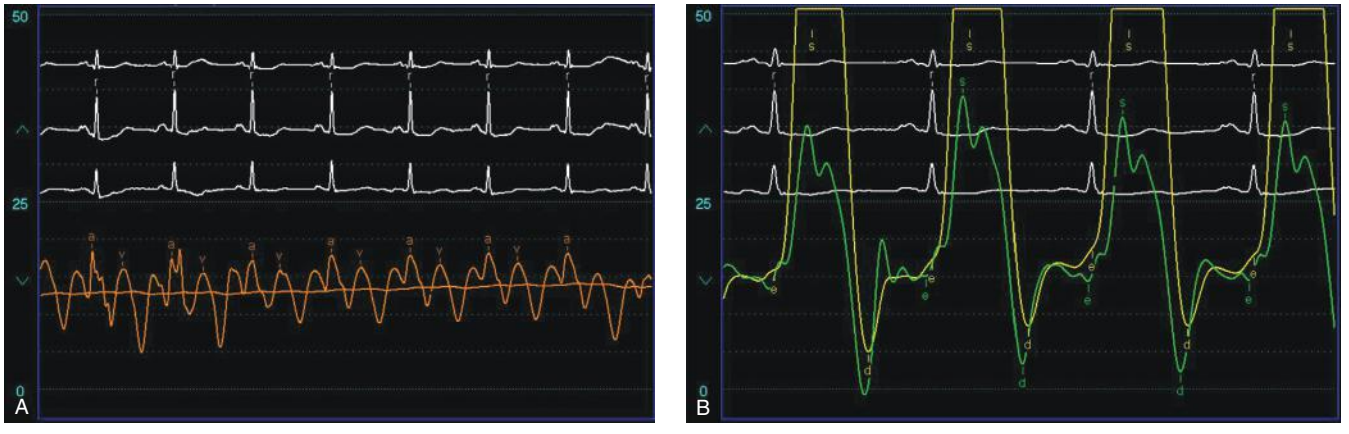

FIGURE 35.4. A: Right atrial pressure recording in a patient with constrictive pericarditis. Note the steep *x* and *y* descents, corresponding to the changes visible in the jugular venous contour. **B:** Simultaneous recording of LV (*yellow*) and RV (*green*) (pressure in the same patient). Note the near equalization of LV/RV pressures in diastole and the "square root" or "dip and plateau" sign reflecting abrupt cessation of ventricular filling due to pericardial constraint.

and pulsus paradoxus is typically absent, except in cases associated with pericardial fluid under pressure (constrictive–effusive pericarditis).

Like tamponade, constriction is characterized by elevation and equalization of left- and right-heart filling pressures, but there are important clinical differences. Distinct from tamponade, venous pressure contours show prominent *y* as well as *x* troughs. The *y* descent also tends to be deeper and more precipitous in constriction, as there is torrential filling in early diastole, with abrupt cessation of filling on reaching the pericardial limit. At this point, there may be an intense early diastolic third heart sound (sometimes called a "knock"). Clinical signs of right heart failure (due to elevated diastolic pressures) tend to dominate those of left heart failure, perhaps because cardiac output is relatively well preserved, and neurohormonal stimuli for salt and water retention may accordingly be less than that in systolic heart failure. The precordium is usually quiet to palpation, with no easily identifiable point of maximal impulse and the liver is often palpable and pulsatile. Laboratory findings are rarely diagnostic and are typically those of hepatic congestion and synthetic dysfunction. Hypoalbuminemia may occur as a consequence of liver impairment, malnutrition due to protein-losing enteropathy, or a proteinuric nephrotic syndrome, related to chronically high venous pressures [60]. ECG and chest radiograph findings are entirely nonspecific, though pericardial calcification may occasionally be seen (particularly in patients with tuberculous pericarditis).

Imaging with CT or MRI may support the diagnosis of constriction, and typically demonstrates tube-like ventricles, atrial enlargement, septal changes, and enlargement of the inferior vena cava as well as pericardial thickening. Any thickening greater than 3.5 mm (and more definitively >6 mm) is suggestive and helps to differentiate constrictive from restrictive cardiomyopathy. Although increased pericardial thickness has been considered an essential diagnostic feature of constrictive pericarditis, it should be remembered that in a large surgical series from the Mayo Clinic constriction was present in 18% of the patients with normal pericardial thickness [61]. In addition, constrictive pericarditis may rarely develop only in the epicardial layer in patients with previously removed parietal pericardium [62].

The most difficult pathophysiologic differential is typically between restrictive cardiomyopathy (due to primary myocardial disease such as amyloidosis or hemochromatosis) and constrictive pericarditis (see Table 35.2). Historical features often provide clues to systemic illness that suggest a diagnosis, but additional hemodynamic evaluation is often necessary. Typically, patients with restrictive cardiomyopathies tend to have higher left- than right-sided pressures and show greater inequalities during exercise and slower early- to midsystolic filling. Doppler echocardiography with tissue Doppler imaging or color M-mode imaging may be particularly helpful for distinction, showing marked respiratory variation in the peak early mitral inflow velocity (peak E-variation ≥25%), rapid mitral annular relaxation velocity (Ea ≥8 cm per second), and a slope of more than or equal to 100 cm per second for the first aliasing contour in the flow propagation velocity in patients with primary constrictive rather than restrictive disease [63,64]. Cardiac catheterization has traditionally been the gold standard for differentiation, though hemodynamic profiles may overlap

TABLE 35.2

DIFFERENTIATION OF CONSTRICTIVE PERICARDITIS AND RESTRICTIVE CARDIOMYOPATHY

Feature	Constrictive pericarditis	Restrictive cardiomyopathy
Prominent *y* descent in venous pressure	Present	Variable
Pulsus paradoxus	~1/3 of cases	Absent
Pericardial knock	Present	Absent
Cardiac catheterization		
Equalization of right/left heart filling pressures	Present	Left typically 3–5 mm Hg higher than right
Filling pressures >25 mm Hg	Rare	Common
Pulmonary artery systolic pressure >60 mm Hg	Rare	Common
"Square root" sign on RV/LV diastolic pressure waveform	Present	Present
Respiratory variation in left–right pressures/flows	Exaggerated	Normal
Echocardiography		
Ventricular wall thickness	Normal	Typically increased
Atrial size	Possible left atrial enlargement	Biatrial enlargement
Septal "bounce"	Present	Absent
Inspiratory variation in peak mitral inflow velocity (E)	Typically >25%	Typically varies by <10%
Blunting of pulmonary venous systolic flow (S-wave on PV Doppler)	Absent	Present
Mitral annular relaxation velocity on Doppler tissue imaging	Typically normal or mildly reduced	Diminished
Slope of flow propagation velocity on color M-mode	Increased, >100 cm/s	Diminished
Other		
Pericardial thickness (CT/MRI/TEE)	Increased	Normal
Endomyocardial biopsy	Usually normal or only mildly abnormal	May reveal infiltrative cardiomyopathy or extensive fibrosis, but may be normal

TABLE 35.3

EVIDENCED-BASED MANAGEMENT OF PERICARDIAL DISEASE

- Limited evidence from randomized trials is available to guide therapy of patients with pericardial disease
- The addition of colchicine to conventional medical therapy reduces the recurrence rate in patients presenting with recurrent pericarditis [36]
- The addition of colchicine to conventional medical therapy may also be useful in reducing the duration of symptoms and the recurrence rate in patients with a first episode of acute pericarditis [37]
- Treatment with nonsteroidal anti-inflammatory drugs is not useful in the management of persistent pericardial effusion following cardiac surgery [43]
- Two-dimensional echocardiography is preferable to CT or MRI for the initial evaluation of patients with pericardial effusion or suspected tamponade [50]
- In large observational studies of patients with constrictive pericarditis, older age, prior mediastinal radiation, and advanced heart failure predict poor outcomes following pericardiectomy [62,63]

considerably in the two states. Simultaneous left and right heart pressure recordings reveal equalization and elevation of pressures in the right atrium, right ventricle, left atrium pulmonary capillary wedge pressure (PCWP), and left ventricle during diastole. The right atrial (RA) pressure contour typically shows an "M"- or "W"-configuration with prominent *x* and *y* descents (Fig. 35.4). Systolic right ventricular pressure rises, but usually to less than 50 mm Hg, and the right ventricular end-diastolic pressure to systolic pressure ratio is usually greater than 0.3. Pulmonary hypertension is not a feature of constrictive pericarditis and indicates coexisting cardiac or pulmonary disease. Discordance or separation between right ventricular and left ventricular pressure contours with quiet inspiration or following fluid challenge is a marker of enhanced interventricular interdependence and is a highly specific marker of constriction [65]. Endomyocardial biopsy may also be useful in identifying primary myocardial disease when less invasive diagnostic modalities are inconclusive or ambiguous [66].

Management

Medical management of constrictive pericarditis resembles that of congestive heart failure because most signs and symptoms are related to systemic congestion. Diuretics are the mainstay of therapy and are useful in relieving volume overload and congestive symptoms, but do not alter the course of the disease. Definitive treatment requires surgical pericardiectomy. Access is typically obtained via either anterolateral thoracotomy or median sternotomy, with the target of removing as much pericardium as possible (ideally, from phrenic nerve to phrenic nerve). Areas of strong calcification or dense scaring may be left as islands to avoid major bleeding. Pericardiectomy for constrictive pericarditis carries a perioperative mortality rate of roughly 6%, and normalization of cardiac hemodynamics is reported in the minority of the patients, though most experience clinically relevant functional improvements [67]. Major complications include acute perioperative heart failure (likely due to underrecognized myocardial fibrosis or atrophy present prior to surgery) and ventricular wall rupture.

If an indication for surgery is established early, long-term survival after pericardiectomy may be good, though on average slightly inferior to that of age- and gender-matched controls (57% ± 8% at 10 years). In the reported Mayo Clinic experience, older age at presentation, poor preoperative New York Heart Association functional class, and prior radiation were the strongest predictors of early mortality [68]. A second series of 163 patients undergoing pericardiectomy over a 24-year period at the Cleveland Clinic suggested that in addition to age and prior radiation, poor renal function, elevated pulmonary artery systolic pressure, low serum sodium, and preoperative left ventricular (LV) dysfunction were important correlates of poor overall survival [69]. Seven-year survival in this experience ranged from 88% for patients with idiopathic constrictive pericarditis to 27% for patients with postradiation constrictive pericarditis, suggesting that the outcome of pericardiectomy is highly dependent on the specific cause, the degree of preoperative myocardial injury, and preoperative functional capacity. Early diagnosis and therapy are important because the anticipated postoperative outcome is heavily affected by preoperative heart failure severity. In addition, because pericardiectomy does not affect the course of underlying myocardial disease, careful exclusion of coincidence restrictive heart disease is important in selecting patients for surgery.

CONCLUSION

Pericardial manifestations are seen in a wide spectrum of infectious, inflammatory, and neoplastic disorders. Critical care of patients with pericardial disease depends on a basic understanding of pericardial physiology and thoughtful integration of data from physical examination, electrocardiography, noninvasive cardiovascular imaging, and invasive hemodynamic studies. Although limited data from randomized controlled trials are available to direct the optimal strategy for treatment of patients with acute pericarditis, pericardial effusion, and pericardial constriction, a wealth of observational experience provides important insights into the natural history and clinical management of these conditions.

Advances in critical care of pericardial disease, based on best available evidence, are summarized in Table 35.3.

CHAPTER 36 ■ ACUTE AORTIC SYNDROMES

LEON M. PTASZEK, ERIC M. ISSELBACHER AND AMY E. SPOONER

INTRODUCTION

Representing the most lethal conditions affecting the aorta, acute aortic syndromes are associated with a high mortality rate if not recognized and treated promptly. Although the classical presentation of "aortic agony" is characterized by severe, sudden-onset pain in the chest or back [1], this presentation, although quite recognizable, occurs only in a minority of cases. As the initial manifestations of acute aortic syndromes are frequently variable, arriving at the appropriate diagnosis in a timely manner may be quite challenging. Prompt recognition of the acute aortic syndromes may be the difference between life and death for the afflicted patient. Frequently, the clinician must depend on subtle findings gleaned from history, detailed physical examination, and imaging in order to decide on an appropriate treatment plan. Here, we review the commonly encountered aortic syndromes, with a focus on aortic aneurysm rupture, as well as acute aortic dissection and acute aortic intramural hematoma (IMH). We focus primarily on the means by which these syndromes can be recognized and treated. Attention is also given to etiology and pathophysiology of the specific disease processes to the extent that evaluation of these processes is relevant to diagnostic and treatment strategies. Because patients with suspected acute aortic syndromes are frequently critically ill and require rapid disposition to treatment, we offer a unified evaluation and treatment algorithm. Each individual section serves as a guide to a syndrome-specific evaluation. Key features of a focused history and physical examination are emphasized. In addition, critical laboratory and imaging tests are reviewed.

AORTIC DISSECTION

Definition and Classification

Dissection of the aortic wall involves longitudinal cleavage of the muscular media, leading to the formation of a second (or false) vessel lumen. The inciting event for a typical aortic dissection is thought to be a tear in the intima that leads to exposure of the underlying media, presumably weakened by medial degeneration. Once created, this cleavage front advances due to wall strain created by physiologic blood pressure. The cleavage front typically advances in the direction of blood flow, but dissection against the direction of flow is also observed [2].

There are multiple consequences of dissection. The native (or true) lumen is frequently compressed, leading to compromised downstream blood flow. The false lumen of the dissected aorta may also be less able to withstand physiologic blood pressure, due to changes in both its shape and its thinner external wall. The damaged aorta may therefore be more prone to rupture.

Aortic dissections are generally classified by location and extent. Dissections originate in the ascending aorta (65%) or in the descending aorta just distal to the origin of the left subclavian artery (20%). Dissection in the aortic arch (10%) and the abdominal aorta (5%) also occur [3]. Two classification systems for dissection location are in common use (Fig. 36.1). The DeBakey system includes three types of aortic dissection. Type I involves dissection of both the ascending and descending aorta, and/or the arch. Type II dissection involves only the ascending aorta proximal to the brachiocephalic artery, and type III involves only the descending aorta distal to the left subclavian artery [4]. The Stanford system includes two dissection types. All dissections involving the ascending aorta are included in type A: this includes types I and II in the DeBakey system. Stanford type B includes all dissections that do not involve the ascending aorta [5]. Classification of the location of a dissection carries prognostic and treatment importance. Surgery is indicated for dissection of the ascending aorta, whereas medical management is frequently the treatment of choice for descending dissection.

Chronicity of the dissection is defined as the time interval between onset of symptoms and evaluation. Dissections that are present for less than 2 weeks are defined as acute, whereas those that are present longer are defined as chronic [6]. It is noteworthy that the mortality associated with untreated ascending aortic dissection reaches 75% at 2 weeks [7].

Not all cases of aortic dissection are associated with an identified area of intimal tear. Several analyses have revealed that up to 13% of cases of apparent dissection turn out to be an IMH: a hemorrhage within the media that does not communicate with the intraluminal space [7–9]. In some cases, an atherosclerotic ulcer that penetrates from the intima beyond the internal elastic lamina is thought to precipitate intramural bleeding [10]. Classical aortic dissection and IMH are discussed separately later.

CLASSIC AORTIC DISSECTION

Epidemiology

Estimates of the incidence of aortic dissection range from 2 to 4 per 100,000 per year [11]. The highest incidence occurs in patients in their sixth and seventh decades of life. Incidence among men is double that for women [1,12]. Recent studies show that women tend to present later and with a more advanced disease state [12]. In addition, it has been shown that aortic dissection exhibits diurnal and seasonal rhythms. Dissections are most likely to occur in the morning or early afternoon, and more commonly in winter [13]. This seasonal difference does not appear to depend on climate [14].

Mortality rates associated with dissection are very high, and many patients do not survive to hospital admission. For those patients with aortic dissection who survive to admission, the early mortality rate is estimated to be as high at 1% per hour during the first day [7]. If left untreated, the associated mortality is estimated at 50% at 7 days and greater than 90% at 90 days [15]. Among patients who receive treatment, mortality during initial hospitalization ranges between 15% and 27.5%, as reported in several longitudinal studies [1,16,17].

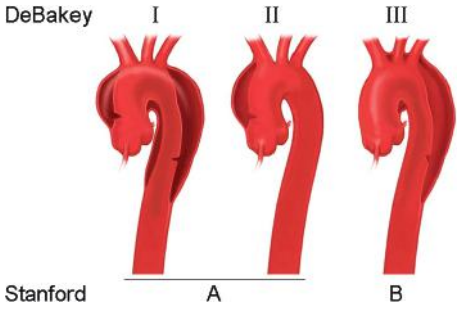

FIGURE 36.1. Dissection classification (DeBakey/Stanford). [© Massachusetts General Hospital Thoracic Aortic Center. Used with permission.]

Etiology and Pathophysiology

Any process that causes damage to the aortic tunica media, leading to medial degeneration, increases the risk for aneurysm or dissection. In the case of typical aortic dissection, the precipitating event is thought to be the creation of a tear in the intimal layer overlying a damaged area of the media. In the elderly patient with dissection, the presence of medial degeneration is correlated with the effects of aging, hypertension, and atherosclerotic disease [18–20]. Indeed, hypertension is found in 70% to 80% of patients with aortic dissection [1].

In the younger patient with aortic dissection, medial degeneration is still the culprit, but the constellation of correlated risk factors tends to differ [21]. Typically, young patients are more likely to have hereditary connective tissue disorders that compromise the integrity of the extracellular matrix in the tunica media, most notably Marfan syndrome, Ehlers–Danlos syndrome, bicuspid aortic valve, or familial thoracic aortic aneurysm syndrome (FTAAS) [1,6,21]. Young patients, defined in a recent study as being 40 years of age or younger, are also less likely to be hypertensive, and may have a larger aortic diameter on presentation. Paradoxically, mortality in this younger cohort does not appear to be lower than that in older patients [21]. All of these syndromes have been associated with breakdown of the fibrillin and collagen components of the extracellular matrix in the media, leading to medial degeneration. Aortic dissection risk is also increased in patients with Turner and Noonan syndromes [6]. Increased risk for dissection is found in a number of other conditions, including aortitis, especially in the context of giant cell arteritis and Takayasu arteritis [6,22,23]. Cocaine use has also been associated with dissection, ostensibly on the basis of increases in cardiac output, blood pressure, or as a consequence of direct vascular injury from cocaine itself (i.e., cocaine-induced vasculitis/endarteritis). In particular, crack cocaine has been identified as a potential precipitant of dissection [24,25].

As is the case for aortic aneurysm, the presence of certain structural abnormalities may be associated with an increased risk of dissection. In particular, a correlation has been described in patients with bicuspid aortic valve or, uncommonly, aortic coarctation. This association does not appear to be related to the hemodynamic effects of the abnormalities [26].

Notably, pregnancy is an independent risk factor for aortic dissection. The highest incidence of dissection is observed in the third trimester or early postpartum period. This risk is high particularly in pregnant women with a bicuspid aortic valve, Marfan, Ehlers–Danlos, or Turner syndrome [27,28]. In pregnant women with Turner syndrome, the risk of dissection or rupture exceeds 2%, and the risk of death is increased 100-fold [29]. Sporadic aortic dissections may occur in women without these predisposing conditions, possibly due to the elevated levels of relaxin and inhibin associated with pregnancy.

Iatrogenic injury to the aortic wall, sustained in the context of cardiac catheterization, intra-aortic balloon pump placement, or cardiac surgery, increases the risk of future aortic dissection [30–32]. Cardiac surgery involving the aortic valve appears to pose the greatest risk. Damage sustained by the aorta may take up to several years to develop into aneurysm and/or dissection [32,33].

Blunt trauma or rapid deceleration injury is frequently associated with injury to the aortic isthmus. Although this type of injury may be associated with tearing or transection of the aorta, a true dissection is uncommon [34,35].

Clinical Manifestations

There is no single physical examination finding that allows for positive identification of dissection: only imaging of the aorta verifies the diagnosis. Consequently, the initial evaluation and examination must incorporate a high index of suspicion and careful assessment.

The classic initial symptom of acute aortic dissection is severe chest or back pain. The severity of this pain is characteristically at its maximum at the point of inception. This is in sharp contrast with the typical crescendo onset of myocardial infarction pain [1]. The quality of the pain is often described as being "tearing" or "stabbing." Acute pain is present in 85% of the patients described in the International Registry of Aortic Diseases (IRAD) and is present in up to 96% of patients described in other studies [1,6,36]. Of the patients in the IRAD registry, 90% described this discomfort as being the worst pain they ever experienced. Indeed, patients may be prone to writhing or pacing because of the pain. The initial location of the pain is correlated to the location of the dissection: of the patients in reported clinical series who presented with anterior chest or neck pain, 65% to 90% were found to have dissection of the ascending aorta. Interscapular or back may also represent dissection of the descending aorta [6]. On occasion, the patient may report a migration of the pain in association with extension of the dissection. In a series reported by Spittell et al., 17% of patients reported pain migration [6]. Recently, it was noted that aortic dissection may, in some instances, present with abdominal pain [37].

A common finding at the time of presentation is hypertension. Of the patients in the IRAD series, 36% of patients with type A dissection had elevated blood pressure, whereas 70% of patients with type B dissection had hypertension. Conversely, hypotension may also be a presenting feature of aortic dissection. This is a particularly ominous finding, as it likely represents developing shock. Hypotension is seen more frequently in patients with type A than type B dissection (25% vs. 4%, respectively) [1]. It is also noteworthy that patients with dissections who present with a "deadly triad" of hypotension/shock, an absence of pain, and evidence of branch vessel involvement exhibit a markedly higher mortality [38].

Evidence of heart failure, most notably pulmonary edema and hypotension, is found in up to 7% of patients with aortic dissection [1,6]. This finding is most frequently due to aortic regurgitation caused by a type A dissection [39]. However, in a recent report, a surprisingly high percentage of patients with heart failure at the time of dissection actually had a type B syndrome, with heart failure presumably due to myocardial ischemia or diastolic dysfunction with hypertension.

Syncope is present in up to 9% of patients with dissection. In these patients, syncope that is associated with focal neurologic signs is usually the result of occlusion of a branch vessel. Syncope in the absence of any other neurologic findings, present in up to 5% of dissection patients, likely represents aortic rupture into the pericardial space with tamponade. This finding portends rapid decline and requires emergent surgery.

Pericardial tamponade in the context of type A aortic dissection is a surgical emergency, as it represents a tenuously compensated rupture of the aorta. Unless the patient is in extremis, pericardiocentesis should not be performed, as the release of pressure in the pericardial space may precipitate a rise in blood pressure, recurrent hemorrhage into the pericardium, and cardiovascular collapse [40]. Dissection into the pleural space may also lead to hypotension and syncope, and similarly requires immediate surgical intervention.

A number of other vascular complications of aortic dissection may be apparent on initial evaluation. In up to 20% of the cases reported in the IRAD series, subjects presented with signs and symptoms consistent with occlusion of branch vessels. These occlusion events are typically the result of the extension of the dissection into a branch vessel ("static" occlusion), occlusion of the ostium of the vessel due to migration of the intimal flap ("dynamic" occlusion), or impaired flow in the true lumen due to distention of the false lumen. The spectrum of clinical findings associated with aortic side-branch involvement ranges from no signs and symptoms, to subtle findings, to florid manifestations, including severe ischemia of the affected territories. The mass effect of the dissection may lead to focal neurologic defects in rare cases. Involvement of a subclavian artery may lead to a difference in measured blood pressure between the two arms or pulse deficit. Impaired flow in the mesenteric arteries leads to signs and symptoms consistent with mesenteric ischemia. Dissections may also lead to occlusion of the renal arteries, leading to acute renal failure or renal infarction. Rarely, dissection leads to spinal artery occlusion with resultant paraparesis or paraplegia [1,6]. Lower limb ischemia may also occur in type B dissection [41].

On occasion, type A dissection may extend proximally to the ostia of the coronary arteries, leading to myocardial infarction. Three percent of the patients in the IRAD series presented with dissection-related myocardial infarction, with attendant chest pain and biomarker elevation [1].

There is not yet a specific biomarker in common clinical use that allows the clinician to confirm the diagnosis. For example, the D-dimer is elevated in dissection, but has limited diagnostic utility [42,43]. Recent work has highlighted several specific biomarkers that are elevated in acute aortic dissection and may become diagnostically useful in the future. The most promising assay is an enzyme-linked immunosorbent assay (ELISA) for myosin heavy chain. The sensitivity and specificity of this test, when it is performed within 12 hours of the acute event, are 90% and 97%, respectively. The primary advantage of this test is its ability to distinguish dissection from other events, such as myocardial infarction. Assays for other compounds elevated in aortic dissection but not in other acute cardiac events, such as serum heart-type fatty acid–binding protein, elastin, and calponin, are also in development [44–47].

Imaging

Prompt imaging is critical in the evaluation of suspected aortic dissection. Multiple modalities are at the disposal of the clinician; however, the patient is best served by the modality that offers adequate image quality without delay or transport time. The specific technique of choice may differ among hospitals, as not all facilities have the same capabilities. Following is a discussion of the relative strengths and weaknesses of the commonly available imaging techniques in the diagnosis of aortic dissection. The decision regarding the optimal technique to be used in a specific context is left to the individual clinician. Frequently, multiple imaging modalities must be used in a single patient. In addition, a single patient may require serial studies if his/her signs or symptoms evolve [48].

In most hospital settings, a chest x-ray (CXR) is performed as a matter of course in the evaluation of chest pain. The CXR, which is noninvasive, inexpensive, and routinely performed at the bedside, offers much useful information. In the patient with an aortic dissection, the CXR may reveal an abnormal aortic silhouette [1,6]. Widening of the mediastinum is a variable finding, observed in 15% to 60% of cases. Another suggestive finding is separation of intimal calcium, if present, from the soft-tissue border of the aorta. In addition, extravasation of blood into the pericardial space may be visualized as expanded and blunted heart borders. Pleural effusions are also easily visualized on CXR. Although useful, the CXR cannot be considered a definitive study. Therefore, other modalities should be used, notably echocardiography, computerized tomography (CT) scanning, and magnetic resonance imaging (MRI) (Table 36.1).

Transthoracic echocardiography (TTE) is a readily available, noninvasive, and portable imaging modality that may be considered. A focused study can be performed within 15 minutes at the bedside. Dissected segments of aorta can be measured directly: this is typically restricted to the ascending aorta, as neither the aortic arch nor the descending aorta can be reliably visualized via an external approach. TTE is also a very reliable technique for the visualization of pericardial effusion. The intimal flap of aortic dissection may be seen as a "double" aortic wall. Direction of Doppler flow may also help the clinician distinguish between the "true" and "false" lumens of aortic dissection. It should be noted that sensitivity for type A dissection varies between 70% and 90%, and sensitivity for type B dissection is approximately 40% [49]. Given this suboptimal sensitivity, performing a TTE should not delay a more sensitive imaging study. Despite its convenience, TTE is limited in that it does not offer an unobstructed view of all portions of the aorta. Body habitus may also adversely affect the quality of TTE images.

A far more accurate ultrasound study for suspected aortic dissection is transesophageal echocardiography (TEE). By virtue of the close proximity of the aorta to the ultrasound probe in the esophagus, this technique offers clear views of most portions of the thoracic aorta and affords excellent information regarding aortic valve function. TEE may be useful to guide surgical intervention for type A aortic dissection. TEE, like TTE, is portable and can be performed easily at the bedside, which makes it the procedure of choice for evaluation of critically ill or medically unstable patients who may be at higher risk during transportation for radiographic examinations.

In aortic dissection, TEE is superior to TTE in visualization of the intimal flap; sensitivity varies between 90% and 100%, and specificity is approximately 90%. Color Doppler imaging may identify the blood flow between the true and false lumens. Perhaps the most important procedural drawback regarding TEE is the need for conscious sedation, which may be difficult to administer in a patient who is hemodynamically unstable.

CT scanning allows for a full view of the entire aorta. Consequently, the sensitivity (90% to 100%) and specificity (90%) for visualization of the intimal flap in aortic dissection are comparable to TEE [49]. Specific CT techniques, such as spiral CT, also allow for facile three-dimensional reconstruction. The "double barrel" produced by dissection can be quite distinct. In classic aortic dissection, an intimal flap can be seen, separating a true and false lumen. Pericardial and pleural effusions may be easily visualized, but blood flow and tamponade physiology cannot be assessed directly. A diagnostic CT scan requires intravenous contrast, and care must be taken to address the risks of allergic reaction and contrast nephropathy. Many patients presenting with the acute aortic syndromes may also have renal insufficiency or failure; however, in the critically ill patient in whom aneurysm rupture is suspected, definitive diagnosis and treatment of the aortic process should take priority.

TABLE 36.1

IMAGING MODALITIES FOR PATIENTS WITH SUSPECTED ACUTE AORTIC SYNDROMES

	Key findings	Advantages	Disadvantages
TTE	Intimal flap in ascending aorta Dilatation of aortic root Aortic valve regurgitation Pericardial effusion Color Doppler differentiation of flow in dissection-related "true" and "false" lumens	Readily available Noninvasive Quickly performed at bedside No ionizing radiation Intravenous contrast not required Aortic valve function can be directly assessed	Only aortic root and ascending aorta can be reliably assessed Image quality may be affected by body habitus Branch vessels and intramural hematomas are not reliably visualized
TEE	Intimal flap in aorta Dilatation of aorta Aortic valve regurgitation Pericardial effusion Color Doppler differentiation of flow in dissection-related "true" and "false" lumens	Readily available Noninvasive Quickly performed at bedside No ionizing radiation Intravenous contrast not required Image quality not affected by body habitus Ascending aorta, arch, and proximal descending aorta may be visualized Aortic valve function can be assessed directly	Distal thoracic and abdominal aorta cannot be visualized May only be performed by trained personnel Sedation required Branch vessels are not reliably visualized
CT	Intimal flap in aorta Dilatation of aorta in any segment Pericardial effusion Dissection-related "true" and "false" lumens or intramural hematoma accentuated with contrast	Readily available Noninvasive Quickly performed Image quality not affected by body habitus Full aorta may be assessed in single scan Most widely used first imaging test in suspected dissection	Requires use of ionizing radiation and intravenous contrast Transportation to scanner may be required in some centers Patient monitoring during scan may be difficult Aortic valve function cannot be assessed directly
MRI	Intimal flap in aorta Dilatation of aorta in any segment Pericardial effusion Dissection-related "true" and "false" lumens or intramural hematoma may be differentiated	Noninvasive No ionizing radiation Image quality not affected by body habitus Full aorta may be assessed in single scan Branch vessel visualization is excellent Contrast not required to visualize intramural hematoma or to differentiate between true and false lumen Aortic valve function can be directly assessed	Not readily available at many hospitals Transportation to scanner may be required in some centers Patient monitoring during scan may be difficult Scan time longer than other modalities
Aortogram	Intimal flap in aorta Dilatation of aorta in any segment True and false lumens may be differentiated with contrast	Best modality for branch vessel visualization Allows for assessment of full aorta	Invasive Study not as readily available due to required assembly of trained personnel Ionizing radiation and intravenous contrast required Intramural hematoma cannot be reliably assessed

CT scanning and MRI share several of the same advantages, such as high image resolution and the ability to scan the entire aorta. Overall, the sensitivity and specificity of intimal flap detection by MRI are nearly 100% [49]. MRI does not require the use of IV contrast, which represents an advantage over CT scanning; however, MRI is more expensive and not as readily available or as rapidly performed as CT scanning. The primary limitation of MRI is lack of availability: not all hospitals have MR scanners available for emergent use. Even when available, issues of transporting a potentially unstable patient are still present. MRI is also contraindicated in patients in whom vascular clips, implantable cardioverter-defibrillators (ICDs) or pacemakers are present.

In the past, retrograde aortography was considered the gold-standard technique for aortic imaging. Because aortography is

an invasive test that requires the assembly of a catheterization laboratory team and the use of IV contrast and ionizing radiation, it is typically reserved for those cases where diagnostic uncertainty remains after one or more other imaging studies have been obtained. The ability of aortography to detect aortic dissection depends on the presence of blood flow between the true and false lumens; therefore, in cases where blood flow between these chambers is limited, the aortogram may be nondiagnostic. Overall, among patients with classic aortic dissection, the sensitivity and specificity for intimal flap visualization are 80% to 90% and 90% to 95%, respectively [49]. Aortography is still the study of choice for visualization of aortic branch vessels, which may not be visualized with other imaging modalities as well. In addition, aortography is particularly useful if endovascular treatment is contemplated.

Management

The primary goal of treatment in a patient with aortic dissection is to minimize the effects of the dissection while rapidly evaluating the patient's candidacy for surgical repair, if indicated (Figure 36.5). Initial medical management while waiting for possible surgery should focus on management of pain, decrease of blood pressure to a minimum acceptable level, and decrease in the force of left ventricular contraction (dP/dt). In general, long-acting agents are not favored, as such agents are difficult to titrate rapidly. Early observation should occur in an intensive care setting, with an arterial line in place. For patients presenting with evidence of heart failure, pulmonary artery catheter placement may be considered, but is usually not necessary.

Pain management is titrated aggressively in patients with dissection. The goals of pain treatment are patient comfort and decrease in adrenergic tone. Narcotic analgesics are effective in rapid reduction of symptom severity, especially when administered in intravenous form. Long-acting oral formulations of narcotics are not recommended.

Blood pressure and dP/dt can be simultaneously decreased with a beta-blocker. Noncardioselective agents such as propranolol, labetalol, and esmolol have been used extensively in this context. Beta-blockers should be considered even in patients who are not hypertensive at presentation, as the reduction in dP/dt is thought to be beneficial in reducing the advancement of dissection. The goal heart rate is 60 beats per minute, and the goal systolic blood pressure is no higher than 120 mm Hg. In the event that a patient's blood pressure is still elevated even after a goal heart rate has been reached with β-blockade, nitroprusside may also be administered as a constant intravenous infusion; however, intravenous nitroprusside should not be used without concomitant β-blockade, given the possibility of an increase in heart rate and dP/dt accompanying its potent vasodilatory effects.

In the event that a beta-blocker cannot be used, due to contraindications such as bronchospasm, nondihydropyridine calcium channel blockers are the second-line agents. Verapamil and diltiazem, both of which have vasodilator and negative inotropic/chronotropic effects, may be used. Some patients have hypertension that is resistant to blockade of both β-adrenergic receptors and calcium channels. In this case, dosing of an intravenous angiotensin converting enzyme inhibitor, such as enalaprilat, may be indicated.

Hypotension may be seen in conjunction with dissection. It should be noted that the mode of blood pressure measurement should be scrutinized before changing a treatment plan; "pseudohypotension" may occur if dissection propagates into the limb in which blood pressure is being measured. In such cases, it is recommended that hypotension be verified by measurement of blood pressure in other limbs prior to discontinuation of beta-blockers or calcium channel blockers (Tables 36.2 and 36.3).

Surgical Intervention

The primary concept that relates to the optimal choice of therapy has not changed for nearly 30 years. In most cases, the location of the dissection determines whether the patient should undergo immediate surgery. Type A dissection is treated with surgery in virtually all cases, as the outcomes associated with surgical repair are superior to outcomes with medical management: 26% versus 50% mortality at 30 days in the IRAD series [1]. The one relative contraindication to attempted surgical repair of type A dissection is stroke in evolution, due to high risk of hemorrhagic transformation of the stroke during surgery [50]. In aggregate, survival of patients with acute type A dissection who are treated with surgical repair has improved over the last 25 years [51]. Aortic dissection repair is

TABLE 36.2

COMMONLY USED MEDICATIONS WITH ROUTES/DOSES

Agents for heart rate and blood pressure reduction in acute aortic syndromes		
Class	**Medication**	**Dosing[a]**
Beta-blockers	Metoprolol	2.5–5.0 mg IV q 5 min, up to three doses followed by 5–10 mg IV q 4–6 h
	Labetalol	20 mg IV administered over 2 min followed by 40–80 mg IV q 10 min with maximum initial dose 300 mg, to be followed by 2 mg/min IV infusion with 10 mg/min maximum rate
	Esmolol	500 μg/kg IV bolus dose, followed by 50 μg/kg/min IV infusion with 300 μg/kg/min maximum rate
Calcium channel blockers	Diltiazem	Bolus 5–10 mg IV, maximum dose 25 mg IV infusion 5–15 mg/h for up to 24 h 30–90 mg PO qid, maximum 360 mg/d
	Verapamil	80–120 mg PO tid–qid maximum 480 mg/d
	Nifedipine	10–20 mg PO tid, start with 10 mg dose, maximum 180 mg/d
	Nicardipine	20–40 mg PO tid, start with 20 mg dose, maximum 120 mg/d
	Nisoldipine	20–40 mg PO qd, start with 10 mg dose, maximum 60 mg/d
Vasodilators	Nitroprusside	0.3–10 μg/kg/min IV infusion up to 3 d

[a]Therapeutic goals include maintenance of systolic blood pressure 100–110 mm Hg, heart rate approximately 60 beats per minute.

TABLE 36.3

SUMMARY OF ADVANCES IN THE IDENTIFICATION AND MANAGEMENT OF ACUTE AORTIC SYNDROMES[a]

- Risk factors for aortic dissection in patients younger than 40 include familial thoracic aortic aneurysm syndrome (FTAAS); pregnancy; bicuspid aortic valve; and Marfan, Ehlers–Danlos, Turner, and Noonan syndromes [1,7,22,28,29]
- Risk factors for aortic dissection in older patients include cigarette smoking, hypertension, and atherosclerotic disease [1]
- Crack cocaine use has been recently identified as an independent risk factor for aortic dissection, especially in the descending aorta [25,26]
- Preferred treatment for type A dissection is typically urgent surgery, whereas medical management is preferred for type B aortic dissection, except for those cases involving aortic rupture or branch vessel compromise [1,38]
- β-Blockade for reduction of dP/dt is critical to the treatment of all the acute aortic syndromes, unless a clear contraindication is present [1,39,40]
- Pericardial tamponade in the context of type A aortic dissection should be treated with definitive surgical correction of the dissection rather than pericardiocentesis, unless hemodynamic collapse is present, in which case small-volume aspiration of pericardial fluid may be necessary [40]
- Endovascular stent grafting has been used successfully to treat type B dissections, as well as branch vessel disease associated with both type A and B dissections: this technique is an alternative to intimal flap fenestration [53–57]. The Investigation of Stent Grafts in Aortic Dissection (INSTEAD) study shows no advantage to use of endovascular stents for treatment of chronic type B dissection [58]
- Management strategy of intramural hematoma is informed by location in a manner that mirrors classic dissection: type A intramural hematoma should be treated surgically, whereas type B intramural hematoma should be treated medically unless another indication for surgical or endovascular management is present [10,62,74]
- The use of biomarkers to differentiate acute aortic syndromes from other etiologies of chest pain is not yet a validated component of standard clinical practice [42–47]

[a]Based on recent observational studies.

complex surgery, and each patient's medical comorbidities need to be addressed in detail before surgery as time allows. In the past, patients older than 80 were thought to have an operative survival rate too low to justify attempted repair. A recent multicenter study reported acceptable outcomes in aortic dissection repair performed in selected octogenarians. Although this study raises the possibility of aortic dissection repair in this age group, this approach remains controversial and each patient must be approached individually [52].

Patients with type B dissections are generally managed without urgent surgery, as mortality in patients undergoing surgical repair is roughly equal to the mortality in those patients treated medically [1,38,39]. Typically, patients with type B dissections are only treated surgically in the context of impending or established aortic rupture or branch vessel compromise, especially with malperfusion. Neither recurrent pain nor severe hypertension has been shown to predict adverse outcome in patients with type B dissection of the aorta, and neither alone should be considered a primary indication for urgent surgery [53,54].

Recent studies have investigated the use of percutaneous repair for managing type B dissection. Although percutaneous fenestration of the "false" lumen had previously been the therapeutic option of choice in this setting [1], this technique has been largely supplanted by the more definitive endovascular stent repair. It is thought that the minimally invasive nature of this technique may decrease perioperative mortality and thus improve outcomes. Initial results and short-term outcomes with endovascular therapy of acute type B dissections are promising [55–57]. A recently published randomized trial assessing the impact of endovascular stent grafting in addition to medical therapy in uncomplicated type B dissection revealed no advantage with stenting [58].

INTRAMURAL HEMATOMA

Not all cases of apparent aortic dissection involve communication between the true and false lumens via a tear in the intima. In 1988, the first cases of an "atypical" form of dissection without intimal rupture were described [59]. Intramural hematoma (IMH) is defined as a spontaneous collection of blood within the aortic media that does not apparently communicate with the lumen. The natural history of IMH is not fully understood. It is thought that it may represent a predecessor of aortic dissection with eventual intimal rupture [48,60].

Both classic aortic dissection and IMH are generally associated with the same set of risk factors [9,48] and may be indistinguishable clinically [9]. Diagnostic imaging studies, notably transesophageal echocardiography, CT angiography, or MRI, are required to distinguish them (Fig. 36.2). Consequences of untreated IMH suggest a similar risk for adverse outcome as in typical aortic dissection.

Epidemiology

IMH occurs in a minority of the patients presenting with an apparent aortic dissection. Acute dissection events included in the IRAD registry were found to be due to IMH 10% of the time [1]. Serial imaging of IRAD patients with IMH revealed that 16% evolved to dissection with intimal tear [48]. There was no statistically significant difference in mortality rate for typical dissection and IMH in this series. Other studies reveal that IMH can progress to typical dissection, as determined by serial scanning, in up to 45% of cases [61].

Although the risk factors [9,48] and clinical presentations of classic aortic dissection and IMH are indistinguishable, certain important differences are recognized. Compared to those with typical aortic dissection, patients with IMH tend to be older, tend to have more atherosclerotic disease, and are more likely to have a distal acute aortic syndrome; two-thirds of IMH cases are type B, in contrast with typical dissections, 65% of which are type A.

Long-term follow-up of patients with IMH reveals that the hematoma evolves most commonly into a true or false aortic aneurysm or especially when associated with penetrating atherosclerotic ulcer (PAU). Up to 45% of such aneurysms that are located in the ascending aorta lead to rupture [61]. Spontaneous regression occurs in up to one-third of cases. Regression is most likely with IMH not associated with increased aortic

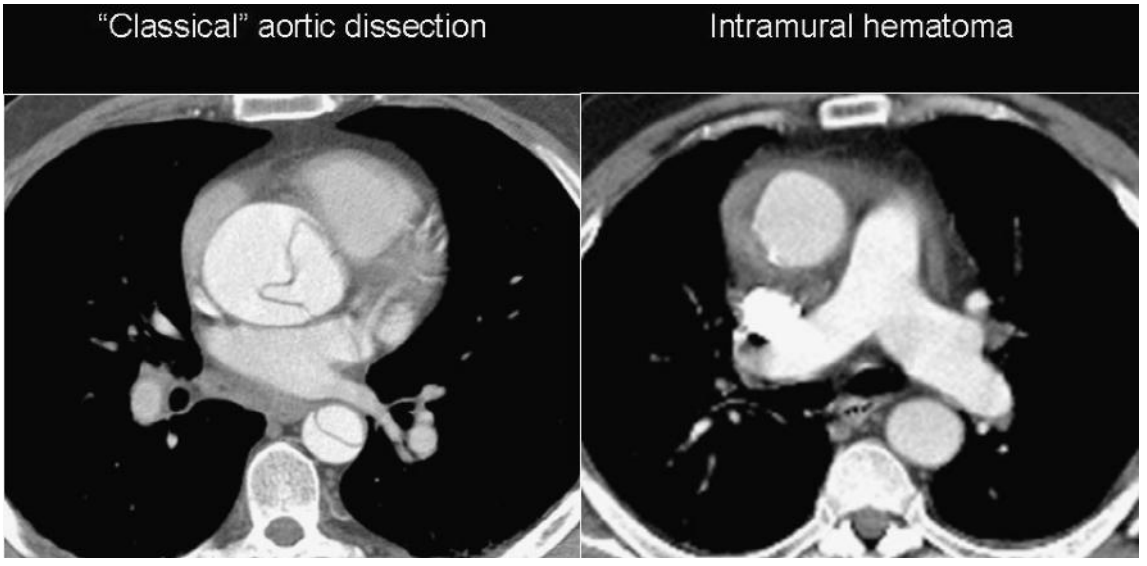

FIGURE 36.2. CT angiograms demonstrating the typical appearance of a "classical" aortic dissection, versus that of an aortic intramural hematoma. Note the smooth crescentic thickening of the wall of the ascending aorta in the patient with intramural hematoma and the obvious intimal flap seen in the patient with the acute dissection. [© Massachusetts General Hospital Thoracic Aortic Center. Used with permission.]

diameter at the time of presentation [62]. Clinical and radiographic progression of IMH is more likely when PAU is present (Fig. 36.3). IMH in the absence of PAU appears to follow a more stable course, especially when located in the descending thoracic aorta [63].

Etiology and Pathophysiology

There are two proposed mechanisms by which an IMH may form. The first is the rupture of the vasa vasorum in the aortic wall, which may be the result of medial degeneration. The other leading mechanism is the invasion of a PAU beyond the internal elastic lamina of the vessel, compromising the integrity of the media [64,65]. Once in the media, this ulceration can lead to hematoma formation. Both of these events could ostensibly be at work simultaneously.

Clinical Manifestations

The clinical presentation of IMH mirrors that of typical aortic dissection, and the two cannot be reliably distinguished on the basis of clinical criteria alone [48].

Imaging

Because the clinical presentation of IMH can overlap with that of classic dissection, prompt imaging is critical. The same set of imaging modalities used for classic aortic dissection is to be

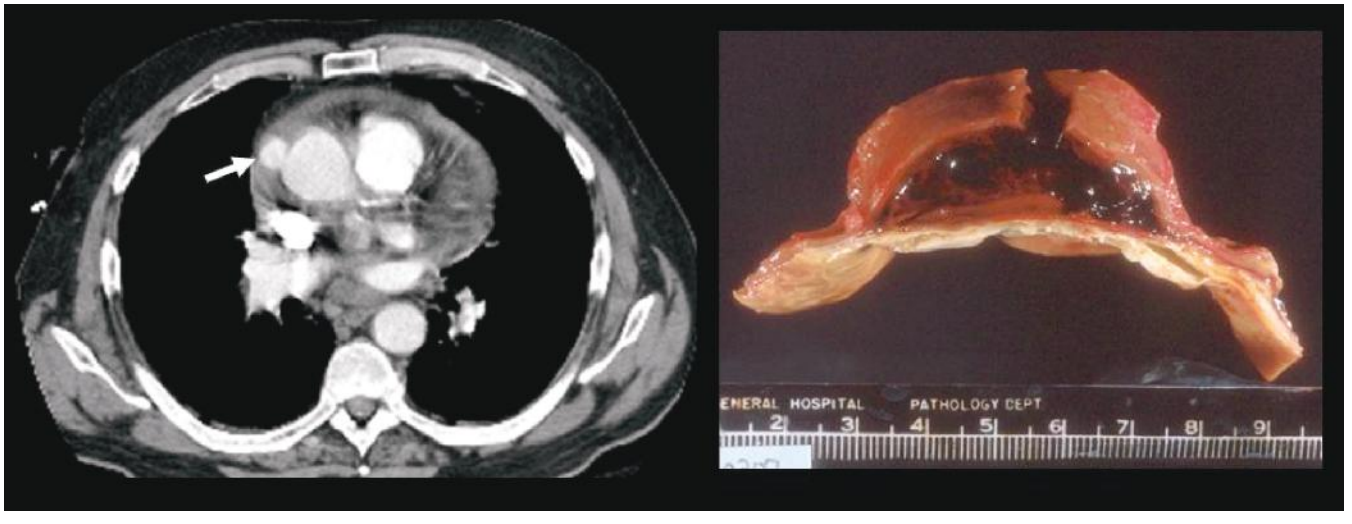

FIGURE 36.3. CT angiogram of an acute penetrating atherosclerotic ulcer, with corresponding pathologic specimen from the patient after ascending aortic repair.

used to image IMH. Some differences in utility exist, and are worthy of note. As with classic aortic dissection, it is frequently the case that multiple imaging modalities must be used in a single patient. As IMH frequently evolves, affected patients often require serial studies [48].

CXR findings associated with IMH mirror those for classic aortic dissection. Affected patients may exhibit an abnormal aortic silhouette or a widened mediastinum, but this finding is not as well validated as in classic dissection [1,6]. Separation of intimal calcium from the aortic border may also be visible. These are simply associated findings; differentiation of IMH from classic dissection requires other imaging modalities.

TTE does not allow for definitive, reliable diagnosis of IMH [9]. With TEE, IMH may appear as an echogenic, crescent-shaped segment of aortic wall. This is not a definitive modality, as in some cases, the thickened wall segment can be difficult to distinguish from atherosclerotic thickening [66].

With CT scanning, IMH appears as a crescent-shaped thickening of the aortic wall, but with a normal-appearing aortic lumen. A contrast study is required for a definitive diagnosis. The most important feature that distinguishes an IMH from a classic dissection is the absence of contrast within the aortic wall. MRI allows for diagnosis of IMH without the use of contrast. The intensity of the hematoma can be determined by the signal sequence. Aortography is not a useful method for evaluating IMH, as the sensitivity for identification of IMH is less than 20% [66].

Management

As is the case for management of typical dissection, early imaging and surgical consultation are the central components of the management of a patient with an IMH, which can be a rapidly progressive disease. Frequent reevaluation of the diseased aortic segment may also be warranted, especially if the patient presents with new hypotension or progressive symptoms. The most dangerous consequence of IMH is continued expansion and progression to typical dissection and/or aortic rupture. Given the high-risk nature of IMH in the ascending aorta, management is similar to typical aortic dissection: surgery for type A syndromes and medical management for type B syndromes [9]. The recent literature contains some controversy regarding the potential role for medical management of IMH in the ascending aorta, but at this time, there is no strong evidence to suggest that medical management is sufficient [48,67–72].

For type B IMH, medical management appears to be the consistently validated early treatment approach, unless a surgical indication is present. In-hospital mortality for patients in the IRAD series is less than 10% for patients receiving medical management [48].

There may be a role for prophylactic endovascular stent placement in patients with IMH who are thought to be in imminent danger of hematoma expansion and aortic rupture. Type B IMH should be frequently reassessed and reimaged as indicated, as these patients are at increased risk for evolution into classical dissection or rupture [73]. Several studies have suggested that a small proportion of IMH will resorb in short-term follow-up, and this appears to be correlated with smaller aneurysm size at presentation. However, a significant proportion of patients will go on to develop enlarging aortic aneurysm and/or pseudoaneurysm, classic aortic dissection, or rupture [62,74,75]. The role of endovascular stents in preventing these late outcomes is currently under investigation [76,77]. The use of endovascular stent grafting to manage a complication of a type B IMH with subsequent dissection is demonstrated in Figure 36.4. A summary of recommended management strategies for patients with acute aortic dissection or IMH is shown in Figure 36.5.

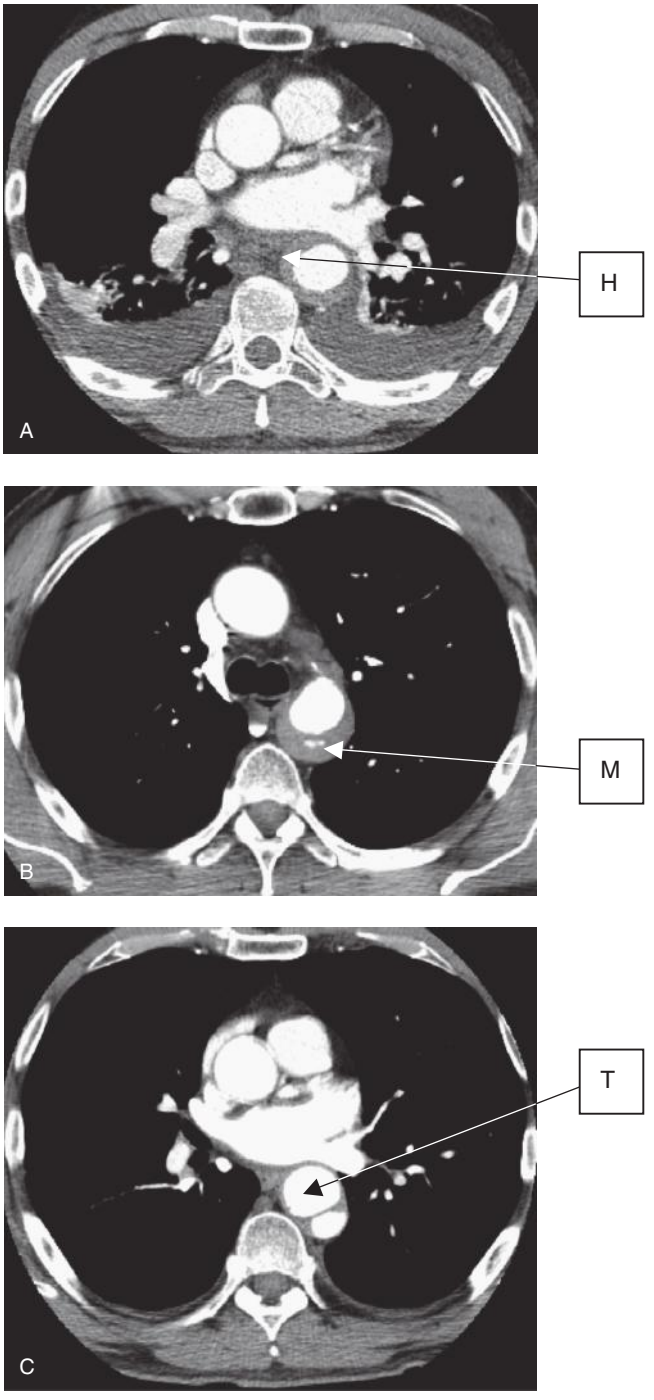

FIGURE 36.4. A–C: Endovascular aortic stent grafts for nonsurgical management of Stanford type B dissection. This patient initially presented with acute type B dissecting intramural hematoma. Panel A shows a contrast-enhanced (CT) scan of the chest demonstrating acute intramural hematoma just inferior to the pulmonary artery bifurcation with a circumferential, crescentic appearance (H). The IMH extended from just distal to the takeoff of the left subclavian artery down to the level of the celiac axis. Panel B shows evidence of active hemorrhage into the aortic media (M) at the proximal descending thoracic aorta. Panel C shows a follow-up contrast-enhanced chest CT of the same patient at 36 days after initial presentation, with evidence of evolution of the IMH into a classic dissection, with true lumen (T) and filling of the false lumen at the same level in the proximal descending aorta as shown in Panel A. (*continued*)

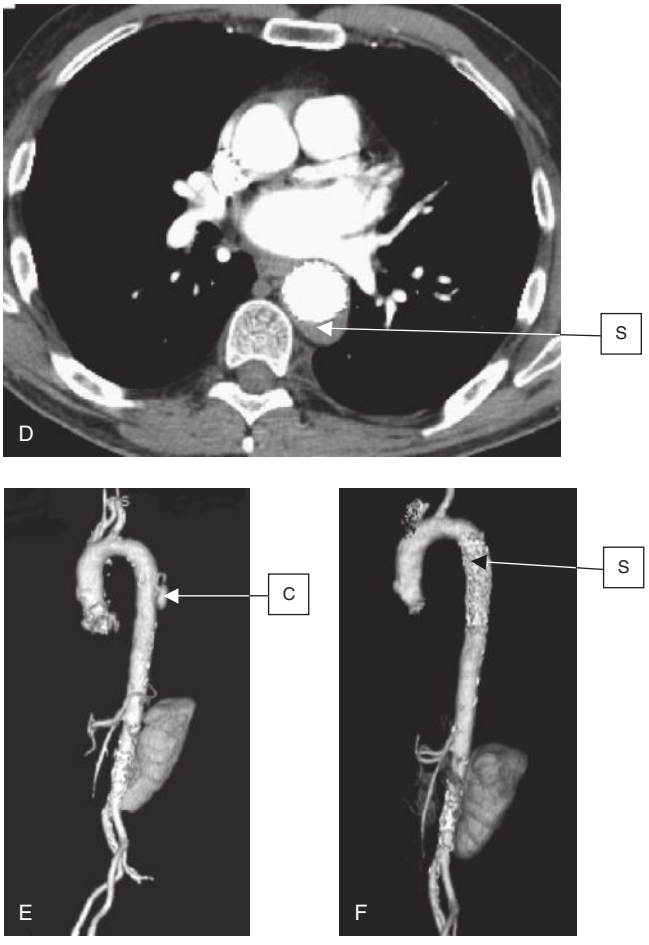

FIGURE 36.4. (*Continued*) **D–F:** Panel D shows the contrast-enhanced chest CT scan after placement of a stent graft (S) in the proximal descending aorta at the site of presumed communication between false and true lumen, demonstrating complete exclusion of the hematoma. Panel E demonstrates a three-dimensional reconstruction of the contrast-enhanced CT scan of the aorta in the left anterior oblique view of the same patient 36 days after initial presentation with extravasation of contrast (C) (corresponding to the image in Panel C), and Panel F shows the same left anterior oblique view of the aorta status-post endovascular stent grafting procedure (S, stent).

EXPANDING AORTIC ANEURYSM AND RUPTURE

Definition and Classification

An aortic aneurysm is broadly defined as a segment of the aortic lumen whose diameter exceeds 1.5 times the normal diameter for that segment [78]. The risk of aneurysm rupture increases as a function of diameter. In addition, rupture risk is thought to be higher in rapidly expanding aneurysms [79,80]. Aneurysms are also classified according to location (e.g., thoracic vs. abdominal), morphology, and etiology. All segments of the aorta can be affected and multiple aneurysms may be found in a single patient. Up to 13% of patients with an identified aortic aneurysm are found to have multiple aneurysm; as such, in patients in whom a single aneurysm has been detected, consideration should be given to scanning the entire aorta for additional aneurysms [81]. In the general population, abdominal aneurysms are more common than thoracic aneurysms [82].

The most commonly encountered aortic aneurysm morphology is fusiform—specifically, a symmetrical dilatation of an aortic segment, involving the entire circumference of the vessel wall (Fig. 36.6). Aneurysms may also be saccular, or may involve only a portion of the vessel, leading to an asymmetric dilatation. It is also important to distinguish between true and false aneurysms: a true aneurysm involves all three layers of the vessel wall, whereas a false aneurysm is typically a collection of blood underneath the adventitia or outside the vessel altogether. This collection is frequently the result of a defect in the aortic wall. The presence of a suspected saccular aneurysm deserves special note, as it may actually represent a false aneurysm caused by a partially contained rupture of the aortic wall.

Aortic aneurysms are frequently asymptomatic at the time of diagnosis, and tend to be detected with tests ordered for other reasons [83]. Indeed, an aortic aneurysm may not be associated with any symptoms until the time of rupture. As the clinical presentations of ruptured thoracic and abdominal aortic aneurysms (AAAs) frequently differ, they are discussed separately.

ANEURYSMS OF THE THORACIC AORTA

Epidemiology

The overall annual incidence of thoracic aortic aneurysm (TAA) is 6 per 100,000 [83], and up to 40% of all patients are asymptomatic at the time of diagnosis [84]. The risk of aneurysm rupture or dissection increases as a function of size. An abrupt increase in risk has been noted at a diameter of 6 cm: for aneurysms greater than 6 cm, the rupture rate has been observed to be 3.7% per year [79]. The most commonly affected segments are the aortic root and ascending aorta; 60% of observed cases involve these segments. Aneurysms of the descending aorta account for 40% of cases, and the aortic arch accounts for 10%.

The surgical treatment strategy for asymptomatic aortic aneurysms differ on the basis of location, size, and etiology: for an aneurysm in the aortic root or the ascending aorta, surgical repair is indicated for a diameter of 5.5 cm or more, although for patients who are at increased risk of rupture, such as patients with a bicuspid aortic valve (which is associated with an intrinsic defect in the medial smooth muscle layer) or Marfan syndrome, 5 cm (or less in certain cases, such as in patients with strong family histories for premature aortic dissection or rupture) is the recommended operative threshold [85,86]. In the descending aorta, surgery is recommended at a diameter of 6 cm or more [82].

For patients with large TAAs, survival without surgical repair is poor, with 5-year survival after initial identification at 20%. Rupture occurs in 32% to 68% of patients whose TAAs are not repaired surgically [87,88]. Of those patients whose rupture occurs outside a hospital setting, it is thought that less than half will arrive to a hospital alive. For those patients who survive until hospital admission, mortality at 6 hours is 54%. At 24 hours, mortality without surgery is 76% [89].

Etiology and Pathophysiology

Multiple factors have been implicated in the formation of TAAs, including atherosclerotic disease, specific gene defects, and infectious processes. In many cases, a central pathophysiologic process is medial degeneration, which leads

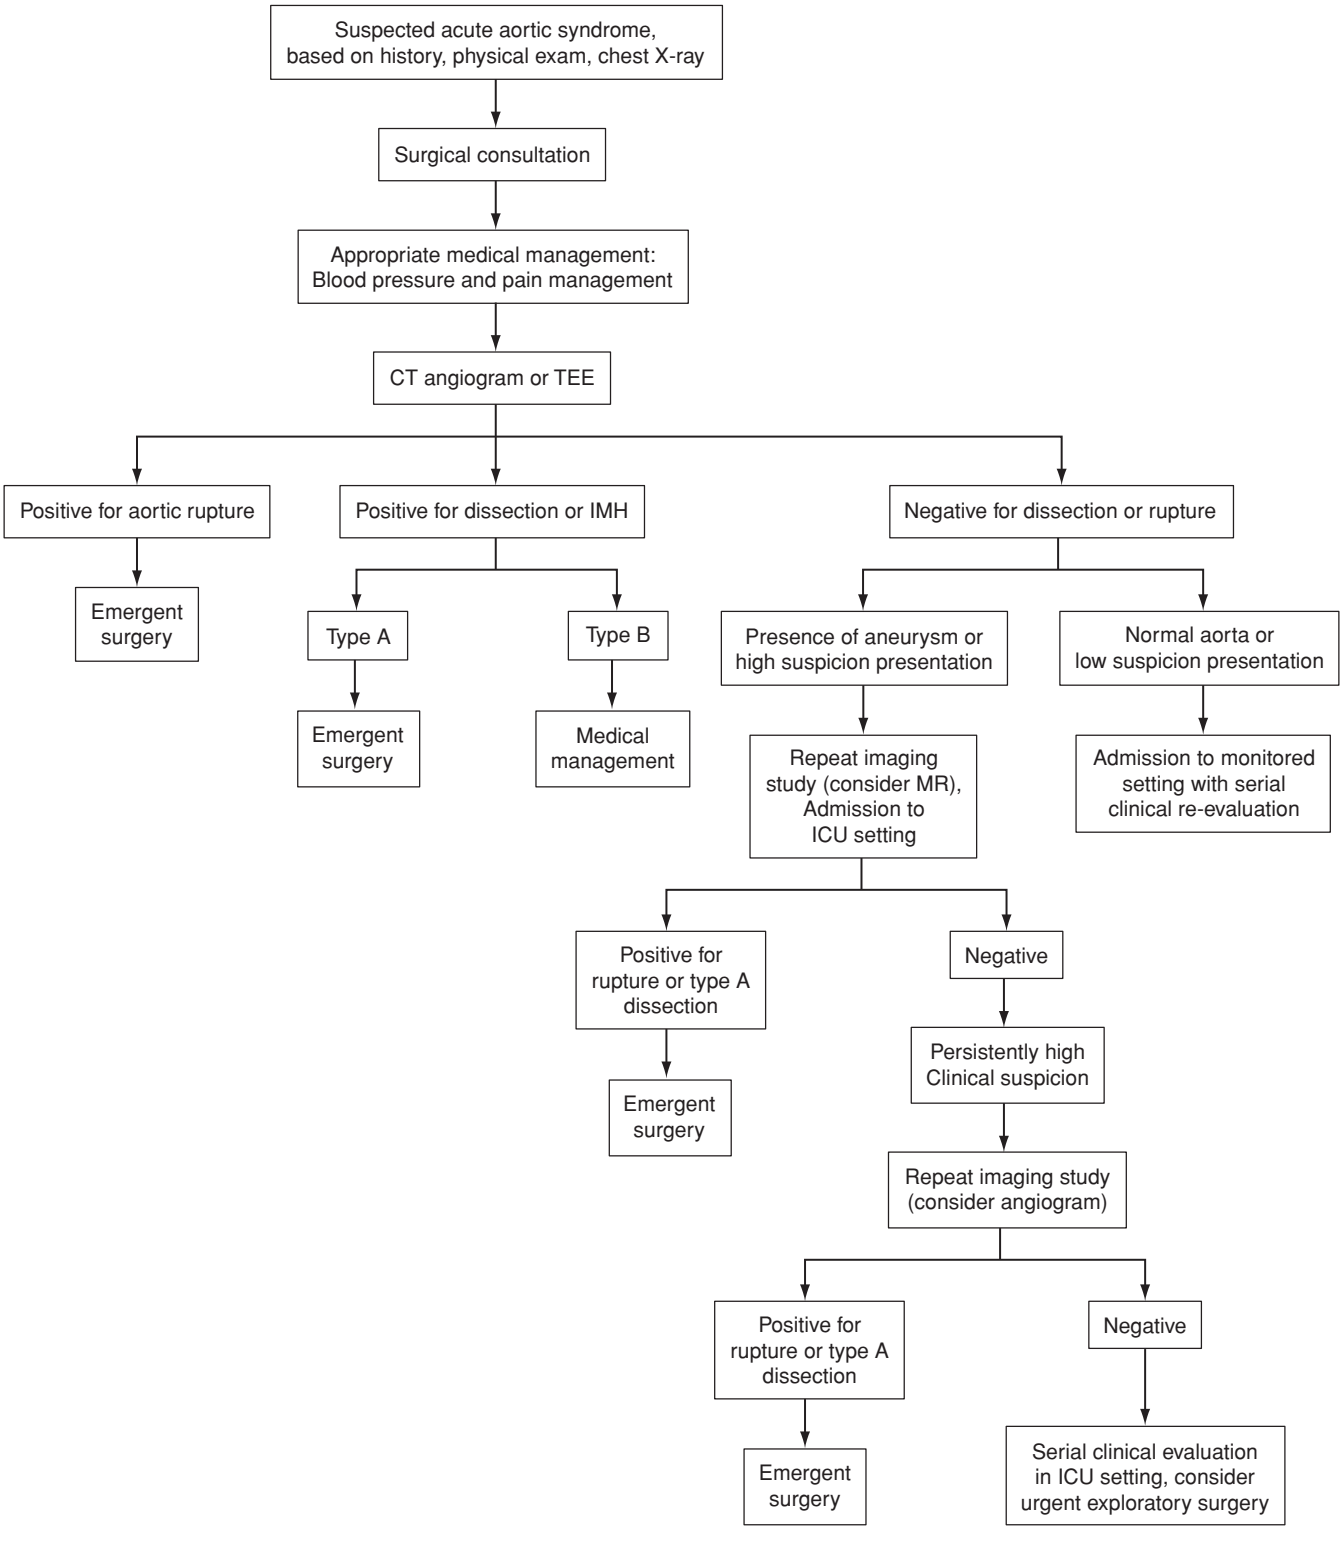

FIGURE 36.5. A suggested management strategy for patients with suspected acute aortic syndrome.

to the loss of elastic fibers and smooth muscle cells. This process, which is frequently correlated with aging, causes progressive stiffening and weakening of the vessel wall, leading to progressive dilatation. Hypertension accelerates dilatation due to the increase in wall strain [82,84,90]. The inciting factor that leads to aneurysm formation influences which portion of the aorta is affected and the age at which the abnormality tends to be diagnosed.

Aneurysms in the aortic root and ascending aorta are frequently associated with inherited defects in structural genes or with inflammation caused either by infection or by vasculitis. In general, aneurysms associated with structural genetic

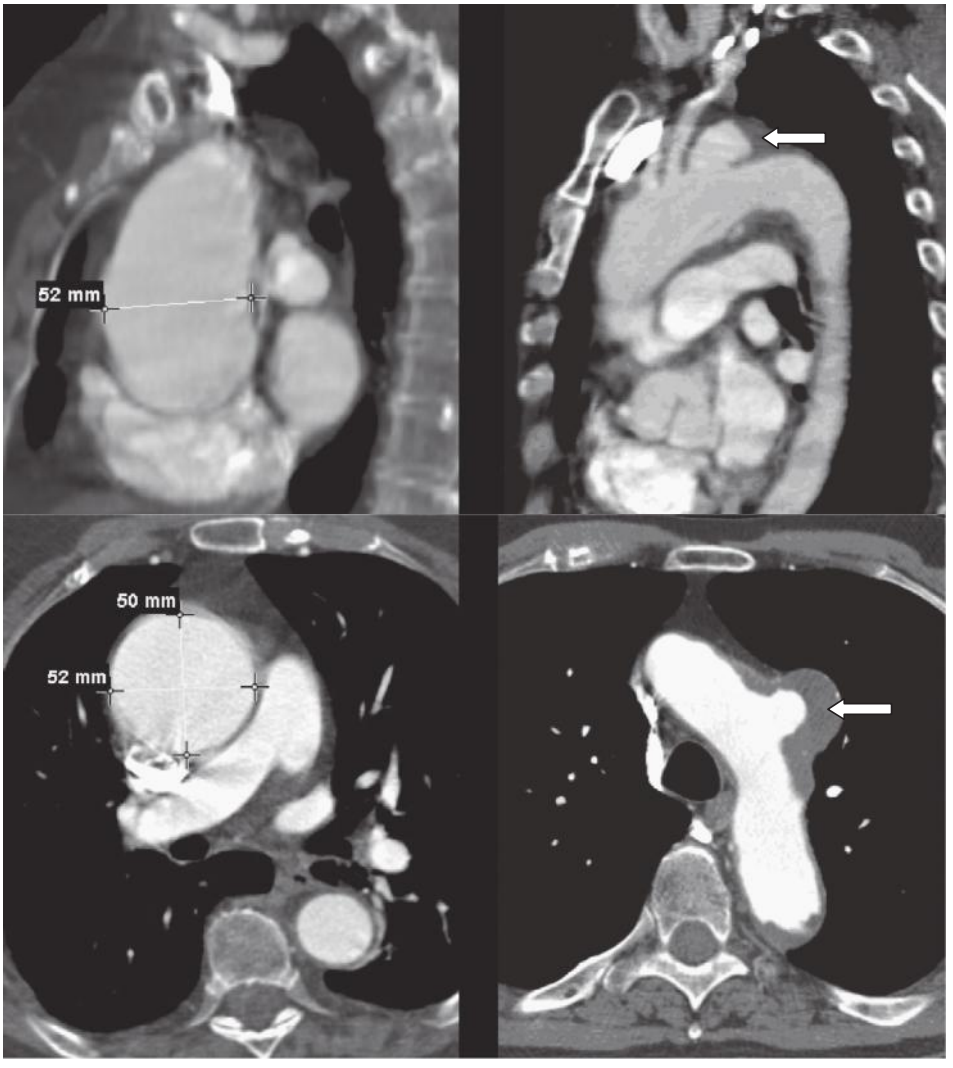

FIGURE 36.6. CT angiograms of a fusiform aneurysm (left-hand panels, with dimensions) and a saccular aneurysm (right-hand panels, *white arrows*).

mutations tend to occur at a younger age, in some cases during the second and third decades of life. Identified connective tissue disorders, such as Marfan and Ehlers–Danlos syndromes, have been established as causes for aneurysms in this portion of the aorta [90,91]. These syndromes are caused by deficits in fibrillin-1 and type III collagen, respectively. The specific protein deficits lead to weakening of the vessel wall due to medial necrosis with resultant ectasia. A growing body of evidence reveals a hereditary syndrome (FTAAS) that does not lead to overt manifestations of connective tissue disease but is associated with aneurysm of the ascending aorta. Multiple loci have been identified, but routine genetic testing for this spectrum of disorders is not yet available [92–95]. A bicuspid aortic valve is also associated with aneurysm of the aortic root/ascending aorta. Dilatation of this segment of the aorta has been shown to be due to medial degeneration that is independent of the potential hemodynamic effects of the abnormal valve. An acquired defect in the integrity of fibrillin-1 may also occur in some of these patients [96]. A growing body of evidence suggests that the enzymatic activity of several matrix metalloproteinases (MMPs) may play a central role in the loss of connective tissue integrity in patients with bicuspid aortic valve [97]. Turner syndrome is associated with an increased incidence of bicuspid aortic valve, as well as with aortic coarctation and aneurysm of the ascending aorta [98].

Ascending aortic aneurysm may also be caused by infectious processes, such as bacterial endaortitis or chronic spirochetal infection. Syphilis, once a common cause of aneurysm in the ascending aorta, is now rarely seen in the developed world. The aortitis caused by bacterial infection leads to both fusiform and saccular aneurysms [99]. Inflammation-related aneurysm in this area may also be caused by vasculitic processes, most notably Takayasu or giant cell arteritis [100,101]. Although typically associated with stenotic lesions of the aorta or great vessels, Takayasu arteritis may present acutely, with the development of aortic aneurysms that are associated with signs of systemic and focal aortic inflammation; in rare cases, patients with acute aortic dilatation associated with Takayasu arteritis have suffered acute aortic rupture. Patients with Takayasu arteritis are typically younger Asian females, who may show involvement of the pulmonary arteries as well. In contrast, aneurysms associated with giant cell arteritis are more frequently diagnosed in older Caucasian females with prior polymyalgia rheumatica and/or symptomatic temporal arteritis [100–102].

Aneurysms in the descending aorta are generally caused by atherosclerosis. As such, these aneurysms are more commonly found in men and are not frequently seen before the sixth decade of life. These aneurysms are found beyond the branch point of the left subclavian artery and are typically fusiform.

Saccular aneurysms may be found at the aortic isthmus, and are frequently the result of rapid deceleration trauma.

Clinical Manifestations

Expanding aneurysms of the ascending and descending thoracic aorta produce symptoms due to compression of neighboring thoracic structures and compromise of aortic valve function (see later in the chapter). Compression leads to chest and back pain in as many as 37% and 21% of cases, respectively [103]. Specific thoracic structures, when compressed by the aorta, lead to distinct signs and symptoms, including superior vena cava syndrome, pulmonary symptoms due to tracheal compression, or dysphagia due to esophageal compression. In addition, stretching of the recurrent laryngeal nerve may lead to unilateral vocal cord paralysis, with hoarseness (Ortner's syndrome).

Symptoms from rupture of a TAA are largely related to blood extending into adjoining thoracic spaces. The sudden onset of acute chest or back pain is a common feature of aneurysm rupture in all segments of the thoracic aorta. Perhaps the most salient feature of this pain is the fact that its maximal intensity occurs at onset. In patients whose aneurysms have produced prior symptoms, the pain at the time of rupture may be a more intense form of the same sensation, often at the same location. The quality of this pain does not necessarily have a tearing quality, as is often the case with dissection.

The most common area of blood flow from a rupture in the ascending aorta is the left pleural space, followed by the intrapericardial space. Blood flow into these areas lead to hemothorax and hemopericardium. Tamponade physiology may be present. Rupture of the descending aorta can lead to erosion into the esophagus: over time, an aortoesophageal fistula may form, leading to severe hematemesis. No matter where the point of blood egress is found, rapid loss of intravascular volume leads promptly to hypotension and shock if unrepaired. Ancillary warning signs include decreased urine output and altered mental status.

The heart examination may also exhibit distinct abnormalities with expanding aneurysm and rupture. Progressive dilatation of the aortic root may lead to dilatation of the valve annulus with consequent signs of aortic regurgitation. This phenomenon is associated with a diastolic murmur heard best over the left sternal border with the exception of aneurysms associated with ectasia of the aortic root, such as syphilitic aortitis, where the murmur of aortic regurgitation may be more noticeable along the right sternal border. Critical levels of regurgitation may be associated with left-sided heart failure. This murmur may be present in the absence of rupture. When rupture of one of the sinuses of Valsalva occurs, the murmur may be continuous; in this setting, the ruptured area may communicate with a cardiac chamber, such as the right atrium or ventricle.

In the context of acute rupture, the electrocardiography frequently shows evidence of ventricular "strain" or ischemia. Over time, markers of myocardial necrosis may be elevated as well. Several studies show an elevation in D-dimer in the context of aortic dissection, but elevation of this marker has not yet been validated in aneurysm progression or rupture [104]. There is currently no widely available biomarker in use to detect vascular injury in the context of aneurysm or rupture.

Imaging

Aortic aneurysm may be visualized as a widened mediastinum on anteroposterior views. Although this technique offers invaluable information, it cannot be considered a definitive study. TTE allows for the evaluation of the aortic root and ascending aorta. TEE is well suited to the evaluation of potentially aneurysmal segments in the aortic arch and descending aorta. As noted previously, perhaps the most important procedural drawback regarding TEE is the need for conscious sedation, which may be difficult to administer in a patient who is hemodynamically unstable.

CT scanning allows for evaluation of potentially aneurysmal segments in the entire aorta. Contrast CT imaging may also be helpful in identification of areas of blood extravasation in ruptured aortic aneurysms. MRI may be used for aortic measurement and identification of aneurysmal segments without contrast. Evaluation of blood extravasation with MRI is possible, but thought to be less sensitive than CT with contrast, especially for slow or low-volume extravasation. Aortography is a highly sensitive technique for assessing extravasation. The use of this technique in the acute setting is ordinarily reserved for those cases where neither CT scanning nor MRI is available.

Rupture of a Thoracic Aortic Aneurysm: Management

Rupture of a TAA is a surgical emergency. Open repair of the vessel is the most established repair technique. Typically, the procedure is performed with deep hypothermic circulatory arrest. The type of repair is determined by the location of the rupture and the presence or absence of aortic valve involvement. Dacron grafts are generally placed to replace the diseased vessel segment, with various strategies for aortic valve repair or replacement when necessary [105]. Recent work indicates that a less invasive form of repair, retrograde endovascular stent placement, may be useful in the repair of aneurysms in the descending aorta.

Patients with aneurysm of both ascending and descending segments present an additional challenge. Standard methods entail surgical replacement of diseased segments in a "staged" fashion; however, newer methods involving a hybrid approach of surgical replacement of the ascending aorta, with subsequent endovascular therapy of the distal segments, appear promising [106].

It may be that a particular patient presents with complaints raising concern for a ruptured aortic aneurysm. In the event that no rupture is found and the patient is hemodynamically stable, it is possible that expansion of the aneurysm is responsible for the symptoms. In such a case, the focus of immediate clinical treatment should be to decrease aortic wall strain and systemic blood pressure through the use of beta-blockers in the context of a critical care setting. Prompt surgical consultation plays a vital role in the continuing care of these patients.

ANEURYSMS OF THE ABDOMINAL AORTA

Epidemiology

AAAs are far more common than TAAs. The estimated prevalence of AAAs ranges between 1.3% and 8.9% in men and between 1.0% and 2.2% in women older than 60 years [107–110]. Most cases are observed in men older than 55 years and women older than 70 years. AAAs have been found to be correlated with smoking [111]. Overall prevalence of abdominal aneurysms has risen substantially over the past 30 years

[112]. This trend has been linked to the increased prevalence of atherosclerosis, which is thought to be the major etiology responsible for abdominal aneurysms. In addition, improvements in imaging technology have increased the rate of detection.

Rupture of AAAs is estimated to cause approximately 15,000 deaths per year in the United States [112,113]. The total mortality rate for patients with rupture ranges from 65% to 85% [107]. One prospective study revealed that 25% of patients with AAA rupture die before arriving at a hospital. Of those who arrived at the hospital alive, 51% died before surgery. Patients who did have surgery sustained a 46% operative mortality rate. Total 30-day survival rate for this population was 11% [80]. Given the poor prognosis associated with rupture, elective repair is recommended when possible. As is the case with TAAs, the risk of rupture increases as a function of aortic diameter. Recently published guidelines recommend elective surgery for AAA 5.5 cm or more in men and 5 cm in women [114].

Etiology and Pathophysiology

Incidence of AAA is closely correlated with the presence of atherosclerotic disease in the aorta. In general, the infrarenal segment of the aorta is most heavily affected by atherosclerosis, and this is also the segment where most abdominal aneurysms are observed. These aneurysms are typically fusiform, but saccular aneurysms may also be found.

The risk factor most closely associated with abdominal aneurysms is smoking, followed by age, hypertension, and hyperlipidemia [115]. There is also a strong association between gender and abdominal aneurysm formation [108]. Family history of AAA is associated with a 30% increase in risk for AAA formation, but there are not yet any specific genes linked with this finding [82,116].

Damage to the vessel wall, caused by atherosclerotic plaque, has been shown to cause local inflammation. This inflammatory process is thought to cause degradation of extracellular matrix proteins, notably elastin and collagen. In addition, it is thought that the proinflammatory cytokine milieu leads to cell death in the vessel wall. Weakening of the vessel wall follows, potentially accelerated by the action of multiple proteases, including MMP and cathepsin L [117,118]. There is some speculation that MMP polymorphisms may lead to a change in susceptibility to abdominal aneurysms, but there are no screening tests currently available to the clinician [119]. Hypertension increases the wall strain on the weakened vessel wall, leading to accelerated expansion. The full effects of smoking on aneurysm formation and expansion are not known, but increased atherosclerosis and hypertension are thought to be contributors.

Aneurysms in the descending thoracic aorta tend to be caused by atherosclerosis. These aneurysms often extend into the abdominal cavity, superior to the renal arteries. Such aneurysms are referred to as thoracoabdominal, and their management mirrors the management of aneurysms in the abdominal cavity.

Aneurysms in the descending thoracic or abdominal aorta may also be caused by acute bacterial infections. This is not a common finding, but tends to be found more often in patients who are intravenous drug users or who have traveled recently from a country where exposure to typical organisms (*Salmonella* and *Brucella*) is more likely to occur. Chronic tuberculosis is rarely associated with abdominal aneurysms. Syphilis may also be associated with abdominal aneurysms, but it is more commonly associated with the ascending aorta. Connective tissue disorders, such as Marfan and Ehlers–Danlos syndromes, do not typically affect the abdominal aorta; however, some systemic inflammatory disorders, notably Takayasu arteritis or Behcet's disease, may be associated with abdominal aneurysms [120,121].

Clinical Manifestations

As is the case with thoracic aneurysms, most abdominal aneurysms are asymptomatic and tend to be discovered with testing performed for other reasons. Those patients who do have aneurysm-related complaints tend to report pain in the hypogastric area and/or pain in the lower back. This pain is caused by the expansion of the aneurysm and tends to last for hours or days at a time, and is usually dull and steady. In the abdomen, fewer structures tend to be affected by the expanding aorta. The most common consequence of aortic expansion is compression of the ureter or kidney, leading to hydronephrosis or potentially renal failure.

An episode of rupture tends to be announced by a sudden onset or increase in abdominal and/or back pain. The most notable feature of this pain is that it is at its maximum at the time of onset. Rupture most frequently leads to blood leakage into the left retroperitoneal space. These patients may present with an initial episode of pain associated with the first rupture, followed by temporary tamponade of the retroperitoneal space. A larger, life-threatening bleed inevitably follows. Less frequently, the aneurysm may erode into surrounding structures, most notably the duodenum, leading to either formation of an aortoduodenal fistula or potentially massive gastrointestinal (GI) bleeding [113,122].

Physical examination of a patient with an AAA may reveal a palpable, pulsatile mass in the midline. This mass is easiest to palpate in the hypogastric or paraumbilical region. The sensitivity of the manual examination is suboptimal: 82% for aneurysms 5 cm or greater. Furthermore, a mass may be difficult to appreciate [123]. Consequently, the absence of a pulsatile mass on physical examination should not be interpreted as an absence of aneurysm. On rupture of an abdominal aneurysm, most patients become hypotensive, tachycardic, and diaphoretic. Patients may also exhibit signs of peritoneal irritation on examination. As noted, the patient may also present with evidence of GI bleeding. Laboratory analysis may reveal evidence of elevation in D-dimer or an elevation in cardiac biomarkers, due to demand-related myocardial ischemia.

Imaging

X-ray plain film is not an adequately sensitive technique for the assessment of AAAs. Echocardiography is not helpful for the evaluation for extrathoracic segments of the aorta. Transcutaneous ultrasound is a noninvasive and readily available technique for the evaluation of the abdominal aorta. This method is frequently used to track the size of abdominal aneurysms, though it is not the imaging modality of choice for the acute aortic syndromes. Like TTE, abdominal ultrasound is often limited by body habitus. As with thoracic aneurysms, the most definitive evaluations are provided by CT scanning and MRI. Aortography may provide useful information regarding aortic aneurysm, but it is not the modality of choice in the acute setting unless CT scanning and MRI are not available.

Rupture of an Abdominal Aortic Aneurysm: Management

Rupture of an AAA is a surgical emergency. Open repair, with replacement of the diseased segment with a Dacron graft, is the most established technique. Intraoperative mortality after

rupture is very high, as noted previously. Retrograde endovascular stent placement is a promising technique [124–126], but it is not yet in common use in the acute setting [127,128]. Timely, but elective, surgical or endovascular intervention on the basis of size criteria, as assessed with longitudinal imaging, is the most effective means to prevent progression to rupture.

CHAPTER 37 ■ EVALUATION AND MANAGEMENT OF HYPERTENSION IN THE INTENSIVE CARE UNIT

BENJAMIN M. SCIRICA AND ROBERT J. HEYKA

HYPERTENSIVE URGENCIES AND EMERGENCIES

Patients with elevated blood pressure (BP) in the intensive care unit (ICU) present with either a BP that threatens to cause imminent target organ damage (TOD) to vascular beds or a transient, usually more benign elevation in BP without threat of TOD.

Definitions

Hypertensive syndromes have diverse etiologies and often have little in common besides a similar presentation. The terms used to describe these clinical syndromes are mostly of historic significance. In original usage, they applied to specific clinical findings often without an appreciation of their systemic abnormalities. They are often misapplied. *Hypertensive crisis* is loosely defined as any clinical situation with a severe elevation in BP [1]. Hypertensive emergencies and urgencies are categories of hypertensive crisis that may be life threatening and occur (a) against the background of worsening chronic essential hypertension, (b) with secondary forms of hypertension, or (c) in patients without previously known hypertensive disease.

There are not reliable data regarding the actual yearly number of hypertensive emergencies; however in the United States, hypertension is the primary diagnosis in more than 500,000 hospital admission [1]. Patients with essential hypertension who present to emergency rooms with hypertensive crises tend to be aware of their diagnosis of hypertension, on medication but noncompliant, are African-American or Hispanic, young males, and of lower socioeconomic status [2]. Other secondary forms of hypertension, including renovascular disease or endocrine causes [3] are found in a significant percentage of patients with hypertensive crisis.

In hypertensive crises, the elevation in BP tends to be severe with diastolic blood pressures (DBPs) greater than 120 mm Hg. However, the level of systolic blood pressure (SBP), DBP, or mean arterial pressure (MAP) does not distinguish them. Rather, it is the presence or absence of acute and progressive TOD [4,5].

Hypertensive emergency means the BP elevation is associated with ongoing neurologic, myocardial, vascular, hematologic, or renal TOD, whereas *hypertensive urgency* means that the potential for TOD is great and likely to occur if BP is not soon controlled. Examples of hypertensive emergencies are provided in Table 37.1. In many instances, a better term for urgencies is simply *uncontrolled BP* [4,5]. Many patients present to emergency rooms with inadequately treated BP and no evidence of TOD [6]. There is no evidence of benefit from rapid reduction in BP in these asymptomatic patients [7], and their difficult-to-control hypertension can be evaluated as outpatients [8].

Accelerated and *malignant hypertensions* are older terms named on the basis of ophthalmologic findings and refer to categories of hypertensive crises with exudative retinopathy, retinal hemorrhages, or papilledema. They probably represent a continuum of organ damage [9].

Accelerated hypertension may be an urgency or emergency with grade III Keith–Wagener–Barker retinopathy: that is, constriction and sclerosis (i.e., grades I or II) plus hemorrhages and exudates (grade III). The presence of exudate is more worrisome than hemorrhage alone. *Malignant hypertension* is grade IV Keith–Wagener–Barker retinopathy and with papilledema that signifies central nervous system (CNS) involvement, is a *hypertensive emergency*. It is frequently associated with diffuse TOD, such as hypertensive encephalopathy, left ventricular

TABLE 37.1

EXAMPLES OF HYPERTENSIVE EMERGENCIES

Severely elevated blood pressure and the presence of:
- Acute ischemic stroke
- Acute hemorrhagic stroke/subarachnoid hemorrhage
- Acute myocardial infarction
- Acute pulmonary edema
- Acute aortic dissection
- Encephalopathy
- Perioperative hypertension
- Postoperative bleeding
- Severe epistaxis
- Eclampsia
- Pheochromocytoma crisis
- Recreational drug abuse with cocaine, lysergic acid diethylamide (LSD), ecstasy, amphetamines
- Acute renal failure
- Hemolytic anemia
- Monoamine–oxidase inhibitor interactions

failure, renal fibrinoid necrosis, or microangiopathic hemolytic anemia. In the 1930s, the term *malignant* was given to reflect the dismal survival among these patients, approximately 60% at 2 years after diagnosis and less than 7% at 10 years. With the introduction of effective hypertensive therapy, the prognosis has significantly improved, with a 5-year survival of 74%. The most common causes of death are renal failure (40%), stroke (24%), myocardial infarction (11%), and heart failure (10%) [10].

IMPORTANCE OF TARGET ORGAN DAMAGE

Most organ beds can regulate the amount of blood flow they receive over a wide range of systemic pressures by autoregulation: OBF = OPPr/OVR, where OBF is organ blood flow, OPPr is organ perfusion pressure, and OVR is organ vascular resistance [11]. Small arteries and arterioles constrict or dilate in response to local myogenic effectors acting on the endothelium that respond to transmural (perfusion) pressure gradients. A decrease in OPPr leads to vasodilation; an increase in OPPr leads to vasoconstriction and limits pressure-induced damage when systemic pressure rises. The cerebral circulation can maintain perfusion with changes in MAP from about 60 to 150 mm Hg [11]. When MAP exceeds the usual autoregulatory range, breakthrough or loss of autoregulation occurs.

Sustained BP greater than the usual autoregulatory range leads to damage of the endothelial lining of capillaries and arterioles, resulting in leakage of plasma into the vascular wall. Fibrin deposition reduces lumen diameters and precipitates local edema and sclerosis. In patients with chronic hypertension, the loss of autoregulation typically occurs only at extremely elevated BPs, whereas in patients without any significant hypertension, in whom the protective autoregulation has not developed, edema and the consequent organ-specific symptoms can be seen with DBPs greater than 100 mm Hg [12].

When OPPr falls to lesser than the lower limits of autoregulation, organ ischemia and infarction may occur. Limits of critical perfusion pressure and tolerance to variation in OPPr vary among individuals. The elderly or patients with chronic hypertension tolerate an elevated MAP because of an upward shift in their cerebral autoregulation curve but have a diminished tolerance to hypotension with vessel functional and structural changes [12]. Patients without antecedent hypertension may develop a hypertensive crisis with acute conditions such as acute vasculitis, subarachnoid hemorrhage (SAH), unstable angina, or eclampsia at lower systemic BP.

Cerebral circulation is the most sensitive vascular bed to breakthrough and ischemia [13]. Cardiac perfusion tolerates a more pronounced drop in BP, even with underlying atherosclerotic disease, because myocardial oxygen demands decrease dramatically when pressures decrease. In organ beds such as the kidneys with antecedent atherosclerotic, acute BP changes are less tolerated and may worsen renal perfusion [4,5].

In most patients with hypertensive crises, the pathophysiologic abnormality is an increase in systemic vascular resistance (SVR), not an increased cardiac output (CO) (MAP = CO × SVR). The increase in SVR elevates BP, overrides local autoregulation, and leads to organ ischemia.

APPROACH TO THE PATIENT

In the ICU, therapy must often begin before a comprehensive patient evaluation is completed. A systematic approach offers the opportunity to be expeditious and inclusive (Table 37.2).

A brief history and physical examination should assess the degree of TOD and rule out obvious secondary causes of hypertension. The history should include prior hypertension, other significant medical disease, medication use, compliance, recreational drugs use, and, most importantly, symptoms from TOD to neurologic, cardiac, or renal systems. Examination should verify BP readings in both arms, supine and standing, if possible and eliminate the rare but important finding of pseudohypertension due to extensive arterial calcification using Osler's maneuver, which is performed by inflating the BP cuff to greater than the brachial systolic BP. A palpable radial or brachial artery, despite being pulseless, signifies a significantly stiff artery and the likely overestimation of the true BP [14]. Intra-arterial monitoring may be necessary to verify readings and monitor treatment. Also include direct ophthalmologic examination looking for hemorrhages, exudates, or papilledema; auscultation of the lungs and heart; and evaluation of the abdomen for masses or bruits and the peripheral pulses for bruits, masses, or deficits. Signs of neurologic ischemia include altered

TABLE 37.2

INITIAL EVALUATION OF HYPERTENSIVE CRISIS IN THE INTENSIVE CARE UNIT

1. Continuous blood pressure monitoring
   a. Direct (intra-arterial)—preferred
   b. Indirect (cuff)
2. Brief initial evaluation, including history and physical examination with attention to
   a. Neurologic including funduscopic examination and cardiac, pulmonary, renal symptoms
   b. Assessment of organ perfusion and function (e.g., mental status, heart failure, urine output)
   c. Blood and urine studies—electrolytes, blood urea nitrogen, creatinine, complete blood cell count with differential, urinalysis with sediment; if indicated, serum catecholamines, cardiac enzymes
   d. Electrocardiogram (assess for strain or ischemia)
   e. Chest radiograph (assess size of aorta, cardiomegaly, or heart failure)
3. Initiation of therapy (within 1 h of presentation if TOD is identified)
4. Further evaluation of etiology once stabilized

TOD, target organ damage.

mental status, headaches, nausea, and vomiting in addition to focal neurologic deficits. Ancillary evaluation should include electrolytes, blood urea nitrogen and creatinine, complete blood cell count with differential, or echocardiogram (ECG), chest radiograph, and assessment of recent urine output. As the patient's condition stabilizes, further evaluation of unexplored reasons for the hypertensive crisis can be considered and pursued.

Patients with Neurologic Symptoms

In patients with neurologic symptoms, a noncontrast computed tomogram of the head is important to exclude intracerebral hemorrhages (ICHs) or mass effect. Magnetic resonance imaging is more sensitive for detecting early ischemic strokes, as well as the edema and white matter changes in the parieto-occipital region (posterior leukoencephalopathy syndrome) associated with hypertensive encephalopathy [15]. Early identification of acute vascular events such as ischemic strokes or ICHs is critical as early management and BP goals differ from hypertensive encephalopathy.

TREATMENT

Most studies of hypertensive emergencies are either nonrandomized or suffer from (a) tremendous variation and inconsistency in definitions and cutoffs, (b) absence of important and long-term outcomes such as mortality, (c) being underpowered with wide confidence intervals, and (d) inconsistent reporting of adverse effects. Thus, treatment recommendations for hypertensive emergencies are not based on a large body of randomized controlled studies. One systematic review of hypertensive urgencies and emergencies studies found no evidence supporting any one agent over another. For hypertensive emergencies, nitroprusside, captopril, and clonidine were acceptable choices. For urgencies, a number of agents were used and effective [16]. A systematic review for the Cochrane collaboration, which included more recent studies, again failed to detect any specific agent or strategy that was superior to another. There was well-documented efficacy for BP reduction with nitrates (including nitroprusside), angiotensin-converting enzyme (ACE) inhibitors, diuretics, α-adrenergic antagonist, calcium channel blockers, and dopamine agonists [17]. Given this lack of data to guide therapy, how should we proceed?

The intensity of intervention must be determined by the clinical situation. In many situations, intubation, seizure control, hemodynamic monitoring, and maintenance of urine output can be as important as control of BP. Initial therapy should terminate ongoing TOD, *not* return BP to normal. Because cerebral circulation is the most sensitive to ischemia, the lower limit of cerebral autoregulation for each patient determines the initial goal. This floor is approximately 25% lesser than the initial MAP or a DBP in the range of 100 to 110 mm Hg [11]. Reasonable initial therapy is to decrease MAP by 25% with an agent that decreases SVR, considering the medical history, initiating events, and ongoing TOD [5]. Patients with acute left ventricular failure, myocardial ischemia, or aortic dissection require more aggressive treatment [18–20].

The decision to use oral or parenteral therapy depends on several factors. Atherosclerotic disease puts the patient at higher risk if therapy overshoots the mark. The answers to the questions in Table 37.3 guides the decision of parenteral versus oral therapy. Table 37.4 lists recommendations and precautions for therapeutic agents, and Table 37.5 lists proper dosing for each agent.

Once the patient is stable, additional diagnostic studies may proceed. An oral regimen can be started as the situation stabilizes. Because the ICU is an artificial environment, physicians should avoid attempts to normalize BP especially if large doses of medications are required. Further fine-tuning of BP to levels suggested by Joint National Committee VII [6] or the European Society of Hypertension/European Society of Cardiology guidelines for the management of hypertension [21] should occur once the patient resumes his or her usual diet, activity, and compliance at home.

TABLE 37.3

PARENTERAL VERSUS ORAL THERAPY OF HYPERTENSION IN THE INTENSIVE CARE UNIT

Is this a hypertensive emergency?
Is rapid onset of effect needed?
Is rapid lowering of blood pressure needed?
Is a shorter duration of action important?
Is the patient at risk for overshoot hypotension?
Atherosclerotic heart disease
Renovascular hypertension
Cerebrovascular disease
Dehydration
Other recent antihypertensive therapy

SPECIFIC HYPERTENSIVE CRISES

Acute Left Ventricular Heart Failure

Decreases in SVR and MAP improve left ventricular function by decreasing cardiac work, left ventricular wall tension, and oxygen demand. Intravenous nitroglycerin or nitroprusside are the agents of choice in acute heart failure because they rapidly reduce preload and diminish pulmonary congestion [20]. Nitroprusside, a balanced vasodilation with a decrease in both preload and afterload, is usually administered with other acute therapy for pulmonary edema, such as diuretics. Nitroglycerin has greater effect on the venous (preload) side than on the arterial side. Nitroglycerin is preferred for management of ischemic heart failure [20]. Because of the fairly rapid development of tachyphylaxis to nitrates, alternative and more chronic therapy should be instituted within 24 hours of initiation of therapy. The use of an intravenous ACE inhibitor in this situation is contraindicated though oral agents can be resumed or initiated.

Myocardial Ischemia or Infarction

Treatment of elevated BP is only part of the overall therapy to preserve and restore cardiac perfusion with anti-ischemic medications, antithrombotic agents, thrombolytic therapy, percutaneous coronary intervention, or surgery. Therapy should maintain local coronary arterial flow and not induce a steal syndrome with differential relaxation of coronary vessels. Because nitroprusside may actually divert the flow away from poststenotic areas, nitroglycerin is preferred. Beta-blockers given intravenously also act to maintain coronary perfusion in the face of decreased systemic pressures and decrease myocardial oxygen demand by lowering heart rate and BP. The use of an intravenous ACE inhibitor in patients with an acute myocardial infarction and depressed left ventricular function should be avoided as it may precipitate symptomatic hypotension. Uncontrolled hypertension (SBP >180 mm Hg or DBP >110 mm Hg) is a relative contraindication to treatment with fibrinolytic treatment [18].

TABLE 37.4

TREATMENT OF HYPERTENSIVE EMERGENCIES

Type	Recommended drugs	Target of treatment
Neurologic		
Hypertensive encephalopathy	Nimodipine, labetalol	15%–25% decrease in MAP over 3–6 h
Intracerebral hemorrhage or subarachnoid hemorrhage	Nitroprusside, labetalol, nicardipine	Same (debated)
Cerebral infarction	Nitroprusside, labetalol, nimodipine, nicardipine	Same (debated)
Head injury	Nitroprusside	Same
Cardiovascular		
Myocardial ischemia, infarction	Nitroglycerin, beta-blockers, labetalol	Control of ischemia
Aortic dissection	Beta-blockers, nitroprusside, labetalol	Goal of SBP 120 mm Hg in 20–30 min
Acute left ventricular failure	Nitroprusside, nitroglycerin, loop diuretics, converting enzyme inhibitors	Improved Sx
Renal failure		
Acute renal failure	Fenoldopam, nitroprusside, labetalol	Decrease MAP 25%
Other		
Hemorrhagic	Nitroprusside, labetalol, others as needed	Control risk of bleeding
Malignant hypertension	As with encephalopathy; oral agents may be considered	
Obstetric	Hydralazine, methyldopa, $MgSO_4$	DBP <90 mm Hg

DBP, diastolic blood pressure; MAP, mean arterial pressure; SBP, systolic blood pressure; Sx, signs and symptoms.

Aortic Dissection

Aortic dissection is the most common acute aortic syndrome. It is imperative to begin therapy for aortic dissection immediately to prevent extension or rupture, regardless of the ultimate therapy. Uncomplicated acute type B dissection is usually treated with medication. Therapy is directed to lower BP and the rate of the rise of pressure (dp/dt). BP should be lowered rapidly to the lowest level, permitting continued good organ perfusion (i.e., no change in mental status or new neurologic symptoms and continued urine output). Intravenous beta-blockade is the initial therapy of choice, in particular with labetalol or esmolol. Any acute therapy that decreases BP without also decreasing dp/dt or induces reflex tachycardia can extend the dissection and should be avoided. Once beta-blockade is started, vasodilation with nitroprusside can be added if necessary [19,22].

Hypertensive Encephalopathy

Hypertensive encephalopathy occurs with severe BP elevation as cerebral autoregulation is overwhelmed and can lead to blindness, seizures, coma, and death. Pathologic findings include endothelial dysfunction, cerebral edema, petechial hemorrhages, and microinfarcts [11]. The typical patient has chronic untreated hypertension and the slow development of neurologic symptoms, especially headaches, over 48 to 72 hours. Hypertensive encephalopathy is much less common with better access to antihypertensive medication. Any degree of control of hypertension can dramatically decrease the likelihood of encephalopathy. As mentioned previously in the chapter, patients with severe hypertension and neurologic symptoms should have neuroimaging to exclude acute ischemic strokes or hemorrhages, in which the goals of hypertension management differ from hypertensive encephalopathy. Treatment with short-acting parenteral agents should lead to rapid resolution of symptoms. Continued symptoms suggest other CNS pathology [23].

Ischemic Stroke

Elevated BP is common in patients presenting with acute ischemic strokes. Both low and high BPs are associated with poor outcomes. For every increase in 10 mm Hg greater than 180, there is a 40% increase in the risk of worsening neurologic status [24]. Once ischemia occurs, a central core of dense ischemia of variable size is surrounded by less severe ischemia that can potentially be salvaged, termed the *ischemic penumbra* [25]. This area of stunned, but viable, tissue depends on continued blood flow and may need higher pressures for continued perfusion. Because of the concern about abrupt reduction in BP in patients presenting with acute strokes has led the American Heart Association and American Stoke Association guidelines for the early management of adults with ischemic stroke give a consensus recommendation that emergency use of BP-lowering agents should be withheld unless the DBP is greater than 120 mm Hg or the SBP is greater than 220 mm Hg. In patients who are potentially eligible for reperfusion therapy, it is recommended to consider therapy for levels greater than 185 mm Hg SBP or 110 mm Hg DBP with labetalol, nitroprusside, or nicardipine. Thrombolytic therapy should not be given if the BP remains elevated to greater than 185/110 mm Hg. After reperfusion therapy, labetalol or nicardipine is recommended for SBP levels greater than 180 mm Hg or DBP levels greater than 105 mm Hg and nitroprusside for SBP levels about 230 mm Hg [24]. If clinical deterioration is noted with BP reduction, higher BPs must be accepted.

Subarachnoid Hemorrhage

The treatment of SAH is complicated and unsettled. It is unclear if uncontrolled hypertension increases the risk of rebleeding [26,27]. A Cochrane review found that oral, but not intravenous, calcium channel blockers (CCB) reduce the risk of poor outcome and secondary ischemia [28], which is based primarily on studies using nimodipine. If vasospasm occurs later,

TABLE 37.5

PROPER DOSING FOR AGENTS TO TREAT HYPERTENSIVE CRISIS

Agent	Administration	Onset	Duration	Special indications
Direct vasodilators				
Nitroprusside	IV infusion: 0.25–10.0 μg/kg/min	Immediate	1–2 min	Hypertensive emergencies
Nitroglycerin	IV infusion: 5–200 μg/kg/min	2–5 min	5–10 min	Heart failure or cardiac ischemia
Fenoldopam	IV infusion: 0.1 μg/kg/min uptitrated by 0.05–0.1 μg/kg/min increments to maximum 1.6 μg/kg/min	5–15 min	30 min	Most hypertensive emergencies; avoid in glaucoma
Hydralazine	IV bolus: 10–20 mg	10–20 min	1–4 h	Eclampsia
Adrenergic blockers				
Phentolamine	IV 5–15 mg	1–2 min	10–20 min	Pheochromocytoma, catecholamine surge
Esmolol	IV bolus 250–500 μg /kg/min IV bolus—repeat after 5 min IV infusion 50–100 mg/kg/min; give new bolus when increase infusion	5–10 min	10–30 min	Most hypertensive emergencies
Labetalol	IV bolus: 20–80 mg q10 min IV infusion: 0.5–2 mg/min	5–10 min	3–6 h	Most hypertensive emergencies; not in decompensated heart failure
Calcium antagonists				
Nicardipine	IV infusion: 5–15 mg/h	5–10 min	1–2 h	Most hypertensive emergencies; not in heart failure
Nimodipine	IV infusion: 5–10 mg/h ↑ by mg/h, up to 15 mg q30 min, 60 mg q4h × 21 d; repeat	15–30 min	3–6 h	Subarachnoid hemorrhage
Clevidipine	IV infusion: 1–2 mg/h, double dose q90 s. As approach goal BP, ↑ by less than double and lengthen uptitration to q5–10 min. Typical goal is 4–6 mg/h	2–4 min	5–15 min	Most hypertensive emergencies
Angiotensin-converting enzyme inhibitors				
Captopril	PO 6.25–25 mg, repeat q30 min, if necessary	1 h	1–4 h	
Enalaprilat	IV bolus: 1.25–5.0 mg (over 5 min) q6h	15–30 min	6–8 h	Acute left ventricular failure; not in myocardial infarction
Central-acting agonists				
Clonidine	PO 0.2 mg initially; 0.2 mg/h (total 0.7 mg)		3 h	
Miscellaneous				
Trimethaphan	IV infusion: 0.5–5 mg/min	1–5 min	5–15 min	

IV, intravenous; PO, oral.

increases in BP with "triple-H" therapy (hypervolemia, hypertension, and hemodilution) is recommended but not proven [26].

Intracerebral Hemorrhage

Similar cautions apply to ICH. BP is often markedly elevated in patients with ICH. With severely elevated BP and neurologic symptoms, the differentiation of structural pathology from hypertensive encephalopathy can be difficult. The American Heart Association and American Stroke Association guidelines for the treatment of ICH acknowledge the lack of randomized trial data to guide therapy, but recommend initiation of therapy for (i) SBP levels greater than 200 mm Hg or MAP greater than 150 mm Hg and (ii) SBP levels greater than 180 mm Hg or MAP greater than 130 mm Hg, with evidence of increased intracerebral pressures to maintain a perfusing pressure of 60 mm Hg or more. In patients with SBP levels greater than 180 mm Hg or MAP greater than 130 mm Hg without any evidence of elevated intracerebral pressures, a target of an MAP of 110 mm Hg or BP of 160/90 mm Hg is likely beneficial [29].

ELEVATED BLOOD PRESSURE WITHOUT HYPERTENSIVE CRISIS

Elevated BP is seen in the ICU without TOD. Patients may require treatment of (a) chronic hypertension; (b) new, transient, and usually mild elevations in BP; or (c) elevated BP in the perioperative setting. The goal of treatment is not based solely on BP readings, but on an appreciation of the acute and chronic care of the patient [5].

Continued Therapy of Chronic Hypertension

Patients in the ICU often have a history of hypertension. BP levels may rise if the patient is unable to continue his or her usual antihypertensive regimen; therefore, alternative agents should be instituted. BP elevation in patients who have recently discontinued chronic therapy can be severe and present as rebound or *discontinuation syndrome*. The likelihood of rebound hypertension is proportional to the prior dose of medication.

TABLE 37.6

NEW ONSET OF HYPERTENSION IN THE INTENSIVE CARE UNIT

- Situational
  - Pain
  - Anxiety
  - New-onset angina
  - Hypocarbia
  - Hypoxemia
  - Hypothermia with shivering
  - Rigors
  - Volume overload
- Rebound or discontinuation syndrome
- Prior, undiagnosed, untreated hypertension

Hypotension may develop in patients with chronic hypertension who were noncompliant with medication but have all medications given as prescribed on admission. BP may drop and require ICU admission for volume and pressor support. If noncompliance is suspected, it is better to start with lower doses and adjust upward.

New Onset of Hypertension

New and usually temporary increases in BP may occur in the ICU. Many factors may cause short-term elevations in BP (Table 37.6). Low doses of short-acting agents should be used to avoid sharp drops in BP in this usually self-limited situation. Undiagnosed essential or secondary hypertension should be considered especially if evidence of TOD is present.

Perioperative Hypertension

Uncontrolled BP can induce new TOD, can increase the risk of vascular suture breakdown or bleeding, and may worsen overall prognosis.

Preoperative Evaluation

Moderate chronic hypertension is not a major risk factor for surgery in otherwise stable patients, but it is a marker for potential coronary artery disease (CAD) [30]. Routine BP therapy should be continued as usual up to the morning of surgery and resumed either orally or intravenously as soon as possible postoperatively. Surgery should probably be delayed if BP is greater than 180/110 mm Hg in patient with CAD [31].

Perioperative Hypertension

A useful classification of hypertension associated with cardiovascular surgery considers the clinical situation and time of onset [32] (Table 37.7). Acute postoperative hypertension usually starts 2 to 6 hours after surgery and may persist for 24 to 48 hours. The immediate postoperative period (up to 2 hours) represents a time of significant patient instability, and BPs can vary widely mediated by increased catecholamines [33]. The goal is to avoid overshoot hypotension or TOD. Intravenous infusions or minibolus therapy allows the most controlled approach to BP regulation [34]. Nitroprusside or labetalol is effective in most situations; nitroglycerin is also beneficial [31].

TABLE 37.7

HYPERTENSION WITH CARDIOVASCULAR SURGERY

- Preoperative period
  - Anxiety
  - Pain
  - Angina
  - Discontinuation of antihypertensive or cardiac therapy
  - Rebound hypertension
- Intraoperative period
  - Induction of anesthesia
    - Drug effects—vasodilation, inotropic changes
    - Manipulation of viscera or trachea, urethra, and rectum
    - Sternotomy, chest retraction
  - With initiation of cardiopulmonary bypass
- Postoperative period
  - Early (0–2 h)
    - Hypoxemia, hypercarbia, hypothermia with shivering, postanesthetic excitement or pain
    - After myocardial revascularization, valve replacement, repair of aortic coarctation
- Intermediate (12–36 h)
  - As given previously
  - Fluid overload, mobilization
  - Reaction to endotracheal, nasogastric, chest, or bladder tube

PHARMACOLOGIC AGENTS

The choice between parenteral and oral therapy rests on the answers to several questions (Table 37.3). In a true hypertensive emergency, parenteral therapy with arterial BP monitoring offers a more controlled onset and offset of effect (Table 37.5).

The following are summary statements of available agents and are not meant to be inclusive. Additional information on the pharmacology of available agents can be found elsewhere [6,16,18,21,23,35–37].

Direct Vasodilators

Sodium Nitroprusside

Sodium nitroprusside has the longest track record for the treatment of severe hypertension. It dilates both arterioles and venules, reduces afterload and preload, and lowers myocardial oxygen demand. Its effects are mediated by intracellular cyclic guanosine monophosphate and nitric oxide in an endothelial-independent mechanism shared with other nitrosovasodilators. Nitroprusside has rapid onset and offset of action. Drug resistance is rarely observed. Nitroprusside is rapidly decomposed nonenzymatically in the blood to cyanide, which is then converted into thiocyanate in the liver. At high doses, acute toxicity occurs with cyanide accumulation (Table 37.8). The metabolite thiocyanate can accumulate with acute or chronic kidney injury, and thiocyanate levels should be monitored. Thiocyanate is removed with dialysis. Nitroprusside is light sensitive and must be wrapped in aluminum foil.

Nitroglycerin

Nitroglycerin preferentially dilates the venous system via cyclic guanosine monophosphate. Left ventricular diastolic pressure is reduced without any significant change in stroke volume or

TABLE 37.8

COMPLICATIONS OF TREATING HYPERTENSION

Complication	Causes
Overshoot hypotension	Infusion rate too rapid Prolonged duration of effect Additive drug effects New cardiac disease Volume depletion
Worsening neurologic status	Cerebral ischemia secondary to low blood pressure Hypertensive encephalopathy Increased intracranial pressure Medication side effect Thiocyanate toxicity Metabolic abnormality
Worsening of hypertension	Volume overload Pseudotolerance Unsuspected secondary hypertension Poor medical regimen Poor compliance
Metabolic acidosis	Cyanide toxicity Tissue hypoperfusion secondary
Worsening renal function	Hypoperfusion Volume depletion Acute tubular necrosis

CO, but MAP usually falls modestly. Nitroglycerin increases flow via collateral coronary blood vessels and can improve epicardial coronary blood flow. Nitroglycerin is useful after coronary bypass grafting, in coronary ischemia, and in heart failure. Nitroglycerin should be avoided in patients who have increased intracranial pressure, aortic stenosis, or hypertrophic obstructive cardiomyopathy.

Hydralazine

Parenteral hydralazine was removed from the market in 1993 and returned in 1994. It is a direct arterial vasodilator that increases CO and heart rate. Metabolism is by hepatic acetylation, the speed of which is genetically determined (slow vs. rapid acetylators). Excretion is renal. It is effective for eclampsia or left ventricular failure. Salt and water retention occur, requiring diuretics and beta-blockers in many cases. It is contraindicated with aortic dissection.

Beta-Blockers

Several beta-blockers, such as propranolol (nonselective), metoprolol (selective), and short-acting esmolol (selective), can be given parenterally. Labetalol is the beta-blocker most commonly used in the ICU.

Labetalol is a racemic mixture of a nonselective beta-blocker and a selective α_1-antagonist, and may be administered as minibolus or infusion, allowing titration of effect, rapid onset, and offset of action with prompt reduction in SVR and BP. The beta-blocker component prevents reflex tachycardia or significant changes in CO. Myocardial oxygen consumption is reduced, and coronary hemodynamics are improved in patients with CAD. Labetalol does not significantly affect cerebral blood flow. There is no dosage adjustment with renal failure, but some adjustment may be needed with severe hepatic disease.

Labetalol is a recommended agent with ischemic CVA or aortic dissection and hypertension [19,24]. It has been used with pheochromocytoma crisis because of its α_1-blocker properties and in aortic dissection because of its beta-blocker properties. The alpha-blocker effects of this agent can cause orthostatic hypotension. The ratio of beta-blockade to alpha-blockade is approximately 7 to 1. Any contraindication to beta-blockers applies to labetalol.

Calcium Antagonists

CCBs, particularly dihydropyridines, are widely used in the ICU. Calcium antagonists have been used for hypertensive urgencies and emergencies and are given via the parenteral or enteral routes.

Dihydropyridines

Nifedipine. It is administered orally, decreases peripheral vascular resistance, and increases collateral coronary blood flow. These effects result in decreased myocardial oxygen consumption, despite a tendency to reflex tachycardia and increased CO and stroke volume (in patients with preserved left ventricle function). Sublingual nifedipine should be abandoned because of safety concerns. The absorption is erratic; serious side effects from prolonged hypotension have been described, and the target BP is difficult to predict. Serious complications have included myocardial infarction or ischemia, worsening renal function, and cerebral ischemia [38].

Nicardipine. It is a rapid-acting systemic and coronary artery vasodilator. It has minimal effects on cardiac conduction and contractile function. Its advantages include potency, rapid onset, and ability to titrate in response to BP changes [39]. Disadvantages include tachycardia, hypotension, nausea, and vomiting. There is minimal cardiac depression, and continuous administration requires continuous monitoring.

Nimodipine. It crosses the blood–brain barrier and has recently been recommended for neurological emergencies [24,29]. A recent review of its use in SAH showed a statistically significant benefit on risk for severe disability, vegetative state, or death, but its putative effect on preventing vasospasm is less clear [28].

Clevidipine. It is a parenteral, short-acting calcium antagonist with a rapid onset that is a potent arterial dilator with little effect on venous capacitance or myocardial contraction. It may also prevent sequelae of ischemic damage through antioxidative properties [40].

Nondihydropyridines (Rate-Slowing Calcium Channel Blockers)

Verapamil. It is a phenylalkylamine CCB, which slows atrioventricular conduction and has a pronounced negative inotropic effect, with a rapid onset of action and a relatively low incidence of serious side effects. Verapamil can be given as repeated small boluses or a continuous intravenous infusion. The disadvantages include induction of various degrees of heart block and worsening heart failure because of its negative inotropic effects.

Diltiazem. It is a benzothiazepine calcium antagonist available as an intravenous preparation. It has effects intermediate between verapamil and dihydropyridines. It is widely used to slow

the ventricular response to atrial fibrillation but not as a primary antihypertensive agent.

Angiotensin Converting Enzyme Inhibitors

Captopril

Captopril was the first ACE inhibitor available in the United States. It is rapidly absorbed, with peak blood levels reached 30 minutes after oral administration. Unlike some ACE inhibitors, captopril is not ingested as a prodrug and is therefore active as soon as it is absorbed. It is particularly effective in patients with heart failure or recent myocardial infarction with depressed ejection fraction. There is a risk of acute hypotension or worsening renal function in patients who are volume depleted, have bilateral high-grade renal artery stenoses, or high-grade stenosis in a solitary functioning kidney. Other acute side effects include bronchospasm, hyperkalemia, cough, angioedema, rash, and dysgeusia. It can accumulate with renal failure.

Enalaprilat

Enalaprilat is the only ACE inhibitor that can be administered parenterally. It is the active form of the oral agent, enalapril. A limited-dose titration response restricts the use of enalaprilat to lesser elevations in BP. Intravenous ACE inhibitor therapy is contraindicated in acute heart failure or acute myocardial infarction complicated by left ventricular dysfunction.

α-Agonists

Clonidine

Clonidine is a central α_2-agonist that decreases peripheral vascular resistance, venous return, and heart rate, and can contribute to reduction in CO. Clonidine is available orally and as a transdermal patch with an effectiveness of approximately 1 week. The patch should not be used to initiate therapy in the ICU, because it takes several days to achieve a steady state. However, patients previously on clonidine who are unable to take oral medications may be converted to a patch. Clonidine has been administered in an oral titration regimen to achieve gradual BP control in a period of 2 to 3 hours. Major disadvantages are sedation, dry mouth, and orthostatic hypotension. Caution should be used in patients requiring monitoring of mental status. Rebound hypertension may be observed if it is abruptly discontinued, particularly at higher doses.

α-Adrenergic Inhibitors

Phentolamine

Several α-adrenergic inhibitors are available for oral administration. The only available intravenous agent with α-adrenergic blocking properties is phentolamine, a nonselective α-receptor blocking agent. Its use is reserved for states associated with excess catecholamine levels, such as pheochromocytoma, rebound hypertension, or drug ingestion. The hypotensive effect of a single intravenous bolus lasts less than 15 minutes and is associated with significant reflex tachycardia. The advantage of phentolamine is its specific effect with pheochromocytoma. It is part of the anesthetic regimen in perioperative control of these patients. Disadvantages include abdominal cramping and pain, vomiting, diarrhea, tachycardia, dizziness, and arrhythmias.

TABLE 37.9

SUMMARY OF RECOMMENDATIONS BASED ON RANDOMIZED CONTROLLED TRIALS

- The best choice of antihypertensive agent in hypertensive urgency remains unclear [17]
- The best choice of antihypertensive agent in a hypertensive emergency remains unclear [17]
- There are no randomized trials comparing different treatment goals in hypertensive emergencies, but it is recommended that blood pressure not be lowered by more than 25% within the first hour and then to 160/100–110 mm Hg within the next 2–6 h [6]
- There is not enough evidence to evaluate the effect of altering blood pressure during acute stroke, though it is recommended to treat extremely elevated systolic (>220 mm Hg) or diastolic blood pressures (>120 mm Hg) [24]
- There is not enough evidence to recommend specific blood pressure management in acute intracerebral hemorrhage though it is recommended to treat extremely elevated systolic (>200 mm Hg) or diastolic blood pressures (>150 mm Hg) [29]

Fenoldopam

Fenoldopam is a specific dopamine I receptor agonist that is free of α- and β-adrenergic receptor effects. It reduces SVR, increases renal blood flow, increases fractional excretion of sodium, and increases water clearance. It is metabolized in the liver to multiple metabolites with uncertain clinical activity and may be particularly effective with impaired renal function, although a recent randomized controlled trial showed no difference compared to dopamine in renal protection [41].

Disadvantages are related to vasodilation, including flushing, headache, hypotension, nausea, and occasional ECG changes.

Diuretics

Many patients are actually hypovolemic from pressure natriuresis [5]. Patients with postoperative hypertension, cardiac dysfunction, or evidence of pulmonary edema may require diuresis. Many parenteral antihypertensive agents can cause fluid retention. Loop diuretics can help control intravascular volume, maintain urine output, and prevent resistance to antihypertensive therapy. They are given as a bolus or a slow infusion and have a threshold effect. Response—increased diuresis and natriuresis—is not seen unless sufficient drug reaches the renal tubules. Doses are titrated until increased urine output is seen or maximum doses are reached when other therapy must be initiated.

CONCLUSIONS

Advances in evaluation and management of hypertension in the ICU, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 37.9. Given the scarcity of data to support one particular hypertensive agent above another, the choice and goals of therapy are largely based on consensus recommendations and should be guided by the suspected etiology of the hypertension, the extent of TOD, and the individual hemodynamic profile of the patient.

CHAPTER 38 ■ UNSTABLE ANGINA/ NON–ST-SEGMENT ELEVATION MYOCARDIAL INFARCTION

SUZANNE J. BARON, CHRISTOPHER P. CANNON AND MARC S. SABATINE

The spectrum of acute coronary syndromes (ACS) ranges from unstable angina (UA) to non–ST-segment elevation myocardial infarction (NSTEMI) to ST-segment elevation myocardial infarction (STEMI) [1]. The latter condition is usually caused by acute total obstruction of a coronary artery [2,3], and urgent reperfusion is the mainstay of therapy. In contrast, the non–ST-segment elevation acute coronary syndromes (NSTEACS)—UA and NSTEMI—are usually associated with a severe, although nonocclusive, lesion in the culprit coronary artery [4].

Every year in the United States, approximately 1.3 million patients are admitted to the hospital with ACS; about 900,000 of these patients are suffering from UA/NSTEMI as compared with approximately 400,000 patients suffering from STEMI [5,6]. Worldwide, these numbers are each several times the totals in the United States. In the past few years, numerous advances have been made in the understanding of the pathophysiology, diagnosis, risk stratification, and management of UA/NSTEMI.

DEFINITION

The definition of UA is largely based on the clinical presentation. Angina pectoris is characterized by a poorly localized chest or arm discomfort or pressure (rarely described by patients as "pain") that is typically and reproducibly associated with physical exertion or emotional stress, and relieved by rest or sublingual nitroglycerin. UA is defined as angina pectoris (or equivalent type of ischemic discomfort) with one of three features: (a) occurring at rest (or with minimal exertion), usually lasting more than 20 minutes; (b) being severe and of new onset (i.e., within 1 month); or (c) occurring with a crescendo pattern (i.e., more severe, prolonged, or frequent) [7]. Some patients with this pattern of ischemic pain develop evidence of myocardial necrosis on the basis of serum biomarkers in the absence of ST-segment elevations on electrocardiogram (ECG) and thus have a diagnosis of NSTEMI. Previously, this diagnosis has been based on elevation of the creatine kinase (CK)-MB, but elevations in cardiac troponin T or I greater than the 99th percentile of the upper limit of normal now define MI on the basis of their higher sensitivity and specificity for myocardial necrosis and powerful prognostic capability [8].

PATHOPHYSIOLOGY

The development of UA/NSTEMI is due either to a reduction in the supply of blood flow and oxygen, or to an increase in myocardial oxygen demand, or both. The five broad etiologies are (a) plaque rupture with superimposed nonocclusive thrombus; (b) dynamic obstruction (i.e., coronary spasm); (c) progressive mechanical obstruction (i.e., restenosis); (d) inflammation and arteritis; and (e) conditions leading to increased myocardial oxygen demand, such as anemia, sepsis, or hypoxia [9]. Individual patients may have several of these processes contribute to the onset of their UA/NSTEMI.

Plaque Rupture

Atherosclerosis is a silent process that usually begins 20 to 30 years prior to a patient's clinical presentation [10,11]. Plaque rupture can be precipitated by multiple factors, including endothelial dysfunction [12], plaque lipid content [13], local inflammation [14], coronary artery tone at the site of irregular plaques and local shear stress forces, platelet function [15,16], and the status of the coagulation system (i.e., a potentially prothrombotic state) [17,18]. These processes culminate in formation of platelet-rich thrombi at the site of the plaque rupture or erosion and the resultant ACS [19–21].

Thrombosis

Coronary artery thrombosis plays a central role in the pathogenesis of UA/NSTEMI [4,19,20,22–26], as demonstrated in the Thrombolysis in Myocardial Infarction (TIMI) IIIA trial, in which 35% of patients had definite thrombus and an additional 40% had possible thrombus [4]. Thrombosis occurs in two interrelated stages: (a) primary hemostasis and (b) secondary hemostasis [27,28]. The first stage of hemostasis is initiated by platelets as they adhere to damaged vessels and form a platelet plug. With rupture or ulceration of an atherosclerotic plaque, the subendothelial matrix (e.g., collagen and tissue factor) is exposed to the circulating blood. Platelets then adhere to the subendothelial matrix via the glycoprotein (GP) Ib receptor and von Willebrand's factor (*platelet adhesion*). After adhering to the subendothelial matrix, the platelet undergoes a conformational change from a smooth discoid shape to a spiculated form, which increases the surface area on which thrombin generation can occur. This leads to degranulation of the alpha- and dense granules and the subsequent release of thromboxane A2, adenosine diphosphate (ADP), serotonin, and other platelet aggregatory and chemoattractant factors, as well as the expression and activation of GP IIb/IIIa receptors on the platelet surface such that it can bind fibrinogen. This process is called *platelet activation*. The final step is *platelet aggregation*, that is, the formation of the platelet plug. Fibrinogen (or von Willebrand's factor) binds to the activated GP IIb/IIIa receptors of two platelets, thereby creating a growing platelet aggregate. Antiplatelet therapy has been directed at decreasing the formation of thromboxane A2 (aspirin), inhibiting the ADP pathway of platelet activation (thienopyridines), and directly inhibiting platelet aggregation (GP IIb/IIIa inhibitors; Fig. 38.1).

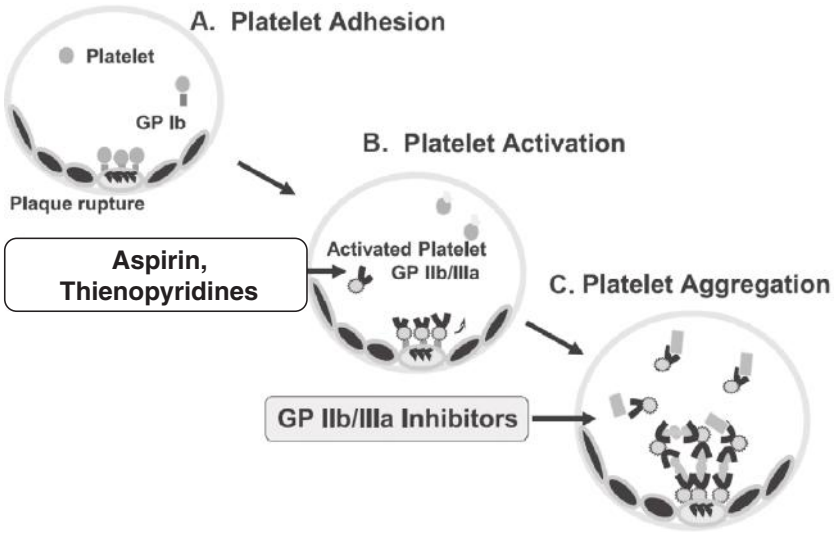

FIGURE 38.1. Primary hemostasis—process of platelet adhesion, activation, and aggregation. Platelets initiate thrombosis at the site of a ruptured plaque: the first step is *platelet adhesion* (**A**) via the glycoprotein (GP) Ib receptor in conjunction with von Willebrand's factor. This is followed by *platelet activation* (**B**), which leads to a shape change in the platelet, degranulation of the alpha and dense granules, and expression of GP IIb/IIIa receptors on the platelet surface with activation of the receptor, such that it can bind fibrinogen. The final step is *platelet aggregation* (**C**), in which fibrinogen (or von Willebrand's factor) binds to the activated GP IIb/IIIa receptors of two platelets. Aspirin (ASA) and clopidogrel act to decrease platelet activation (see text for details), whereas the GP IIb/IIIa inhibitors inhibit the final step of platelet aggregation. [Adapted from Cannon CP, Braunwald E: Unstable angina, in Braunwald E, Zipes DP, Libby P (eds): *Heart Disease: A Textbook of Cardiovascular Medicine*. 6th ed. Philadelphia, WB Saunders, 2001, pp 1232–1263, with permission.]

Secondary Hemostasis

Simultaneous with the formation of the platelet plug, the plasma coagulation system is activated (Fig. 38.2). Following plaque rupture, the injured endothelial cells on the vessel wall become activated and release *protein disulfide isomerase*, which acts to cause a conformational change in circulating tissue factor [29–32]. Tissue factor can then bind to factor VIIa and form a protein complex, leading to the activation of factor X. With the activation of factor X (to factor Xa), thrombin is generated and acts to cleave fibrinogen to form fibrin. Thrombin plays a central role in arterial thrombosis: (a) it converts fibrinogen to fibrin in the final common pathway for clot formation; (b) it is a powerful stimulus for platelet aggregation; and (c) it activates factor XIII, which leads to cross-linking and stabilization of the fibrin clot [27].

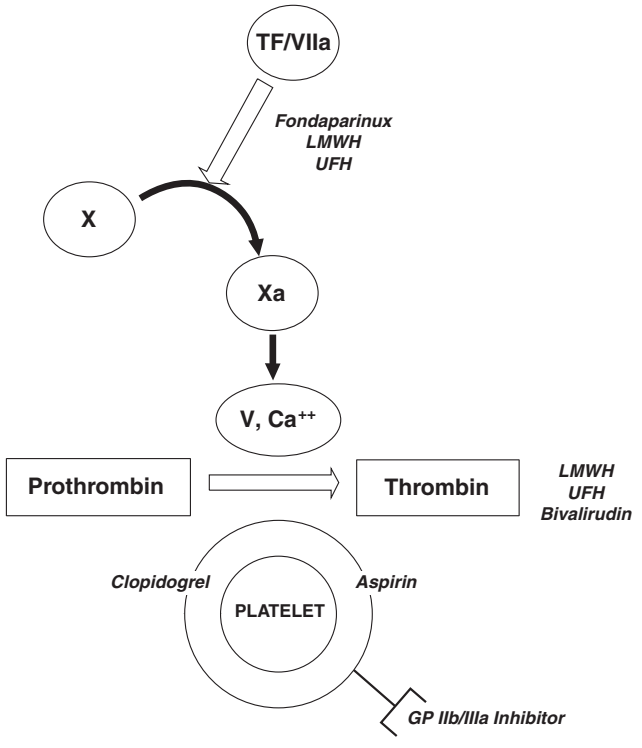

FIGURE 38.2. Diagram of the major components of the clotting cascade and the areas targeted by antithrombotic agents.

Coronary Vasoconstriction

Another etiologic factor in UA/NSTEMI is dynamic obstruction, that is, coronary vasoconstriction. The process is identified in three settings: (a) vasospasm in the absence of obstructive plaque, (b) vasoconstriction in the setting of atherosclerotic plaque, and (c) microcirculatory angina. Vasospasm can occur in patients without coronary atherosclerosis or in those with a nonobstructive atheromatous plaque. Vasospastic angina appears to be due to hypercontractility of vascular smooth muscle and endothelial dysfunction occurring in the region of spasm. Prinzmetal's variant angina, with intense focal spasm of a segment of an epicardial coronary artery, is the prototypic example [33]. Such patients have rest pain accompanied by transient ST-segment elevation. Vasoconstriction more commonly occurs in the setting of significant coronary atherosclerotic plaque, especially those with superimposed thrombus. Vasoconstriction can occur as the result of local vasoconstrictors released from platelets, such as serotonin and thromboxane A2 [34–36]. Vasoconstriction can also result from a dysfunctional coronary endothelium, which has reduced production of nitric oxide and increased release of endothelin. Adrenergic stimuli, cold immersion [37], cocaine [38,39], or mental stress [40] can also cause coronary vasoconstriction in susceptible vessels. A third setting in which vasoconstriction is identified is microcirculatory angina ("syndrome X"). In this condition, ischemia results from constriction of the small intramural coronary resistance vessels [41]. Although no epicardial coronary artery stenoses are present, coronary flow is usually slowed and does not increase appropriately in response to a variety of signals.

Progressive Mechanical Obstruction

Another etiology of UA/NSTEMI results from progressive luminal narrowing. This is most commonly seen in the setting of restenosis following percutaneous coronary intervention (PCI). However, angiographic [42] and atherectomy studies [43,44] have demonstrated that many patients without previous PCI show progressive luminal narrowing of the culprit vessel, likely related to rapid cellular proliferation, in the period preceding the onset of UA/NSTEMI.

TABLE 38.1

BRAUNWALD CLINICAL CLASSIFICATION OF UNSTABLE ANGINA

Class	Definition	Death or myocardial infarction to 1 y[a] (%)
Severity		
Class I	New onset of severe angina or accelerated angina; no rest pain	7.3
Class II	Angina at rest within past month but not within preceding 48 h (angina at rest, subacute)	10.3
Class III	Angina at rest within preceding 48 h (angina at rest, subacute)	10.8[b]
Clinical circumstances		
A (secondary angina)	Develops in the presence of an extracardiac condition that intensifies myocardial ischemia	14.1
B (primary angina)	Develops in the absence of an extracardiac condition	8.5
C (postinfarction angina)	Develops within 2 wk after acute myocardial infarction	18.5[c]
Intensity of treatment	Patients with unstable angina can also be divided into three groups depending on whether unstable angina occurs: (a) in the absence of treatment for chronic stable angina, (b) during treatment for chronic stable angina, or (c) despite maximal anti-ischemic drug therapy. These three groups can be designated subscripts 1, 2, or 3, respectively	—
Electrocardiographic changes	Patients with unstable angina can be further divided into those with or without transient ST-T–wave changes during pain	—

Secondary Unstable Angina

Secondary UA is defined as UA precipitated by conditions extrinsic to the coronary arteries in patients with prior coronary stenosis and chronic stable angina. This change could occur either as a result of an increase in myocardial oxygen demand or as a decrease in coronary blood flow. Conditions that increase myocardial demand include tachycardia (e.g., a supraventricular tachycardia or new-onset atrial fibrillation with rapid ventricular response), fever, thyrotoxicosis, hyperadrenergic states, and elevations of left ventricular (LV) afterload, such as hypertension or aortic stenosis. Secondary UA can also occur as a result of impaired oxygen delivery, as in anemia, hypoxemia (e.g., due to pneumonia or congestive heart failure), hyperviscosity states, or hypotension. Although one might expect secondary angina to be associated with a more favorable prognosis, it appears to have a worse prognosis than primary UA [45] (Table 38.1), likely due to serious patient comorbidities.

CLINICAL PRESENTATION AND DIAGNOSIS

History and Physical Examination

A description of "ischemic pain" is the hallmark of UA/NSTEMI. Ischemic chest pain is usually described as a discomfort or pressure (rarely as a pain) that is brought on by exertion and relieved by rest. It is generally located in the retrosternal region but sometimes in the epigastrium and frequently radiates to the anterior neck, left shoulder, and left arm. The physical examination may be unremarkable or may support the diagnosis of cardiac ischemia [46]. Signs that suggest ischemia are sweatiness, pale cool skin, sinus tachycardia, a fourth heart sound, and basilar rales on lung examination.

Electrocardiogram

The ECG is the most widely used tool in the evaluation of ischemic heart disease. In UA/NSTEMI, ST-segment depression (or transient ST-segment elevation) and T-wave changes occur in up to 50% of patients [47–49]. Two analyses have shown ST-segment deviation even of only 0.5 mm to be a specific and important measure of ischemia and prognosis (see later in the chapter) [47,50]. T-wave changes are generally considered less specific than ST-segment changes and the presence of T-wave inversions of only 1 mm in patients with acute ischemic syndromes may add little to the clinical history. T-wave inversions of greater than or equal to 3 mm are considered significant [47,50].

Cardiac Biomarkers

UA is not associated with any detectable damage to the myocyte. The diagnosis of NSTEMI is made if there is biochemical evidence of myocardial necrosis, that is, a positive cardiac troponin T or I or CK-MB. The cut point for definition of an MI is elevation in troponin T or I greater than the 99th percentile of the upper reference range [8]. Although false-positive troponin elevations do occur [51], elevations in cardiac biomarkers in the absence of other clinical data consistent with an ACS usually do represent true myocardial damage. In these cases, myocyte damage is due to etiologies besides atherosclerotic coronary artery disease, such as myocarditis, LV strain from congestive heart failure, hypertensive crisis, or right ventricular strain from pulmonary embolus [52].

Unfortunately, the limitation of standard troponin assays is that they tend to have a low sensitivity in the first few hours of symptom onset and become positive only usually 6 to 12 hours after symptom onset. However, the recent development of high-sensitivity troponin assays has significantly

improved the sensitivity of this test. Two recent studies have found that the use of high-sensitivity assays improve the early diagnosis of MI with sensitivity now exceeding 90% when tested in patients with chest pain at the time of presentation to the hospital [53,54]. Moreover, high-sensitivity assays can detect elevated levels of troponin in approximately 10% of outpatients with stable coronary disease, and these individuals are at a higher risk of subsequent cardiovascular death [55].

Ultrasensitive troponin assays, which have limits of detection lesser than the levels seen in a normal reference population, are also being developed. In a study looking at patients with NSTEACS, 72% of patients with NSTEMI were found to have circulating troponin levels at baseline greater than the 99th percentile (nano-cTnI >0.003 μg/L) when ultrasensitive troponin assays were utilized; yet all of these patients had an initially negative current-generation troponin assay. When these assays were used in patients presenting with UA (defined as lack of elevation of troponin using a current-generation commercial assay), 44% of patients had circulating troponin levels greater than the 99th percentile and 8 hours later, the percentage had risen to 82% [56]. Similarly, ultrasensitive assays have been used to detect rises in circulating troponin in proportion to the amount of ischemia experienced during exercise stress testing [57]. Thus, in the future, troponin may move from a semiquantitative assay ("negative" in most individuals and quantified in a subset) to quantifiable in all patients. The clinical implications of very low level values reported from ultrasensitive assays will need to be defined.

Cardiac Imaging

Currently, cardiac imaging is assuming increasing importance in the early diagnosis of patients presenting with suspected UA/NSTEMI, especially when the ECG is normal, nonspecific, or obscured by left bundle branch block or a paced rhythm. Myocardial perfusion imaging using technetium sestamibi has been useful for patients presenting with chest pain in the emergency department without a diagnostic ECG or positive biomarkers to discriminate patients with coronary artery disease from those with noncardiac chest pain [58,59]. Similarly, echocardiography is useful to screen for regional or global LV dysfunction, which may help in establishing (or excluding) the diagnosis of ischemic heart disease in patients who present to the emergency department with chest pain [60]. Coronary computed tomography angiogram (CTA) has also been shown to be effective in excluding coronary artery disease in patients presenting to the emergency department with a low-risk story of chest pain, nondiagnostic ECG, and negative biomarkers [61]. All of these modalities can also assess LV function, a powerful determinant of subsequent prognosis after MI (and presumably after UA) [62–64]. Coronary angiography is also used to establish the diagnosis of ACS and is considered the gold-standard modality to define the extent of coronary disease, and as a prelude to percutaneous revascularization (see later in the chapter) [4,48,65,66].

RISK STRATIFICATION

Given the multitude of treatment options for patients with UA/NSTEMI, risk stratification currently refers to two simultaneous processes (frequently carried out at the time of hospital presentation): (a) risk assessment (i.e., prediction of mortality/morbidity risk), and (b) selection of a management strategy (i.e., an early invasive vs. early conservative approach).

Risk assessment, using clinical and laboratory markers, identifies which patients are at highest risk for adverse outcomes. Moreover, data from several trials have demonstrated that early risk assessment (especially using troponins) has also been useful in predicting which patients will derive the greatest benefit from newer and more potent antithrombotic therapies, such as low-molecular-weight heparin (LMWH) and GP IIb/IIIa inhibitors. Risk assessment can similarly be used to determine the most appropriate level of care and monitoring (i.e., between the coronary intensive care unit or the step-down/telemetry unit). The "management strategy" refers to whether early angiography is performed with revascularization as appropriate directly following the index event or whether a conservative or ischemia-driven strategy is carried out, with noninvasive assessment of residual ischemia, and angiography and revascularization performed only if recurrent ischemia is documented (see later in the chapter).

Risk Assessment Using Clinical Predictors

The initial clinical evaluation can be used to risk-stratify patients quickly and assist in the triage [67,68]. As described in the ACC/AHA UA/NSTEMI guideline (Table 38.2), high-risk patients can be identified by the presence of prolonged, ongoing pain at rest, ST-segment depression of greater than or equal to 0.1 mV, positive troponin value, or the presence of hypotension or congestive heart failure on physical examination [67]. Such patients should be considered for the coronary care unit although the cardiac step-down (telemetry) unit may be adequate depending on the clinical situation. Lower risk patients can be adequately monitored and managed in a step-down unit.

Individual High-Risk Subgroups

Trials have identified several clinical subgroups that are at higher risk of adverse outcomes when they present with UA/NSTEMI. These groups derive greater benefit from more aggressive therapy.

Elderly Patients

Elderly patients comprise a subgroup for which outcomes are always worse compared with younger patients. In UA/NSTEMI, elderly patients appear to derive greater benefit from the newer, more potent antithrombotic therapies. In the Efficacy and Safety of Subcutaneous Enoxaparin in Non-Q-Wave Coronary Events (ESSENCE) trial, enoxaparin had greater benefit in patients 65 years or older as compared with younger patients [69]; a similar finding was noted in the TIMI 11B trial [70]. For the GP IIb/IIIa inhibitors, an equivalent relative benefit was observed in older versus younger patients, although the absolute benefit in number of events prevented is higher in elderly patients because they have higher baseline risk [49,71,72]. However, this increase in absolute benefit comes with the added price of an increased incidence of bleeding with GP IIb/IIIa inhibitors in elderly patients [71,72]. With regard to an invasive versus conservative management strategy, patients 65 years or older have better outcomes at 1 year when managed with an invasive strategy (12.5% vs. 19.5%; $p = 0.03$; age interaction $p = 0.04$) [73]. Similarly, in Fragmin and Fast Revascularization during Instability in Coronary Artery Disease (FRISC) II, and Treat Angina with Aggrastat and Determine Cost of Therapy with an Invasive or Conservative Strategy (TACTICS)-TIMI 18, there was a greater absolute benefit of an early invasive strategy in patients 65 years and older [74,75]. Thus, in UA/NSTEMI, elderly patients are at higher risk and derive particular benefit from more aggressive antithrombotic and interventional therapy.

TABLE 38.2

CLINICAL FEATURES ASSOCIATED WITH HIGHER LIKELIHOOD OF CORONARY ARTERY DISEASE AMONG PATIENTS PRESENTING WITH SYMPTOMS SUGGESTIVE OF UNSTABLE ANGINA

Feature	High likelihood (any below)	Intermediate likelihood (no high-likelihood features, but any below)	Low likelihood (no high- or intermediate-likelihood features, but may have any below)
History	History of crescendo symptoms in prior 48 h	Prior history of CAD, PAD, or CVA Prior aspirin use	
Character of pain	Ischemic chest pain that is prolonged (>20 min), ongoing, and occurring at rest	Ischemic, prolonged chest pain that is now resolved Nocturnal angina	Atypical chest pain not consistent with cardiac chest pain
Examination	Age >75 y Signs of CHF (pulmonary edema on CXR; rales and/or S3 on examination) Hypotension New or worsening MR murmur	Age >70 y	
ECG	Angina at rest with transient ST-segment changes >0.5 mm Sustained VT	T-wave changes Pathological Q-waves Resting ST-segment depressions <1 mm	Normal ECG
Cardiac markers	Positive	Normal	Normal

CAD, coronary artery disease; CHF, congestive heart failure; CVA, cardiovascular accident; CXR, chest X-ray; DM, diabetes mellitus; ECG, electrocardiogram; MR, mitral regurgitation; PAD, peripheral arterial disease; VT, ventricular tachycardia.
Adapted from Anderson JL, Adams CD, Antman EM, et al: ACC/AHA 2007 guidelines for the management of patients with unstable angina/non-ST-segment elevation myocardial infarction-2002: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for Management of Patients With Unstable Angina/Non-ST-Segment Elevation Myocardial Infarction). *Circulation* 116:803–877, 2007.

Gender Differences

A patient's gender may factor into the decision regarding which treatment strategy to pursue in patients presenting with UA/NSTEMI. Subgroup analyses from some trials, including FRISC II [76], Randomized Intervention Treatment of Angina (RITA) 3 [77], and Organization to Assess Strategies for Ischemic Syndromes (OASIS) 5 [78], suggested that an early invasive strategy may be associated with a higher risk of death or MI in women, whereas other studies demonstrated that an early invasive strategy resulted in improved outcomes in women as well as men [79]. Because subgroup analyses may be insufficiently powered to address this question, a meta-analysis was performed using the data of eight large-scale trials. This meta-analysis demonstrated that high-risk women (classified as patients with positive biomarkers on presentation) had a 33% lower odds of death, MI or rehospitalization with ACS (OR 0.67) with an invasive strategy, whereas low-risk women (patients with normal biomarkers on presentation) did not have a significant benefit with invasive treatment [80]. These findings are reflected in the 2007 AHA/ACC guidelines for the management of patients with UA/NSTEMI, which recommend that women with high-risk features be considered for invasive treatment, whereas women with low-risk features be treated conservatively [67].

Patients with Diabetes

Patients with diabetes have long been known to be at higher risk than those without diabetes for adverse outcomes with ACS. In a large-scale meta-analysis, patients with diabetes were found to have a significantly higher mortality at 30 days (2.1% vs. 1.1%; $p < 0.001$). Furthermore, having diabetes at presentation with an NSTEMI was associated with a higher mortality at 1 year as well (hazard ratio [HR] 1.65; 95% confidence interval [CI] 1.3 to 2.1) [81].

Given the high risk of adverse cardiovascular outcomes associated with diabetes, researchers have looked to see if certain treatment strategies may be of more benefit in this particular subgroup. The relative benefit of early GP IIb/IIIa inhibition has been found to be significantly higher in patients with diabetes, with a 70% relative reduction in events ($p = 0.002$) [82], as compared with a 30% reduction in the overall population. More recently, a meta-analysis of all placebo-controlled, IIb/IIIa inhibitor trials found a mortality benefit of early IIb/IIIa inhibition in patients with diabetes, with no mortality difference in those without nondiabetes [83]. For an invasive versus conservative strategy, the relative benefit in patients with diabetes of an early invasive strategy was similar to that of those without diabetes, but the absolute benefit was higher among those with diabetes [84]. Similarly in the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel - Thrombolysis in Myocardial Infarction (TRITON-TIMI) 38 trial, patients with diabetes had a 40% reduction in MI (8.2% vs. 13.2%; $p < 0.001$) with the use of more intensive antiplatelet therapy with prasugrel when compared to clopidogrel. Those without diabetes saw only an 18% reduction in MI with prasugrel (7.2% vs. 8.7%; $p = 0.009$) [85]. Thus, patients with diabetes represent a high-risk group that deserves aggressive pharmacologic and revascularization treatments.

Risk Assessment by Electrocardiography

The admission ECG is very useful in predicting long-term adverse outcomes. In the TIMI III registry of patients with

UA/NSTEMI, multivariable predictors of 1-year death or MI included left bundle branch block and ST-segment deviation of 0.5 mm or greater [47]. The presence of only 0.5-mm ST-segment depression on the admission ECG has also been found to be an independent determinant of 4-year survival [50]. In contrast, the presence of T-wave changes was associated with only a modest [50] or no increase in subsequent death or MI risk compared with no ECG changes [47]. Similar findings were observed in predicting 30-day and 6-month outcomes in the Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) IIb study, with the presence of ST-segment deviation of greater than 0.5 mm conferring a higher mortality than T-wave changes [86].

With regard to relative treatment benefit of particular therapies, in the ESSENCE trial, patients with ST-segment deviation treated with enoxaparin had a significant reduction in cardiac events compared with patients treated with unfractionated heparin (UFH; odds ratio [OR] 0:60; $p < 0.01$), whereas those without ST-segment deviation did not [87]. Similar findings were observed in the TIMI 11B trial [70]. In both the FRISC II and TACTICS-TIMI 18 trials, an invasive strategy had a particular benefit in patients with ST-segment depression at presentation [84,88]. Thus, not only ST-segment deviation is a marker of increased risk of adverse outcomes, but it also indicates those patients who may derive greater benefit from aggressive antithrombotic and interventional therapy.

Risk Assessment by Cardiac Markers

Creatine Kinase-MB and the Troponins

Patients with NSTEMI have a worse long-term prognosis than those with UA [73,89]. It has now been shown that patients with elevated troponins, even if their CK-MB is normal, also have a significantly worse prognosis, with a higher risk of subsequent cardiac complications, including mortality [90–92]. Beyond just a positive versus negative test result, there is a linear relationship between the level of troponin T or I in the blood and subsequent risk of death: the higher the troponin, the higher the mortality risk (Fig. 38.3). Furthermore, elevated markers (both troponin T and CK-MB) have been shown to correlate with a higher rate of thrombus at angiography [4,93–96]. Thus, cardiac biomarkers are very useful not only in diagnosing infarction [97] but also in assessing risk for patients who present with acute UA/NSTEMI.

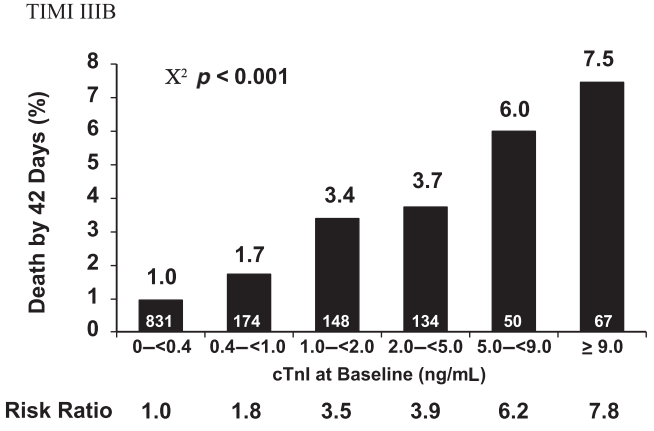

FIGURE 38.3. TIMI IIIB: a direct relationship was observed between increasing levels of troponin I and a higher 42-day mortality. cTnI, cardiac specific troponin I; Ng, negative. [Adapted from Antman EM, Tanasijevic MJ, Thompson B, et al: Cardiac-specific troponin I levels to predict the risk of mortality in patients with acute coronary syndromes. *N Engl J Med* 335:1342–1349, 1996, with permission.]

The presence of elevated biomarkers also correlates with the utility of particular therapies. In a trial examining the benefit of abciximab in patients with NSTEMI, the reduction in death or MI at 6 months was 70% in those who were troponin T positive, whereas there was no significant benefit for those who were troponin T negative ($p < 0.001$) [98] (Fig. 38.4, *left*). These findings have been duplicated with tirofiban versus heparin in the Platelet Receptor Inhibition for Ischemic Syndrome Management (PRISM) (Fig. 38.4, *right*) and PRISM in Patients Limited by Unstable Signs and Symptoms (PRISM-PLUS) trials [99,100] and more recently in the Intracoronary Stenting and Antithrombotic Regimen-Rapid Early Action for Coronary Treatment 2 (ISAR-REACT 2) trials [96]. In the TIMI 11B trial, even when looking at patients who were CK-MB negative, those who were troponin I positive derived a significantly greater benefit from the enoxaparin versus UFH, compared with those who had both markers negative [101]. Research has also demonstrated that biomarkers are useful when choosing an invasive versus conservative strategy in patients with UA/NSTEMI. In both the FRISC II and TACTICS-TIMI 18 trials, patients who had a positive troponin T or I (including those who had very low levels of troponin) had a dramatic reduction in cardiac events after allocation to an invasive strategy [91,102]. Thus, there is now evidence from multiple trials that the use of troponins can assist in both assessing the risk and determining which patients should be treated with newer antithrombotic agents and an invasive management strategy.

Other Biomarkers

Patients with an elevated C-reactive protein (CRP) have an increased risk of death and adverse cardiovascular events [103,104]. Even among patients with negative troponin I at baseline, CRP is able to discriminate high- and low-risk groups [105]. Recently, CRP levels have been shown to significantly add to low-density lipoprotein (LDL) levels in predicting recurrent adverse cardiovascular events in patients' post-ACS [106]. B-type natriuretic peptide (BNP) as well as N-terminal probrain natriuretic peptide (NT-proBNP), both biomarkers of LV wall stress, have also been shown to be a powerful predictor of mortality and heart failure in patients with NSTEMIs [107–110]. More recently, studies involving growth-differentiation factor 15 (GDF-15), a molecule that is induced by inflammation and cellular injury, have shown this molecule to be a similarly powerful predictor of adverse cardiovascular outcomes after NSTEMI [111]. Researchers have even suggested that GDF-15 may be able to direct treatment strategies after NSTEMI. A retrospective study looking at GDF-15 levels in patients with NSTEMI found that patients with markedly elevated GDF-15 levels had lower mortality when an invasive treatment strategy was used as opposed to conservative management [112]. Larger prospective studies are needed to see if GDF-15 will be a useful tool when deciding on the management of patients with NSTEMI. Multimarker strategies have also been employed to improve risk stratification. When using CRP and troponin T together, mortality is 0.4% for patients with both markers negative, 4.7% if either CRP or troponins are positive, and 9.1% if both are positive [105]. Similarly, the combination of troponin, CRP, and BNP can predict up to a 13-fold gradient in mortality post-ACS [113]. It should be noted that although CRP and BNP can be used as prognostic indicators, only troponin and potentially GDF-15 can identify patients who may derive greater benefit from specific interventions.

Combined Risk Assessment Scores

The TIMI risk score uses clinical factors, the ECG, and cardiac markers. It was developed using multivariate analysis, which identified seven risk factors: age 65 years or older, more than

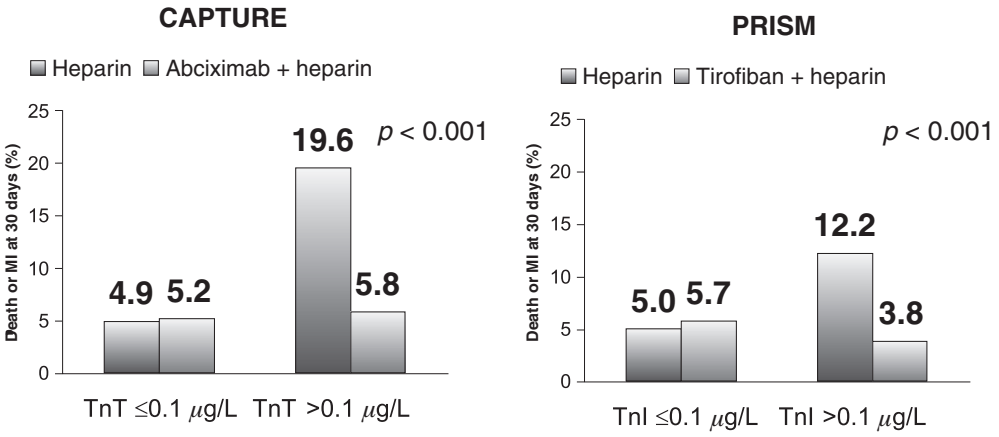

FIGURE 38.4. Use of troponin to determine benefit of GP IIb/IIIa inhibition. Benefit of abciximab in the CAPTURE trial of patients with refractory unstable angina treated with angioplasty in those with positive versus negative troponin T at study entry (*left panel*). Greater benefit of tirofiban versus heparin in patients with UA/NSTEMI was also seen in patients with positive troponin I values in the PRISM trial, with a nearly 70% reduction in death or MI at 30 days with the IIb/IIIa inhibitor (*right panel*). [Data from Hamm CW, Heeschen C, Goldmann B, et al: Benefit of abciximab in patients with refractory unstable angina in relation to serum troponin T levels. *N Engl J Med* 340(21):1623–1629, 1999; and Heeschen C, Hamm CW, Goldmann B, et al: Troponin concentrations for stratification of patients with acute coronary syndromes in relation to therapeutic efficacy of tirofiban. *Lancet* 354(9192):1757–1762, 1999, with permission.]

three risk factors for coronary artery disease, documented coronary artery disease at catheterization, ST-segment deviation of 0.5 mm or greater, more than two episodes of angina in the past 24 hours, aspirin use within prior week, or elevated serum cardiac markers. Use of this scoring system was able to risk-stratify patients across a 10-fold gradient of risk, from 4.7% to 40.9% ($p < 0.001$) [114]. Most importantly, this risk score identified patients who derived the greatest benefit from enoxaparin versus UFH [114], from use of a GP IIb/IIIa inhibitor [115], and from an early invasive management strategy [84].

The GRACE (Global Registry of Acute Coronary Events) risk score also utilized multiple variables to identify those patients who would be at greatest risk of death in the 6 months following an ACS. Those variables that conferred the greatest risk included older age, prior history of congestive heart failure or MI, elevated heart rate and relative hypotension at presentation, the presence of ST-segment depressions, elevated serum creatinine at presentation, elevated cardiac biomarkers, and lack of in-hospital PCI [116]. When applied to patients with NSTEMI, the GRACE risk score is also able to identify those patients who will benefit most from an early invasive strategy. In the Timing of Intervention in Patients with Acute Coronary Syndromes (TIMACS) trial, NSTEMI patients with a GRACE risk score of greater than 140 had a reduction of 35% in the primary end point (composite of death, MI, or stroke) with early coronary angiography when compared to delayed intervention of greater than 36 hours (13.9% vs. 21%; $p = 0.006$). In patients with a GRACE risk score of less than 140, there was no difference between the two groups (7.6% vs. 6.7%; $p = 0.48$) [117]. Therefore, combined risk assessment scores can not only identify those patients at the highest risk for an adverse cardiovascular event, but can also assist the clinician in management decisions regarding angiography and medication choices.

MEDICAL THERAPY

Treatment Goals

The treatment objectives for patients with UA/NSTEMI are focused on stabilizing and "passivating" the acute coronary lesion, treatment of residual ischemia, and long-term secondary prevention. Antithrombotic therapy (e.g., aspirin, P_2Y_{12} ADP receptor blockers such as clopidogrel, anticoagulants, and GP IIb/IIIa inhibitors) is used to prevent further clotting in the coronary artery and allow endogenous fibrinolysis to dissolve the thrombus and reduce the degree of coronary stenosis. Antithrombotic therapy is continued long term so that if future events occur, the degree of thrombosis is reduced. Anti-ischemic therapies (e.g., beta-blockers, nitrates, and calcium antagonists) are used to reduce myocardial oxygen demand. Coronary revascularization is frequently needed to treat recurrent or residual ischemia. After stabilization of the acute event, the many factors that led up to the event need to be reversed. Treatment of atherosclerotic risk factors such as hypercholesterolemia, hypertension, and cessation of smoking, which contributes to stabilization of the cholesterol-laden plaque and healing of the endothelium, is critical.

Aspirin

Several major studies have demonstrated clear beneficial effects of aspirin, with a more than 50% reduction in the risk of death or MI in patients who present with UA/NSTEMI [89,118–120]. Thus, aspirin has had a dramatic effect in reducing adverse clinical events early in the course of treatment of UA/NSTEMI, and is primary therapy for these patients. An antiplatelet meta-analysis found that any dose greater than 75 mg was associated with the same overall benefit [121]. However, preliminary data from the Clopidogrel and Aspirin Optimal Dose Usage to Reduce Recurrent Events - Seventh Organization to Assess Strategies in Ischemic Syndromes (CURRENT-OASIS 7) trial, presented at the European Society of Cardiology Annual Conference in 2009, showed that patients undergoing PCI who were treated with double-dose clopidogrel and high-dose aspirin (300 to 325 mg) had the lowest rate of cardiovascular death, recurrent MI, or stroke at 1 year.

Bleeding is the main side effect of aspirin, and the rate of gastrointestinal (GI) bleeding appears to be higher with higher doses [121]. Data from the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial have shown that doses of 75 to 100 mg have a 50% lower rate of major bleeding (2.0% at 1 year) compared with doses of 200 to 325 mg (4.0% at

1 year); thus, a dose of 75 to 81 mg per day could be the optimal dose for long-term therapy. For acute treatment peri-PCI, a dose of 325 mg is generally used. Absolute contraindications to aspirin include documented aspirin allergy (e.g., asthma or anaphylaxis), active bleeding, or a known platelet disorder. In patients with more minor intolerance to long-term aspirin therapy (e.g., dyspepsia), short-term use of aspirin is recommended on the basis of the large early benefit. However, clopidogrel is a recommended alternative to aspirin for patients who cannot tolerate aspirin [67].

P_2Y_{12} ADP Receptor Blockers

Clopidogrel is a thienopyridine derivative that inhibits platelet activation and aggregation by inhibiting the binding of ADP to the P_2Y_{12} receptor on the surface of the platelet. In the CURE trial, 12,562 patients with UA/NSTEMI were randomized to receive aspirin alone (75 to 325 mg per day) or aspirin plus clopidogrel (300-mg loading dose and then 75 mg per day) [122]. The primary end point of cardiovascular death, MI, or stroke was reduced by 20% (11.4% control vs. 9.3% clopidogrel; $p < 0.0001$) [122]. The reduction was seen in all subgroups, including patients with ST-segment depression, those without ST-segment changes, and those with positive or negative markers. Interestingly, patients with positive cardiac markers and those with negative markers had similar 20% reductions in the primary end point. The combination of clopidogrel plus aspirin was associated with a relative 35% increase in major bleeding (using the CURE trial definition), but the absolute increase was only 1% (from 2.7% to 3.7%). Furthermore, using the standard TIMI definition of bleeding, there was no significant increase in major bleeding risk and no increase in intracranial hemorrhage. In patients who went on to PCI, a significant 30% reduction was observed through follow-up [123]. The Kaplan–Meier event rates began to show a reduction in events starting just 2 hours after randomization. In addition, when analyzing the benefit in the first 30 days versus after 30 days, there was a similar 20% relative risk reduction during both time periods. Thus, it appears that clopidogrel afforded both an early and an ongoing benefit out to 1 year.

When to start clopidogrel in patients with UA/NSTEMI remains a matter of debate. Even with a loading dose, it takes several hours before significant antiplatelet effects emerge. For this reason, the notion of pretreatment with clopidogrel at least several hours prior to the PCI has emerged as a possible means to help ensure that sufficient platelet inhibition is in effect at the start of the PCI. Because clopidogrel, like aspirin, is an irreversible platelet inhibitor, its antiplatelet effect will last for several days after discontinuation. If a patient is found to require surgical revascularization, the procedure should then be put off for several days. The guidelines remained silent on the timing of clopidogrel. However, across the spectrum of ACS, data have emerged that pretreatment with clopidogrel before a patient undergoes PCI significantly reduces the risk of death and ischemic complications post-PCI [123–125]. Thus, the most recent PCI guidelines now recommend clopidogrel pretreatment before PCI, but they also continue to acknowledge that treatment before coronary anatomy is defined remains controversial [126].

Several pharmacogenetic and drug–drug interactions for clopidogrel are notable and can affect patient outcomes. Clopidogrel is a prodrug that requires hepatic biotransformation by CYP450 enzymes into an active metabolite. Approximately 25% to 30% of the population has a reduced-function genetic variant of *CYP2C19*, a member of the CYP450 enzyme family. When treated with clopidogrel, these individuals have lower circulating levels of the clopidogrel active metabolite, thereby leading to less platelet inhibition, and a higher rate of ischemic events including stent thrombosis [127–129].

Metabolism of clopidogrel may also be affected by certain drugs. Some studies had suggested an interaction between clopidogrel and proton pump inhibitors (PPIs), such as omeprazole. Initial data, gathered retrospectively from large registries, suggested that patients treated with both clopidogrel and a PPI had worse outcomes than did patients treated with clopidogrel alone [130]. On discovering this result, researchers began to investigate possible mechanisms to explain this interaction. Indeed, they found that some PPIs have been shown to be inhibitors of the enzyme, *CYP2C19*, and they subsequently hypothesized that simultaneous administration of PPIs and clopidogrel may lead to competitive metabolism by *CYP2C19*, thereby leading to decreased clopidogrel activity. This hypothesis was initially supported by a recent study, which demonstrated that dual administration of clopidogrel and a PPI resulted in reduced platelet inhibition when compared to just clopidogrel alone [131]. However, analysis of data from a clinical cohort of the TRITON-TIMI 38 trial demonstrated no association between PPI use and clinical outcomes in patients on clopidogrel [132]. The safety of the combination of clopidogrel and omeprazole was further demonstrated in the Clopidogrel and the Optimization of Gastrointestinal Events Trial (COGENT), which was recently presented at the 21st Annual Transcatheter Cardiovascular Therapeutics (TCT) Scientific Symposium in 2009. This study randomized patients to clopidogrel alone or a combination pill of clopidogrel plus omeprazole following PCI and they found no difference in cardiovascular outcomes over 4 months, although they did note a significant reduction in GI events in patients taking the PPI. Given the dependence of clopidogrel metabolism on the CYP450 system, certainly extravigilance should be taken when prescribing other drugs with clopidogrel.

Although clopidogrel is currently the most utilized P_2Y_{12} ADP receptor blocker, there are two newer generation drugs of the same class that have gained attention in recent years. Prasugrel is a third-generation P_2Y_{12} ADP receptor blocker. Although also an irreversible inhibitor, prasugrel has a quicker onset of action when compared to clopidogrel (30 to 90 minutes for prasugrel vs. 4 to 6 hours for clopidogrel) and has lower rates of variability in platelet inhibitory effects than clopidogrel, thereby resulting in greater platelet inhibition. The effectiveness of prasugrel in patients with ACS was evaluated in the TRITON-TIMI 38 trial, in which more than 13,000 patients, including 10,000 patients with moderate- to high-risk UA/NSTEMI and 3,000 patients with STEMI, who were scheduled to undergo PCI for treatment of their ACS, were randomized to receive aspirin and either prasugrel or clopidogrel. Patients receiving prasugrel had a 19% reduction in the rate of cardiovascular death, MI, and stroke (9.9% vs. 12.1%; $p < 0.001$) as well as a 52% reduction in stent thrombosis (1.1% vs. 2.4%; $p < 0.001$) [133,134] (Fig. 38.5). These positive effects come at the price of significantly increased rate of major bleeding with prasugrel after PCI (2.4% vs. 1.8%; $p < 0.001$) [133].

Ticagrelor is another P_2Y_{12} ADP inhibitor that has recently been evaluated. Like prasugrel, ticagrelor has a rapid onset of action of 1 to 2 hours and greater platelet inhibition than clopidogrel; however, in contrast to both prasugrel and clopidogrel, ticagrelor's actions are reversible. The Study of Platelet Inhibition and Patient Outcomes (PLATO) study directly compared clopidogrel and ticagrelor in 18,000 patients presenting with ACS, about 15,000 of whom were patients with UA/NSTEMIs. Ticagrelor significantly reduced the rate of death, MI, or stroke when compared to clopidogrel (9.8% vs. 11.7%; $p < 0.001$) (Fig. 38.6) and significantly reduced all-cause mortality by 22% [135]. Although there was no significant difference in the rate of total major bleeding between the two drugs (11.6% vs. 11.2%; $p = 0.43$), a higher occurrence of non-coronary artery bypass grafting surgery (CABG) major bleeding was observed with ticagrelor.

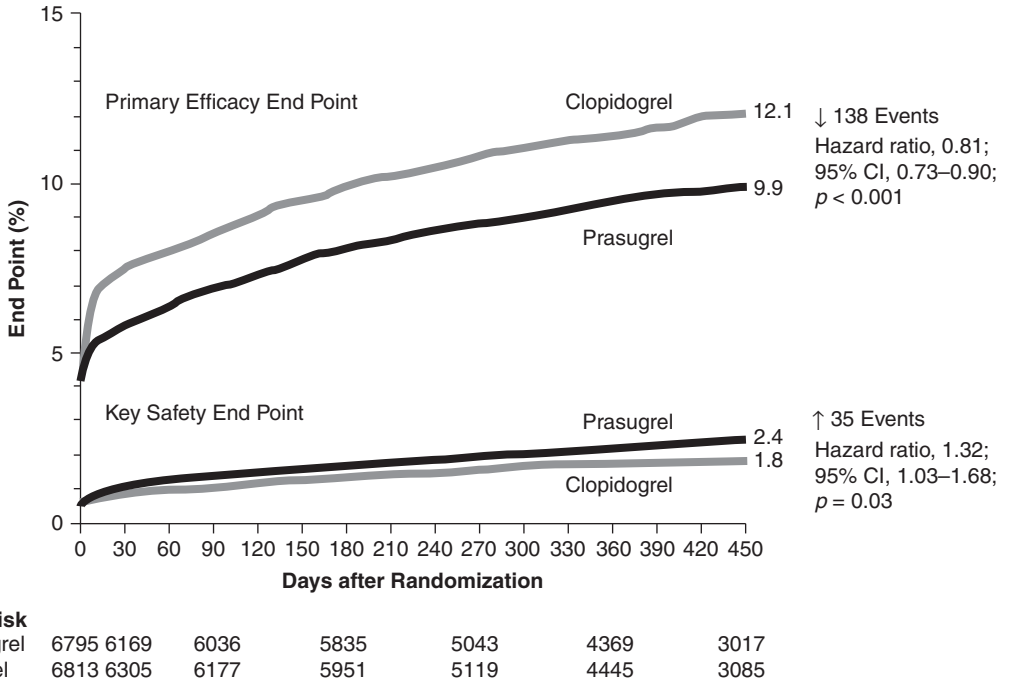

FIGURE 38.5. Kaplan–Meier curves demonstrating the superiority of prasugrel over clopidogrel in decreasing the incidence of the primary efficacy end point (composite of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke) over 16 months. Also shown is the Kaplan–Meier curve comparing the incidence of the primary safety end point (TIMI major bleeding) between the two drugs—here, prasugrel was associated with an increased risk of TIMI-major bleeding. Heparin

Heparin appears to be beneficial in UA/NSTEMI [89,136]. A meta-analysis showed a 33% reduction in death or MI at 2 to 12 weeks' follow-up, when comparing heparin plus aspirin versus aspirin alone, 7.9% versus 10.4% (relative risk [RR] = 0.67; 95% CI 0.44 to 1.02; $p = 0.06$) [136] (Fig. 38.7). Although this reduction did not achieve statistical significance, these are the data cited to support the use of heparin plus aspirin in UA, as recommended in the 2007 ACC/AHA Updated Unstable Angina Guideline [67].

Using the available data, the current optimal regimen appears to be a weight-adjusted dosing (60 U per kg bolus with a maximum of 4,000 U and 12 U per kg per hour infusion with a maximum of 1,000 U per hour), frequent monitoring of the activated partial thromboplastin time (aPTT) (every 6 hours until in the target range and every 12 to 24 hours thereafter), and titration using a standardized normogram, with a target

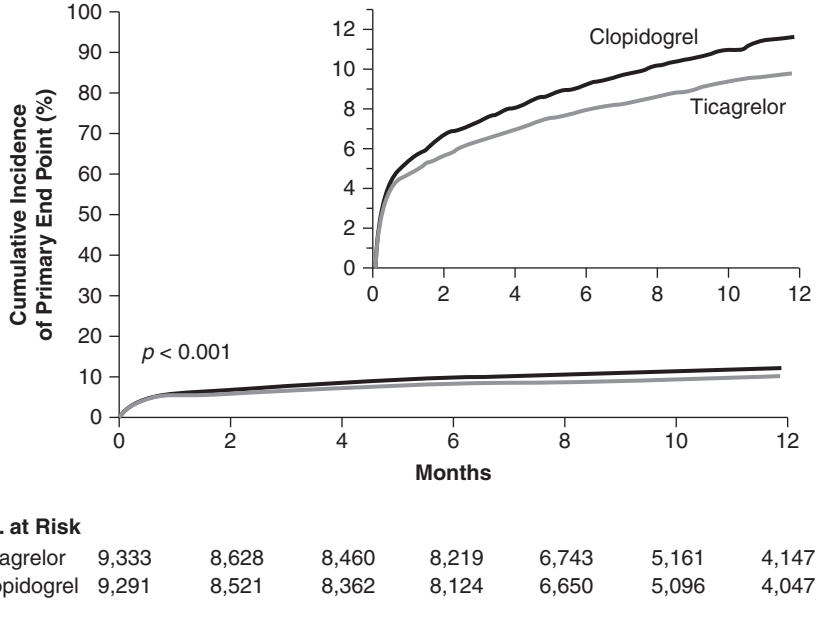

FIGURE 38.6. Kaplan–Meier curves demonstrating the superiority of ticagrelor over clopidogrel in decreasing the incidence of the primary efficacy end point (composite of death from vascular causes, myocardial infarction, or stroke) over 12 months. The primary end point occurred significantly less often with ticagrelor (9.8% vs. 11.7%; $p < 0.001$). [Adapted from Oler A, Whooley MA, Oler J, et al: Adding heparin to aspirin reduces the incidence of myocardial infarction and death in patients with unstable angina. A meta-analysis. *JAMA* 276:811–815, 1996, with permission.]

range of aPTT between 1.5 and 2.0 times control or approximately 50 to 70 seconds [67].

Low-Molecular-Weight Heparin

A major advance in the use of heparin has been the development of LMWHs, which are combined thrombin and factor Xa inhibitors. LMWHs are obtained by depolymerization of standard UFH and selection of those with lower molecular weight [137,138]. As compared with UFH with its nearly equal anti-IIa (thrombin) and anti-Xa activity, LMWHs have increased ratios of anti-Xa to anti-IIa activity of either 2:1 (e.g., dalteparin) or 3.8:1 (e.g., enoxaparin).

LMWH has several potential advantages over standard UFH. First, it inhibits thrombin as well as factor Xa, thereby inhibiting thrombin activity and its generation [138]. LMWH also induces a greater release of tissue factor pathway inhibitor than UFH and is not neutralized by platelet factor IV [137]. LMWH has been found to have a lower rate of thrombocytopenia than UFH [139]. Finally, the high bioavailability allows for subcutaneous administration.

Several trials have compared UFH with LMWH in patients with UA/NSTEMI, and in general, LMWH has been found to be superior [69,140]. In a meta-analysis of all trials of enoxaparin versus UFH in patients with UA/NSTEMI, treatment with enoxaparin significantly reduced the incidence of recurrent MI when compared to UFH (8% vs. 9.1%; $p = 0.005$), although there was no difference in mortality rates (3% vs. 3%; $p = 0.89$). Furthermore, treatment with enoxaparin in patients with NSTEMIs was not associated with an excess of major bleeding (6.3% vs. 5.4%; $p = 0.419$) [141] (Fig. 38.8). As might be expected, the benefit of enoxaparin appears greater in patients managed conservatively (who are typically on heparin for at least 48 hours) rather than in those managed invasively (who go to the catheterization laboratory within 48 hours and have their heparin discontinued thereafter) [142]. Given these results, the 2007 update of the ACC/AHA Unstable UA/NSTEMI Guideline offers a class IIa recommendation that enoxaparin be used over UFH, particularly for those patients who are managed conservatively [67].

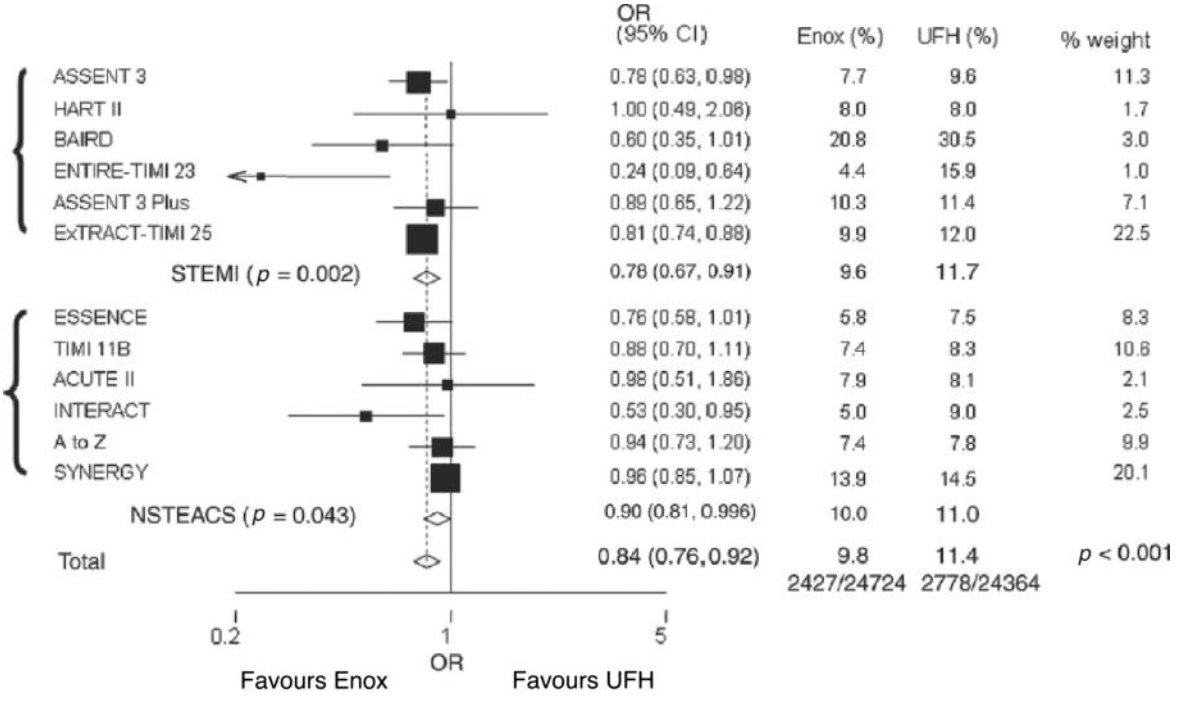

FIGURE 38.8. Meta-analysis of 12 trials, 6 of which evaluated patients with UA/NSTEMI, which compared UFH with enoxaparin. Data from more than 49,000 patients demonstrated that enoxaparin was associated with a lower incidence of death of nonfatal MI. CI, confidence interval; ENOX, enoxaparin; OR, odds ratio; UFH, unfractionated heparin. [From Murphy SA, Gibson CM, Morrow DA, et al: Efficacy and safety of the low-molecular weight heparin enoxaparin compared with unfractionated heparin across the acute coronary syndrome spectrum: a meta-analysis. *Eur Heart J* 28:2077–2086, 2007, with permission.]

Fondaparinux

Fondaparinux is a synthetic pentasaccharide and a specific Xa inhibitor. When comparing fondaparinux and enoxaparin, researchers found that the rates of death, MI, or refractory ischemia throughout the first 9 days were virtually identical with either drug in patients with UA/NSTEMI [143]. The rate of major bleeding was nearly 50% lower in the fondaparinux arm. By 30 days, mortality was significantly lower in the fondaparinux arm. Notably, in the subset of patients undergoing PCI, fondaparinux was associated with more than a threefold increased risk of catheter-related thrombi. Supplemental UFH during PCI appeared to minimize this risk, and consequently, the ACC/AHA recommends that UFH and fondaparinux be used together during PCI. Thus, fondaparinux appears to be a new alternative in patients with UA/NSTEMI and is associated with a lower risk of bleeding; however, this medication needs to be used cautiously in patients undergoing PCI.

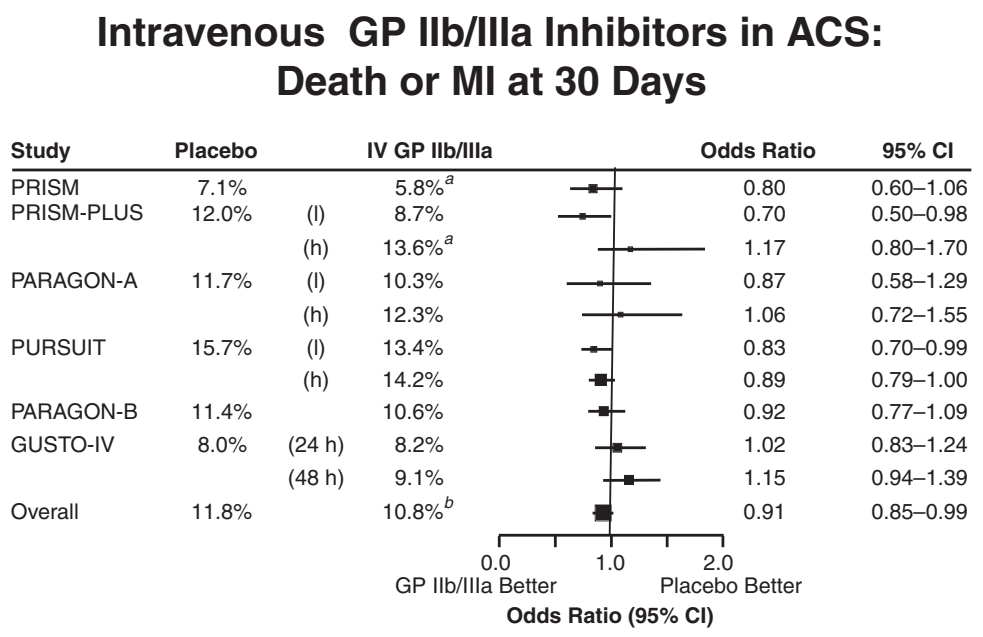
Bivalirudin

Bivalirudin is another antithrombotic drug used in the treatment of UA/NSTEMI, which acts by directly inhibiting thrombin and thus inhibiting clot formation. Bivalirudin was evaluated in the Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial, which randomized 13,820 patients with UA/NSTEMI, who were to be managed with an immediate invasive strategy, to one of three treatments: UFH or enoxaparin plus a GP IIb/IIIa inhibitor, bivalirudin plus a GP IIb/IIIa inhibitor, or bivalirudin alone. The study found no differences in the primary end point of death, MI, unplanned revascularization for ischemia, and major bleeding at 30 days between bivalirudin plus GP IIb/IIIa inhibitor and UFH/enoxaparin plus a GP IIb/IIIa inhibitor [144]. Furthermore, the similar rate of mortality among the groups was borne out at 1 year of follow-up [145]. For the bivalirudin-alone group, when compared with the group receiving UFH/enoxaparin plus a GP IIb/IIIa inhibitor, there were no differences in the efficacy end point, but a lower rate of bleeding was observed (3.0% vs. 5.7%; $p < 0.001$). Thus, use of bivalirudin in patients receiving GP IIb/IIIa inhibitors did not improve efficacy or safety, but the strategy of bivalirudin alone was associated with less bleeding than the combination of a GP IIb/IIIa inhibitor with either UFH or enoxaparin [144].

Oral Anticoagulation

Oral anticoagulation with warfarin following ACS has been examined in several trials, as prolonged treatment might extend the benefit of early anticoagulation with an antithrombin agent. Several trials have found some benefit with initial heparin followed by warfarin [146–152]. Most recently, the Warfarin Reinfarction Study 2 trial randomized 3,630 patients with acute MI to three arms: aspirin 160 mg daily; warfarin alone (target INR 2.8 to 4.2; mean 2.8); and warfarin (target INR 2.0 to 2.5; mean 2.2) plus 80 mg aspirin [153]. The primary end point of death, MI, or thromboembolic stroke was lowest in the combination arm: 20% for aspirin, 16.7% for warfarin, and 15% for warfarin plus aspirin ($p = 0.0005$ for the combination and $p = 0.028$ for warfarin alone vs. aspirin) [153]. The rate of major bleeding was low overall, but was increased from 0.15% per year for aspirin, to 0.58% for warfarin alone, and 0.52% for warfarin plus aspirin. Thus, the combination of warfarin plus aspirin appears to be an effective long-term treatment for secondary prevention of further cardiovascular events. However, the difficulty of maintaining warfarin within a narrow therapeutic window makes the routine use of this medication for this indication inconvenient.

Several other oral anticoagulants are currently under investigation for the treatment of ACS. Rivaroxaban is an oral direct factor Xa inhibitor, which was initially shown to be effective in preventing venous thromboembolism after orthopedic surgeries. The use of rivaroxaban in patients with ACS was studied in the Anti-Xa Therapy to Lower Cardiovascular Events in Addition to Aspirin with or without Thienopyridine therapy in Subjects with Acute Coronary Syndrome (ATLAS-ACS) trial, a phase II study, which found that the composite end point of death, MI, or stroke at 6 months was reduced with rivaroxaban when compared to placebo (3.9% vs. 5.5%; $p = 0.027$) [154]. Apixaban is another oral direct factor Xa inhibitor, which has recently passed through phase II investigation in the Apixaban for Prevention of Acute Ischemic and Safety Events (APPRAISE) trial and, similar to rivaroxaban, also demonstrated a trend toward a reduction in cardiovascular events [155]. A third oral direct thrombin inhibitor, dabigatran has gained notice recently as an alternative to warfarin in stroke prevention for patients with atrial fibrillation. However, this medication has also been evaluated for the prevention of recurrent ischemic events in patients with acute MI. Initial results from the phase II RE-DEEM (Randomized Dabigatran Etexilate Dose Finding Study in Patients with Acute Coronary Syndromes Post Index Event with Additional Risk Factors for Cardiovascular Complications Also Receiving Aspirin and Clopidogrel: Multicentre, Prospective, Placebo Controlled, Cohort Dose Escalation) study, which was presented at the American Heart Association Scientific Sessions in 2009, reported that dabigatran was associated with acceptable bleeding rates and would continue onto phase III studies to evaluate efficacy for use in patients with ACS. The clinical efficacy and utilization of these three oral antithrombin drugs will be borne out in the ongoing phase III trials over the next few years.



Thrombolytic Therapy for Unstable Angina/Non–ST-Segment Elevation Myocardial Infarction

Because thrombolytic therapy is beneficial in the treatment of patients with acute MI presenting with ST-segment elevation, it was hoped that it might play a role in other ACS. In TIMI IIIB, 1,473 patients with UA and non–Q-wave MI were treated with aspirin and heparin and were randomized to receive either tissue-type plasminogen activator (t-PA) or its placebo. No difference was found in the primary end point comparing t-PA with placebo: the incidence of death, postrandomization infarction, or recurrent, objectively documented ischemia through 6 weeks (54.2% for t-PA and 55.5% for placebo; $p =$ not significant [NS]) [48].

The TIMI IIIB results are corroborated by the Fibrinolytic Therapy Trialists' Collaborative Group overview, in which patients with suspected MI and ST-segment depression on the ECG had a higher mortality when treated with a fibrinolytic [156,157]. Accordingly, fibrinolytic therapy is not indicated in UA/NSTEMI.

Glycoprotein IIb/IIIa Inhibitors

GP IIb/IIIa inhibitors prevent the final common pathway of platelet aggregation, that is, fibrinogen-mediated cross-linkage of platelets via the GP IIb/IIIa receptor (see Fig. 38.2). Currently available GP IIb/IIIa inhibitors include abciximab, eptifibatide, and tirofiban. Abciximab is a monoclonal antibody Fab fragment directed at the GP IIb/IIIa receptor, whereas eptifibatide, a synthetic heptapeptide, and tirofiban, a nonpeptide molecule, are antagonists of the GP IIb/IIIa receptor whose structure mimics the arginine–glycine–aspartic acid amino acid sequence by which fibrinogen binds to the GP IIb/IIIa receptor.

[a]Without heparin; [b]with/without heparin; (l), low dose; (h), high dose.

FIGURE 38.9. Meta-analysis of the benefit of IV GP IIb/IIIa inhibitors in acute coronary syndrome (ACS): death or myocardial infarction (MI) at 30 days. [From Boersma E, Harrington RA, Molterno DJ, et al: Platelet glycoprotein IIb/IIIa inhibitors in acute coronary syndromes: a meta-analysis of all major randomized clinical trials. *Lancet* 359:189–198, 2002, with permission.]

The efficacy of the GP IIb/IIIa inhibitors in the treatment of NSTEMIs has been demonstrated in several studies. In the PRISM-PLUS trial involving 1,915 patients with UA/NSTEMI, tirofiban plus heparin and aspirin led to a significantly lower rate of death, MI, or refractory ischemia at 7 days than did placebo (i.e., heparin plus aspirin) (12.9% vs. 17.9%, a 32% risk reduction; $p = 0.004$). These results were borne out at 30 days as well [49]. (Death or MI was reduced by 30%, from 11.9% to 8.7%; $p = 0.03$.) In the PURSUIT (Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression using Integrillin Therapy) trial, which involved 10,948 patients, eptifibatide reduced the rate of death or MI at 30 days by a relative 10% (from 15.7% to 14.2%; $p = 0.042$). A greater benefit was observed in patients who were treated with an early invasive strategy with early PCI plus eptifibatide (31% reduction in death or MI at 30 days; 16.7% vs. 11.6%; $p = 0.01$), whereas the relative benefit was less (7% reduction; $p = 0.23$) in those treated conservatively with delayed PCI or CABG as needed [71]. The benefit of GP IIb/IIIa inhibition appears to be restricted to troponin-positive patients (i.e., those patients with true NSTEMIs) as demonstrated in the ISAR-REACT 2 trial, which studied 2,022 patients and found that abciximab reduced the risk of adverse cardiovascular events by 25% only in patients with NSTEMIs being treated with PCI [96]. There was no difference in cardiovascular events in patients with UA and a normal troponin level.

Although GP IIb/IIIa drugs certainly appear to be useful in the management of patients with NSTEMIs, who are undergoing PCI, the question remains as to what the optimal time for administration of the drug is. Initial analyses of data suggested that perhaps early administration of a GP IIb/IIIa inhibitor was beneficial. A meta-analysis of three trials (PRISM-PLUS, PURSUIT, and CAPTURE [c7E3 antiplatelet therapy in unstable refractory angina]) involving 12,296 patients yielded a 34% relative reduction in death or MI with the early use of the GP IIb/IIIa antagonists, although the absolute difference in event rates was small (3.8% vs. 2.5%; $p = 0.001$) [158]. As was expected, an even greater benefit was seen when the agents were continued during PCI (8.0% vs. 4.9%; $p = 0.001$). These findings were confirmed, although less robustly, in a more recent meta-analysis involving six trials, which again found that the use of GP IIb/III antagonists resulted in a 9% relative reduction in death or MI when compared to placebo [159] (Fig. 38.9). Later studies did not yield the same results. The GUSTO-IV ACS trial failed to show a benefit of abciximab when given upstream of PCI [160]. In addition, the ACUITY-Timing study found that early administration of GP IIb/IIIa inhibitors did not reduce recurrent ischemia when compared to selective administration of the medication in the catheterization laboratory during PCI (7.1% vs. 7.9%; $p = 0.44$), although bleeding was significantly increased with upstream administration (6.1% vs. 4.9%; $p < 0.001$) [161]. More recently, the EARLY ACS (Early Glycoprotein IIb/IIIa Inhibition in Non-ST-Segment Elevation Acute Coronary Syndrome) trial evaluated the use of routine use of upstream GP IIb/IIIa inhibitor eptifibatide versus delayed provisional use of the medication at the time of PCI [162]. In this trial, more than 9,000 patients with UA/NSTEMI, who were planned for an early invasive strategy with early PCI, were assigned to either receive upstream eptifibatide for the 12+ hours prior to catheterization or to the provisional use of eptifibatide after angiography. There was no significant difference in the composite rate of death, MI, urgent revascularization, or thrombotic complication during PCI between the two groups.

Although GP IIb/IIIa inhibitors may be efficacious in preventing adverse cardiovascular events, there are serious side effects associated with this class of drug. Several studies have demonstrated that the rate of major hemorrhage is slightly higher for patients treated with GP IIb/IIIa inhibitors. In PRISM-PLUS, major bleeding occurred in 4% of patients treated with tirofiban plus heparin plus aspirin versus 3.0% for heparin plus aspirin ($p = NS$) [49]. For eptifibatide, the rates of severe or moderate bleeding with eptifibatide versus placebo were 12.8% and 9.9%, respectively ($p < 0.001$) [71]. In EARLY ACS, patients who were given upstream eptifibatide had higher rates of non–life-threatening bleeding (5.8% vs. 3.4%; $p < 0.001$) and more blood transfusions (8.6 vs. 6.7; $p = 0.001$) [162].

Thrombocytopenia is also more common with GP IIb/IIIa inhibitors. For tirofiban in PRISM-PLUS, the rate of severe thrombocytopenia (<50,000 cells per mm^3) was 0.5%, versus 0.3% for heparin ($p = 0.44$). The latter event is associated with increased bleeding and in a smaller proportion of patients, recurrent thrombotic events [163,164]. This syndrome bears resemblance to heparin-induced thrombocytopenia and indicates a need to monitor platelet count daily during the GP IIb/IIIa infusion.

Despite the risks associated with the GP IIb/IIIa inhibitors, the current ACC/AHA guidelines support the use of GP IIb/IIIa inhibitors during PCI in patients with UA/NSTEMI [67]. Nevertheless, the use of a GP IIb/IIIa inhibitor upstream of planned PCI for UA/NSTEMI is now in question and further studies are needed to see if particular subgroups benefit from upstream administration of this medication. When GP IIb/IIIa inhibitors are used either during PCI or with conservative management of UA/NSTEMI, the benefit does appear to be greatest in patients at higher risk (i.e., those who have a positive troponin at baseline [96,98–100,165], those with diabetes [166], those with recurrent angina, or those with prior aspirin use [167]).

Anti-Ischemic Therapy

Nitrates

Nitrates are very useful in the acute management of ischemia and should be given sublingually if the patient is experiencing ischemic pain. Nitrates are provided for symptom relief and do not impart a mortality benefit. Both the Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto miocardico 3 and International Study of Infarct Survival (ISIS) 4 trials failed to demonstrate a survival benefit with nitrates in patients with suspected ACS, either in the overall population of subjects or in the subgroup of patients with NSTEMI [168,169]. If pain persists after three sublingual tablets and initiation of beta-blockade, intravenous nitroglycerin is recommended [67]. Because the goal of nitrate therapy is relief of pain, nitrates can frequently be tapered off during hospitalization.

Beta-Blockers

Several placebo-controlled trials in UA/NSTEMI have shown benefit of beta-blockers in reducing subsequent MI, recurrent ischemia, or both [170–174]. Early intravenous beta-blockade appears to provide early benefits in UA/NSTEMI [175]. In early studies performed in the prethrombolytic era that included patients with ST-segment elevation MI and NSTEMI, beta-blockers were shown to reduce infarct size, reinfarction, and mortality [176–179]. This beneficial effect of beta-blockers (intravenous followed by oral) has also been seen in subgroup analyses of patients with NSTEMI [179–181].

Beta-blockers are recommended for patients with UA/NSTEMI who do not have contraindications to their use (bradycardia, advanced atrioventricular block, persistent hypotension, pulmonary edema, and history of bronchospasm). If ischemia and chest pain are ongoing, early intravenous beta-blockade should be used, followed by oral beta-blockade. It should be noted that a reduced ejection fraction is no longer a contradiction to beta-blockade, and indeed, such patients may derive added benefit given the salutary effects seen with long-term beta-blockade in patients with heart failure [182–184]. However, beta-blockers should not be initiated in patients with evidence of decompensated heart failure until they have become hemodynamically stable [185].

Calcium Channel Blockers

Calcium channel blockers may be used in patients who have persistent or recurrent symptoms, but they are currently recommended only after nitrates and beta-blockade have been initiated [67]. In patients with contraindications to beta-blockade, improved heart rate control can be accomplished with some calcium channel blockers (e.g., diltiazem or verapamil). The Diltiazem Reinfarction Study, which involved 576 patients with non–Q-wave MI, showed that diltiazem reduced the rate of recurrent MI from 9.3% with placebo to 5.2% with diltiazem [186]. Furthermore, some studies have suggested that the use of amlodipine in stable patients with high-risk cardiovascular features can decrease the incidence of major cardiovascular events [187–189]. Some meta-analyses have found no beneficial effect in reducing mortality or subsequent infarction with calcium channel blockers [171,190,191]. Furthermore, in patients with acute MI with significant LV dysfunction or heart failure, a harmful effect has been observed with the administration of certain calcium channel blockers [192]. Nifedipine has been shown to be harmful in patients with acute MI when not coadministered with a beta-blocker in the trial of Early Nifedipine Treatment in Acute Myocardial Infarction [193,194]. Thus, the current guidelines recommend that calcium channel blockers be used only in patients with preserved LV function and without heart failure, and then only if needed for recurrent ischemia despite beta-blockade or for patients in whom beta-blockade is contraindicated [67].

Ranolazine

Although the exact mechanism of its antianginal effects is unknown, ranolazine has been shown to partially inhibit fatty acid oxidation and may improve the efficiency of oxygen utilization in the myocyte. In the Combination Assessment of Ranolazine in Stable Angina (CARISA) trial, researchers found that patients with stable angina, who were treated with ranolazine in addition to beta-blockers or calcium channel blockers, had fewer episodes of angina (one episode less per week than placebo; $p < 0.02$) and showed increased exercise capacity (115.6 seconds vs. 91.7 seconds; $p = 0.01$) [195]. Similar results reflecting the anti-anginal effects of ranolazine in patients with chronic stable angina were demonstrated in the MARISA (Monotherapy Assessment of Ranolazine in Stable Angina) trial [196]. The Metabolic Efficiency with Ranolazine for Less Ischemia in Non-ST Elevation Acute Coronary Syndrome (MERLIN)-TIMI 36 trial expanded the use of ranolazine to the NSTEMI population by evaluating 6,560 patients with NSTEMIs, 3,279 of whom were randomized to receive ranolazine and 3,281 of whom received placebo. Although there was no difference in the primary end point (a composite of cardiovascular death, MI, or recurrent ischemia) between the two groups (21.8% vs. 23.5%; $p = 0.11$), there was a significant reduction in the rates of recurrent ischemia with ranolazine (13.9% vs. 16.1%; $p = 0.03$) [197]. Follow-up analyses of the MERLIN-TIMI 36 trial confirmed the results of the CARISA and MARISA trials and demonstrated that anginal symptoms were improved with ranolazine (HR 0.77; 95% CI 0.59 to 1.00; $p = 0.048$) [198]. Hence, ranolazine remains an attractive addition to beta-blockers and nitrates for treatment of chronic, severe angina.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors have been shown to be beneficial in patients after MI, who have either LV systolic dysfunction (ejection fraction <40%) [199] or heart failure [200]. The Gruppo Italiano per lo Studio della Sopravvienza nell'Infarto miocardico-3, ISIS-4, and Chinese trials showed a 0.5% absolute mortality benefit of early (initiated within 24 hours) ACE inhibition in patients with acute MI [168,169]. However, in the ISIS-4 study, no benefit was observed in patients without ST-segment elevation. Thus, early routine ACE inhibition does not appear to confer survival benefit for patients with UA or NSTEMI.

On the other hand, long-term use of ACE inhibition is applicable to several groups of patients with cardiovascular disease, including those with LV systolic dysfunction [199]. Data based on evidence from the Heart Outcomes Prevention Evaluation trial suggests that ACE inhibition prevents recurrent cardiovascular events in patients with prior MI, peripheral arterial disease, or diabetes, even if ventricular function is preserved [201]. Similar results were also seen in the European Trial on Reduction of Cardiac Events with Perindopril in Stable Coronary Artery Disease (EUROPA) trial [202]. However, a third

trial, the Prevention of Events with Angiotensin Converting Enzyme [ACE] inhibitor (PEACE) trial, did not show any benefit with routine use of trandolapril in this population of patients, perhaps because the patients in this study were relatively low risk and had been treated with more intensive statin therapy and more frequent coronary revascularization [203].

Angiotensin Receptor Blockers

Angiotensin receptor blockers (ARBs) provide an alternative to ACE inhibitors, and may block the renin–angiotensin system more completely than ACE inhibitors, because angiotensin II can be generated via pathways that are independent of ACE [204]. The Valsartan in Acute Myocardial Infarction Trial (VALIANT) was one of the first trials to directly compare ARBs and ACE inhibitors. In this study, about 15,000 patients with a history of MI that was complicated by heart failure were randomized to receive either an ARB (valsartan), an ACE inhibitor (captopril), or a combination of the two drugs [205]. Valsartan was found to be noninferior to captopril at 2 years with regard to mortality ($p = 0.004$) and with regard to recurrent cardiovascular events ($p < 0.001$). The VALIANT trial was subsequently followed by the On-going Telmisartan Alone and In Combination with Ramipril Global Endpoint Trial (ON-TARGET), which randomized patients with known vascular disease or diabetes to receive either telmisartan, an ARB, or ramipril, an ACE inhibitor, or both drugs together [206]. Again, the ARB was shown to be noninferior to the ACE inhibitor with similar rates of death, MI, stroke, or hospitalization for heart failure at 56 months (16.5% vs. 16.7%; RR 1.01; 95% CI 0.94 to 1.09). Furthermore, patients who received telmisartan had less complaints of cough (1.1% vs. 4.2%; $p < 0.001$) when compared to those receiving the ACE inhibitor. Hence, ARBs remain effective alternatives to ACE inhibitors and may even be better tolerated.

Lipid-Lowering Therapy

Long-term treatment with lipid-lowering therapy with statins has been shown to be beneficial in patients with a prior history of either MI or UA [207–209]. In individuals with UA in the Long-term Intervention with Pravastatin in Ischemic Disease Trial, pravastatin led to a 26% reduction in mortality ($p = 0.004$), as well as significant reductions in subsequent MI, coronary revascularization, and stroke [209].

An early benefit on overall clinical outcome has been found in the Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering (MIRACL) trial. In 3,086 patients with UA/NSTEMI, atorvastatin 80 mg as compared to placebo was found to reduce the rate of the composite end point of death, MI, cardiac resuscitation, and angina, leading to rehospitalization by 4 months [210]. Further analysis demonstrated that this difference was mostly due to a reduction in the rate of rehospitalization for angina. In the Pravastatin or Atorvastatin Evaluation and Infection Therapy (PROVE-IT) TIMI 22 trial, intensive lipid-lowering therapy with atorvastatin 80 mg resulted in a 16% reduction in the primary end point and a 25% reduction in death, MI, or urgent revascularization, when compared with only moderate lipid-lowering therapy with pravastatin 40 mg [211]. The benefits emerged after only 30 days post-ACS [212], highlighting the importance of early initiation of intensive statin therapy post-ACS. When comparing the two arms of this study, it was noted that there was a significant difference in the LDLs achieved in each group. The average LDL achieved was 62 mg per dL in the atorvastatin 80 mg group and 95 mg per dL in the pravastatin 40 mg group. Based in part on these results, the adult treatment panel III of the National Cholesterol Education Program issued an update in which they recommended a new optional very low LDL goal of less than 70 mg per dL in patients with high-risk coronary heart disease [213].

TREATMENT STRATEGIES AND INTERVENTIONS

"Early Invasive" Versus "Ischemia-Guided" Strategy of Revascularization

Two general approaches to the use of coronary angiography and revascularization in UA/NSTEMI exist. The first is an "early invasive" strategy, involving routine angiography and revascularization with PCI or bypass surgery as appropriate. The other is a more conservative approach with initial medical management with angiography and revascularization only for recurrent ischemia, which could be termed an *ischemia-guided* strategy. Eight randomized trials have assessed these two general strategies [48,66,73,74,84,117,214] (Fig. 38.10).

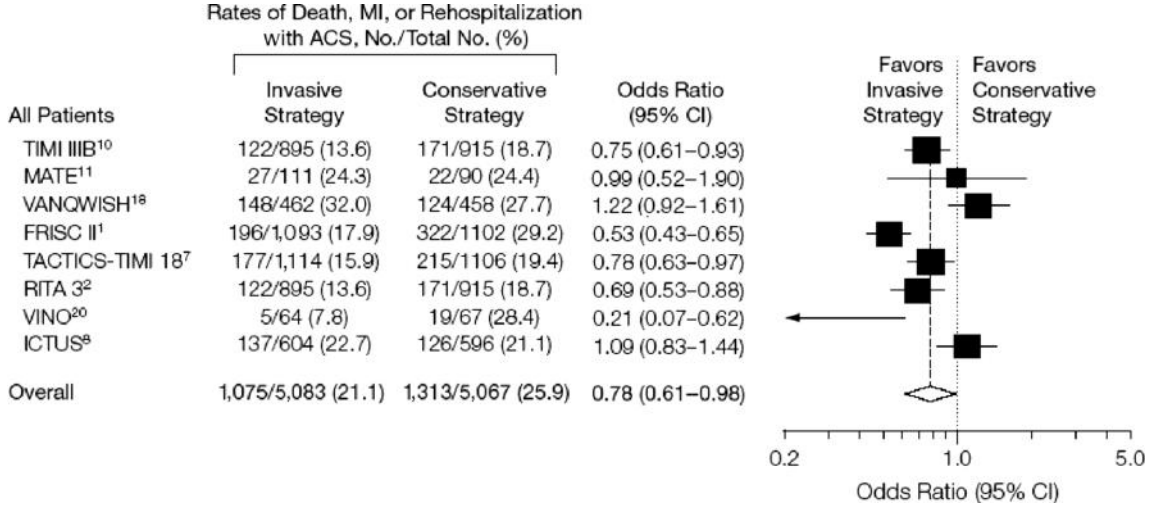


FIGURE 38.10. Meta-analysis of the benefit of a routine invasive versus "selective" invasive (i.e., conservative) strategy for patients with unstable angina or NSTEMI. ACS, acute coronary syndrome. Rate of death or MI or rehospitalization with ACS through follow-up. [From O'Donoghue M, Boden WE, Braunwald E, et al: Early invasive vs conservative treatment strategies in women and men with unstable angina and non-ST-segment elevation myocardial infarction: a meta-analysis. *JAMA* 300(1):71–80, 2008, with permission.]

The initial trials showed no benefit with an early invasive strategy. Subsequently, the FRISC II trial was conducted after coronary stenting had become available and found a significant benefit with an invasive strategy for the risk of death or MI at 6 months (9.4% vs. 12.1%; $p = 0.031$) [215]. At 1 year, there was a significant reduction in mortality in the invasive versus conservative groups (2.2% vs. 3.9%, respectively; $p = 0.016$) and in death or MI (10.4% vs. 14.1%, respectively; $p = 0.005$) [215]. Additional analyses showed greater benefit with the invasive strategy in higher risk groups identified by ST-segment depression on the admission ECG or troponin T greater than or equal to 0.01 ng per dL [216,217].

Subsequently, the TACTICS-TIMI 18 trial, wherein all patients were treated with an "upstream" GP IIb/IIIa inhibitor, found a significant reduction in death, MI, or rehospitalization for an ACS at 6 months with use of the early invasive strategy (from 19.4% in the conservative group to 15.9% in the early invasive strategy—OR, 0:78; $p = 0.025$) [84]. Similarly, death or nonfatal MI was significantly reduced at 30 days (7.0% to 4.7%, respectively; $p = 0.02$) and at 6 months ($p = 0.0498$). These effects were most magnified in patients with ST-segment changes, in those with positive troponin values compared with negative values, and in those with intermediate or high TIMI risk scores. In patients with a troponin I of greater than or equal to 0.1 ng per mL, there was a relative 39% risk reduction in the primary end point with the invasive versus conservative strategy ($p < 0.001$), whereas patients with a negative troponin had similar outcomes with either strategy [91]. Using the TIMI risk score, there was significant benefit of the early invasive strategy in intermediate- (score 3 to 4) and high-risk patients (5 to 7), whereas low-risk (0 to 2) patients had similar outcomes when managed with either strategy [84].

Randomized Intervention Treatment of Angina (RITA) 3 tested an early invasive versus conservative approach in 1,810 patients with UA/NSTEMI, all of whom were managed with enoxaparin [218]. An invasive strategy again proved superior, although the 34% reduction in the primary end point of death, MI, or refractory angina at 4 months was driven primarily by a reduction in refractory angina. Interestingly by 5 years, there was a significantly lower cardiovascular mortality rate in the early invasive arm [219].

The Invasive versus Conservative Treatment in Unstable Coronary Syndromes (ICTUS) trial also examined an invasive versus conservative approach in 1,200 patients. All patients received aspirin, enoxaparin, and abciximab at the time of PCI. At 1 year, there was no significant difference in the rate of the composite primary end point of death, MI, or rehospitalization for angina [220]. In fact, during the index hospitalization, there was a higher rate of MI in the invasive arm. In contrast, the risk of spontaneous MI tended to be lower (RR 0.80, 95% CI 0.46 to 1.34), and the risk of rehospitalization for angina was significantly lower in the invasive arm (RR 0.68, 95% CI 0.47 to 0.98).

Most recently, the TIMACS trial tackled the question of timing of an invasive management strategy in 3,031 patients presenting with UA/NSTEMI. Patients were randomized to undergo either early angiography within the first 24 hours of randomization or delayed angiography anytime after 36 hours after randomization. Similar to the ICTUS trial, at 6 months, there was no significant difference in the rate of the composite primary end point of death, MI, or stroke [117]. Nevertheless, subgroup analyses demonstrated that patients considered high risk did benefit from early invasive therapy with a significant reduction in the primary outcome of 13.9% versus 21% in the delayed intervention group (HR 0.65; 95% CI 0.48 to 0.89; $p = 0.006$). Furthermore, for patients of all risk groups, the secondary outcome of death, MI, and refractory ischemia was significantly reduced in the early invasive group (9.5%) as opposed to the delayed intervention group (12.9%) (HR 0.72; 95% CI 0.58 to 0.89; $p = 0.003$).

Using the available data, an early invasive strategy is likely superior to a conservative strategy in reducing cardiac events, in particular spontaneous MI after hospital discharge and refractory ischemia. This benefit appears greatest in patients at intermediate or high risk (especially those with positive troponin). In contrast, lower risk patients have similar outcomes

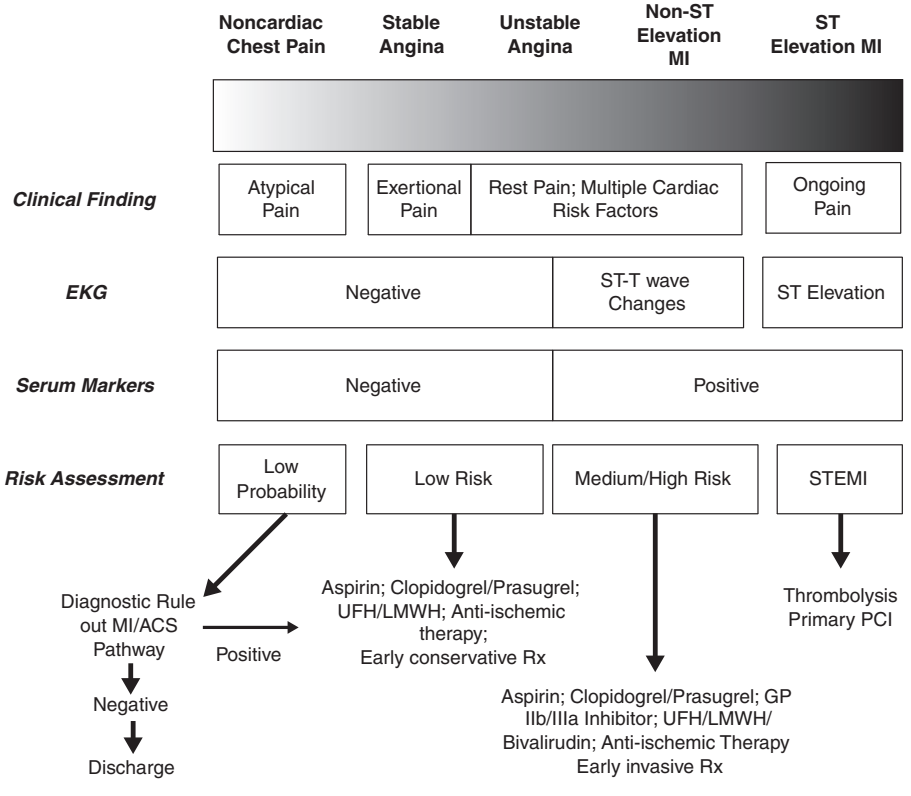

FIGURE 38.11. Algorithm for risk stratification and treatment of patients with UA/NSTEMI. ACS, acute coronary syndrome; DM, diabetes mellitus, ECG, electrocardiogram; LMWH, low-molecular-weight heparin; MI, myocardial infarction, Rx, treatment, STEMI, ST-segment elevation myocardial infarction; UFH, unfractionated heparin.

with either strategy, meaning that either a conservative or invasive strategy can be used in low-risk patients. These results have been incorporated into the update of the ACC/AHA and European Society of Cardiology guidelines for UA/NSTEMI, which recommend broader use of an early invasive strategy.

Percutaneous Coronary Intervention Versus Coronary Artery Bypass Graft

When revascularization is indicated, the choice between PCI versus surgery is faced. In the acute setting, PCI is undertaken much more frequently than CABG surgery. The presence of significant left main coronary artery disease leads to early surgery, with the expectation of improved survival relative to medical therapy alone [221,222]. Six comparative trials have compared PCI with CABG in the nonacute setting; both revascularization strategies resulted in similar rates of death, but a greater need for additional procedures was seen in those initially treated with PCI [223–228]. The SYNTAX (Synergy between Percutaneous Coronary Intervention with TAXUS and Cardiac Surgery) trial recently compared PCI with CABG in 1,800 patients with three-vessel or left main coronary artery disease and confirmed these prior findings—the rates of death were similar between the two groups, though the PCI group experienced relatively more major adverse cardiac or cerebrovascular events over the time course of the study (17.8% vs. 12.4% for CABG; $p = 0.002$) largely because of an increased rate of repeat revascularization with PCI (13.5% vs. 5.9% for CABG; $p < 0.001$) [228]. There was a higher rate of early stroke with CABG surgery. Differences in mortality with PCI and CABG were noted in certain subgroups. In the Bypass Angioplasty Revascularization Investigation trial, patients with diabetes who were treated surgically with a left internal thoracic artery graft were noted to have a significantly lower mortality compared with angioplasty [227]. This finding was further supported by a recent meta-analysis of ten randomized trials comparing PCI and CABG in patients with multivessel coronary disease in which mortality was shown to be lower with CABG in patients with diabetes or in those older than 65 years [229]. Using these data and those of previous trials of CABG versus medical therapy [221,222,230,231] and more recent observational data [232], CABG is recommended for patients with disease of the left main coronary artery, multivessel disease involving the proximal left anterior descending artery, multivessel disease, and impaired LV systolic function or multivessel disease and diabetes [229,233]. For other patients, either PCI or CABG is suitable. PCI has a lower initial morbidity and mortality than CABG but a higher rate of repeat procedures, whereas CABG is associated with more effective relief from angina and the need for fewer medications.

TABLE 38.3

ADVANCES IN MANAGING UA/NSTEMI

- Identification of high-risk patients is key to management of UA/NSTEMI [64,90,97–101]
- Aspirin leads to a more than 50% reduction in the risk of death or myocardial infarction [88,112–114]
- The addition of clopidogrel to aspirin further reduces risk by 20% [116], especially when given prior to percutaneous coronary intervention [117–119]. Prasugrel and ticagrelor are alternative P_2Y_{12} ADP receptor blockers that have been shown to be superior to clopidogrel in the treatment of NSTEMI
- Anticoagulation with one of four agents has been shown to be beneficial: heparin [121], low-molecular-weight heparin (dalteparin and enoxaparin) [128,129], fondaparinux [133], or bivalirudin [136]
- Glycoprotein IIb/IIIa inhibitors can be considered in troponin-positive patients [96–99]; however, the benefit of upstream administration in patients undergoing urgent percutaneous coronary intervention is questionable [162]
- Early, intensive statin therapy is beneficial [186,187]
- An early invasive strategy is beneficial in intermediate- and high-risk patients [76,117,198]

UA-NSTEMI, unstable angina/non–ST-segment elevation myocardial infarction.

CONCLUSIONS

An overall approach to patient management is shown in Figure 38.11. Using the medical history, ECG, and cardiac markers, one can identify patients who have a low likelihood of UA/NSTEMI, for whom a diagnostic "rule-out MI or ACS" is warranted. If this work-up is negative, the patient is discharged home; if positive, the patient is admitted and treated for UA/NSTEMI. These patients are treated with aspirin, a P_2Y_{12} ADP receptor blocker (either clopidogrel or prasugrel, or perhaps ticagrelor in the future), an anticoagulant (UFH or LMWH if at a low risk for bleeding, or bivalirudin if at high risk for bleeding), and anti-ischemic therapy with nitrates and beta-blockers. Risk stratification is used to identify patients at medium to high risk, for whom aggressive treatment with an early invasive strategy is warranted. For patients at low risk, standard treatment is likely sufficient, and a more conservative approach would be reasonable.

Advances in UA/NSTEMI, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 38.3.

CHAPTER 39 ■ ST-SEGMENT ELEVATION MYOCARDIAL INFARCTION

JAMES A. de LEMOS AND DAVID A. MORROW

Advances in the prevention, diagnosis, and management of patients with acute ST-segment elevation myocardial infarction (STEMI) have led to a reduction in mortality from this condition over the past few decades [1]. Rapid delivery of reperfusion therapy remains the cornerstone of management of STEMI. In recent years, substantial improvements in adjunctive therapies and processes of care delivery have been made, and these are expected to contribute to continued improvement in outcomes following STEMI.

PATHOPHYSIOLOGY

The initial pathophysiologic event leading to STEMI is rupture or erosion of a lipid-rich atherosclerotic plaque. The atherosclerotic plaque "vulnerable" to rupture tends to have a dense lipid-rich core and a thin protective fibrous cap, and is often not associated with critical narrowing of the arterial lumen. Molecular factors that regulate synthesis and dissolution of the extracellular matrix appear to modulate integrity of the protective fibrous cap. In unstable atherosclerotic lesions, inflammatory cells accumulate at the "shoulder" region of the plaque and release cytokines that degrade extracellular matrix and weaken the fibrous cap at this critical site [2].

Following plaque rupture, platelets adhere to subendothelial collagen, von Willebrand factor, or fibrinogen, and become activated by various local mediators such as adenosine diphosphate (ADP), collagen, and thrombin. Activated platelets undergo a conformational change and secrete the contents of their α-granules, promoting vasoconstriction and clot retraction. Activated platelets also express glycoprotein (GP) IIb/IIIa receptors in increased number and with greater binding affinity; fibrinogen-mediated cross-linking at this critical receptor leads to platelet aggregation. On the phospholipid surface of

TABLE 39.1

DIFFERENTIAL DIAGNOSIS OF ACUTE MI

Condition	Characterization of pain	Physical findings	ECG findings	Helpful diagnostic tests
Acute coronary syndrome	Pressure-type pain at rest, often radiating to neck or left arm	Examination often normal; check for signs of cardiogenic shock or CHF	ST-segment elevation, ST-segment depression, T-wave abnormalities, LBBB	Measurement of cardiac enzymes
Tako-Tsubo cardiomyopathy	Similar to AMI, but commonly precipitated by emotional stress	Examination often normal; may have signs of CHF	Anteroapical ST-segment elevation commonly with T-wave inversion	Cardiac enzymes only minimally elevated; anteroapical akinesis; normal coronary arteries
Aortic dissection	"Tearing" pain radiating to back	Diminished pulse or blood pressure in left arm	Nonspecific changes, LVH; ST-segment elevation if dissection involves coronary ostia	Chest x-ray, CT scan, or MRI; transesophageal echocardiography; aortogram
Pulmonary embolism	Pleuritic chest pain with dyspnea and cough	Tachypnea; tachycardia; pleural rub; right ventricular heave	Sinus tachycardia with nonspecific ST and T-wave changes; $S_1Q_3T_3$ pattern classic, but rarely seen	High-resolution chest CT; ventilation-perfusion lung scan; pulmonary angiogram
Pericarditis	Positional pain (worse lying flat)	Pericardial friction rub	Diffuse, concave ST-segment elevation with PR-segment depression	Echocardiogram

CT, computed tomography; CHF, congestive heart failure; LBBB, left bundle branch block; MRI, magnetic resonance imaging.

the platelet membrane prothrombin is converted to thrombin, catalyzing the conversion of fibrinogen to fibrin [3].

The distinguishing feature of the platelet–fibrin clot in STEMI is that it completely occludes the epicardial coronary artery, leading to transmural myocardial injury, manifested by ST-segment elevation on the electrocardiogram (ECG). Despite similar initial pathophysiologic features, unstable angina and non-STEMI (NSTEMI) are rarely associated with complete occlusion of the culprit coronary artery and do not benefit from fibrinolytic therapy. The distinction between Q-wave and non–Q wave MI can only be made retrospectively, and is not useful for early patient management. Accordingly, this terminology has been superseded by the terms STEMI and NSTEMI. Without reperfusion therapy, most patients with STEMI suffer transmural infarction and evolve Q-waves over the first few days after MI. Successful reperfusion therapy, however, may limit necrosis to the subendocardial regions and prevent development of Q-waves.

DIAGNOSIS AND RISK ASSESSMENT

History and Physical Examination

The pain of acute MI is qualitatively similar to angina and is classically described as a severe pressure-type pain in the midsternum, often radiating to the left arm, neck, or jaw. Associated symptoms include dyspnea, diaphoresis, nausea, vomiting, and weakness. In the elderly and those with diabetes, pain is often atypical, and may not be present at all [4]. Not uncommonly, inferior STEMI presents with nausea and vagal symptoms rather than chest pain. Silent infarction may occur in 25% or more cases. Characterization of the quality of the pain may help to distinguish MI from other conditions that cause chest discomfort, such as aortic dissection, pulmonary embolism, pericarditis, and gastrointestinal (GI) disorders such as cholecystitis and peptic ulcer (Table 39.1).

Patients with acute MI often appear pale and clammy; in many cases, they are in obvious distress. Elderly patients, in particular, may be agitated and incoherent. In contrast, patients with cardiogenic shock may be confused and listless. The objective of the initial examination should be to rapidly narrow the differential diagnosis and assess the stability of the patient. A focused examination can help to differentiate ischemia from conditions such as pneumothorax, pericarditis, aortic dissection, and cholecystitis (Table 39.1). Concomitant conditions, such as valvular heart disease, peripheral vascular disease, and cerebrovascular disease, may complicate patient management and can be rapidly detected by physical examination. A brief survey for signs of congestive heart failure should be performed. Cool extremities or impaired mental status suggests decreased tissue perfusion, whereas elevated jugular venous pressure and rales suggest elevated cardiac filling pressures. Finally, the hemodynamic and mechanical complications of acute MI can often be detected by careful attention to physical findings.

An increasingly recognized syndrome that may mimic acute MI is Tako-Tsubo cardiomyopathy, or the apical ballooning syndrome. This syndrome, more common among elderly women, is typically precipitated by an acute stress, including severe emotional distress or acute noncardiac medical illness. Chest pain associated with anteroapical ST-segment elevation and T-wave inversions is usually indistinguishable from an evolving anterior infarct. The diagnosis is typically made when normal coronary arteries and the distinctive anteroapical wall motion abnormality (Fig. 39.1) are seen at the time of

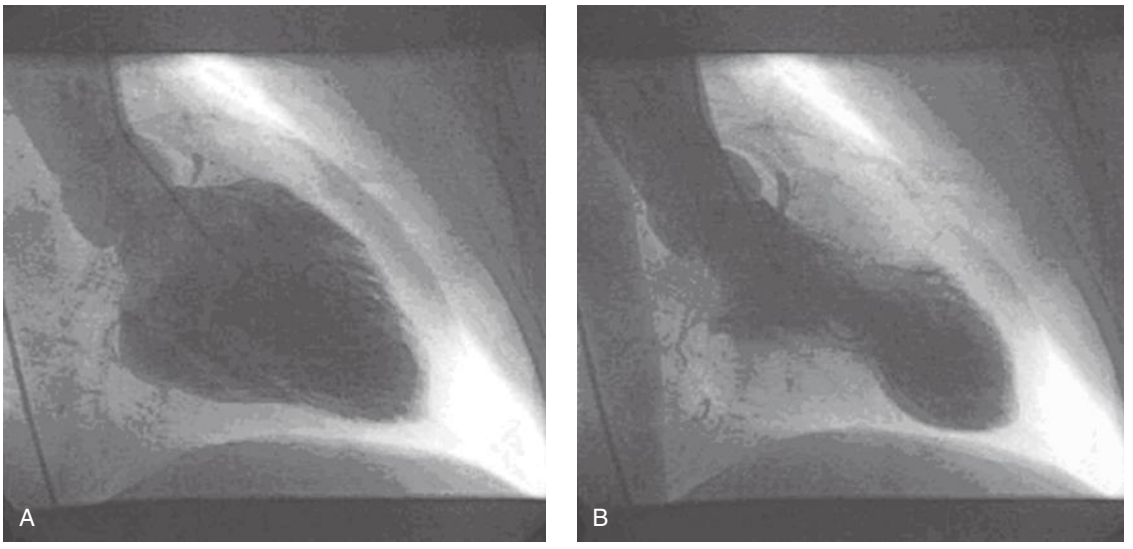

FIGURE 39.1. Representative contrast ventriculogram from a patient with Tako-Tsubo cardiomyopathy, demonstrating an anteroapical wall motion abnormality. The ventriculogram in Panel A was obtained at end diastole and in Panel B at end systole. [From the *Libyan J Med*, AOP: 070707, published July 19, 2007.]

emergent cardiac catheterization. In contrast to acute MI, cardiac enzymes usually elevate only modestly and the left ventricular (LV) functional abnormalities tend to be transient. The pathophysiology of this syndrome is thought to be due to catecholamine-mediated myocardial stunning.

Electrocardiogram

Performance of the 12-lead ECG in the prehospital setting significantly reduces time to reperfusion and shows a strong trend toward reducing mortality [5]. Because only about 25% of patients with STEMI transported by emergency medical services in the United States receive a prehospital ECG, this represents an important target for improvement [5]. The ability to transmit the 12-lead ECG and activate a STEMI care team prior to hospital arrival has provided an opportunity for a major enhancement in systems for STEMI care.

The ST-segment elevation of acute MI must be distinguished from that due to pericarditis or even the normal early repolarization variant. Ischemic ST-segment elevation typically has a convex configuration, is limited to selected ECG leads, and is often associated with reciprocal ST-segment depression (Fig. 39.2). Pericarditis, on the other hand, is typically associated with diffuse ST-segment elevation and depression of the PR segment (Fig. 39.3). The contour of the elevated ST segment in pericarditis and early repolarization variant is typically concave (upward sloping), in contrast to that seen with myocardial injury. Reversible ischemic ST-segment elevation is also seen with coronary vasospasm (Prinzmetal's variant angina).

A *new* (or presumed new) left bundle branch block (LBBB) in a patient with ischemic chest discomfort suggests a large

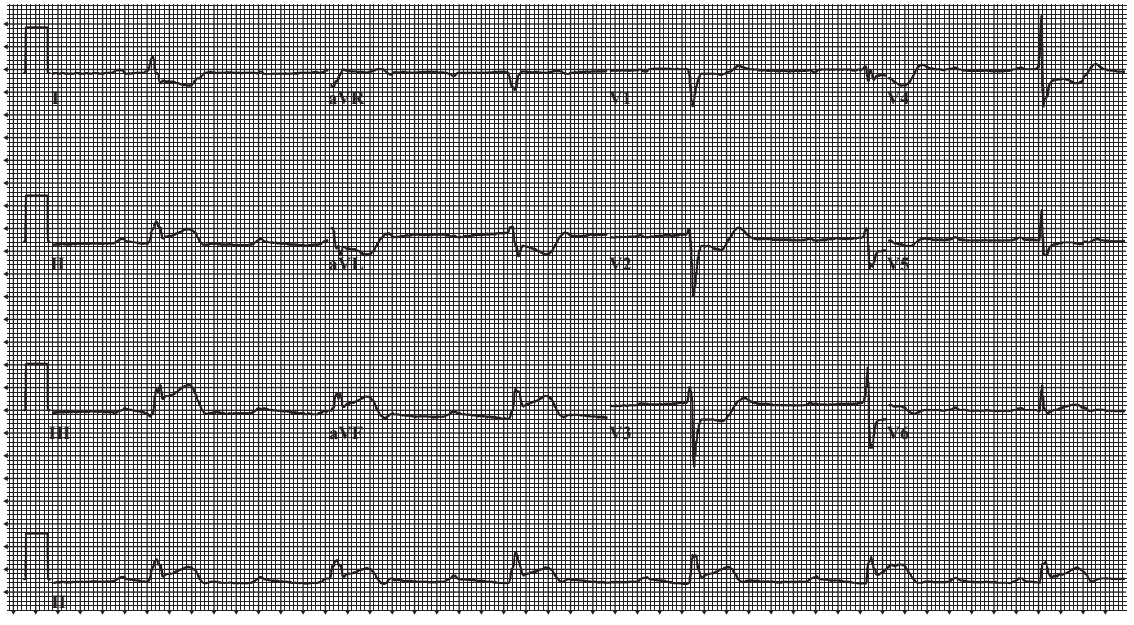

FIGURE 39.2. Inferoposterior ST elevation MI complicated by complete heart block.

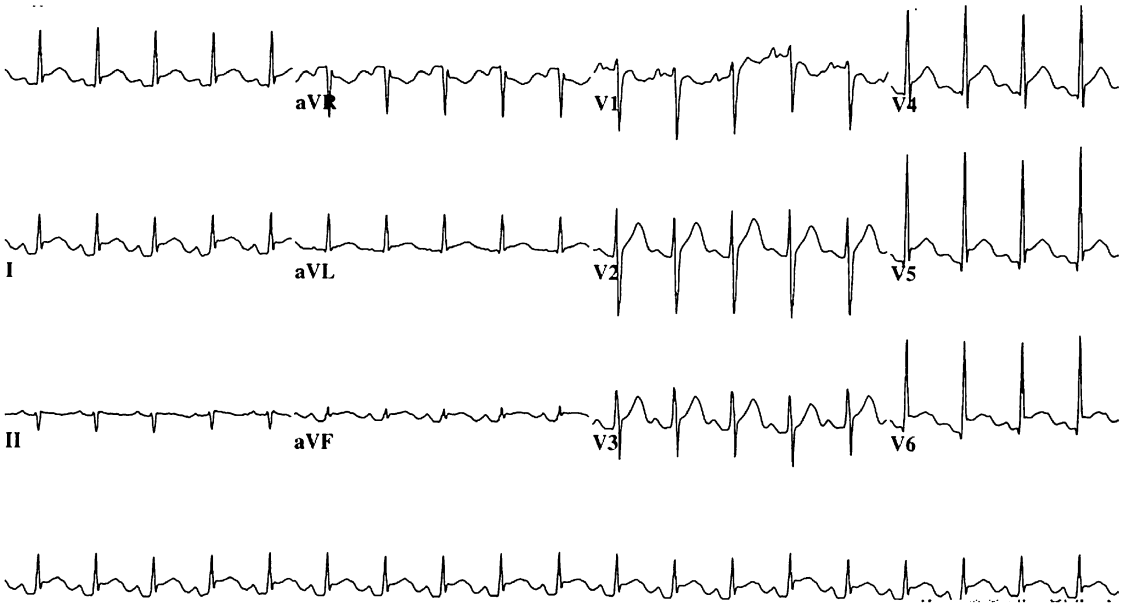

FIGURE 39.3. ECG changes characteristic of pericarditis. Concave (upsloping) ST-segment elevation is seen diffusely, together with PR-segment depression. Importantly, T-waves are essentially normal, another distinguishing feature from ST elevation MI.

anterior infarction, and is also an indication for reperfusion therapy. A LBBB of unknown age, however, presents a diagnostic dilemma, because many of these patients do not have ongoing transmural myocardial ischemia. Here, emergent echocardiography (to look for an anterior wall motion abnormality); bedside testing of serum cardiac markers, such as myoglobin, CKMB, or troponin; and even emergent cardiac catheterization should be considered. It should be emphasized that an acute STEMI leading to LBBB requires a very large ischemic territory, and would not be expected to be a subtle clinical event. In patients with a preexisting LBBB, no ECG criteria are sufficiently sensitive and specific to diagnose acute MI [6], so alternative methods are needed to make the diagnosis.

Cardiac Biomarkers and Other Tools for Risk Assessment

Cardiac biomarkers of necrosis are considerably more important in the initial diagnosis of NSTEMI than they are in the diagnosis of STEMI. For patients with STEMI, cardiac marker measurements are used to confirm the diagnosis in patients with equivocal electrocardiographic changes, to help gauge prognosis, and to estimate the likelihood of successful reperfusion therapy. Cardiac markers also provide prognostic information. Patients with an elevated myoglobin, troponin, or B-type natriuretic peptide level *prior* to initiation of reperfusion therapy are at higher risk for death and congestive heart failure (CHF), even after accounting for baseline variables such as infarct location and time to treatment [7–9]. When combined with subsequent measures of the efficacy of reperfusion therapy, such as the degree of ST-segment resolution, an accurate assessment of prognosis can be made [8]. Although the rate of rise of cardiac biomarkers (particularly myoglobin) can be used to help determine which patients have had successful or unsuccessful reperfusion [10], the clinical role of biomarker testing for reperfusion assessment is limited. The peak levels of troponin, CK, or CKMB provide a crude estimation of infarct size. It should be noted that with successful reperfusion, although the total amount of biomarker released is reduced, the peak value may actually increase, with an earlier peak and more rapid fall in biomarker levels.

Information from the patient's clinical presentation and physical examination are also very valuable for assessing the patient's prognosis. Evidence for heart failure or hemodynamic stress at the time of presentation is weighted heavily in this assessment. For example, it is possible to use the patient's age and vital signs at presentation to rapidly and accurately obtain a preliminary estimate of short-term survival [11]. Anterior infarct location, delays to therapy, and information regarding medical comorbidity all offer additional prognostic information [12]. As such, several tools that integrate age, the physical examination, the ECG, and other clinical parameters such as serum creatinine provide very strong discrimination of short- and long-term mortality risk, and may be implemented using either simple bedside calculation [12,13], handheld devices, or web-based tools [14,15] (Fig. 39.4).

REPERFUSION THERAPY

Rapid provision of reperfusion therapy is the primary treatment objective in patients presenting with STEMI. The managing clinician may choose between two principal reperfusion strategies: pharmacologic reperfusion versus primary percutaneous coronary intervention (PCI). This decision may be based on institutional resources, as well as patient factors as discussed in this section.

The Evolving Definition of "Optimal" Reperfusion

Early successful coronary reperfusion limits infarct size and improves LV dysfunction and survival. These benefits are due at least in part to the early restoration of antegrade flow in the infarct-related artery (IRA). In a retrospective analysis of six angiographic trials of different fibrinolytic regimens, patients who achieved normal (TIMI grade 3) antegrade flow in the IRA had a 30-day mortality rate of 3.6%, versus 6.6% in patients

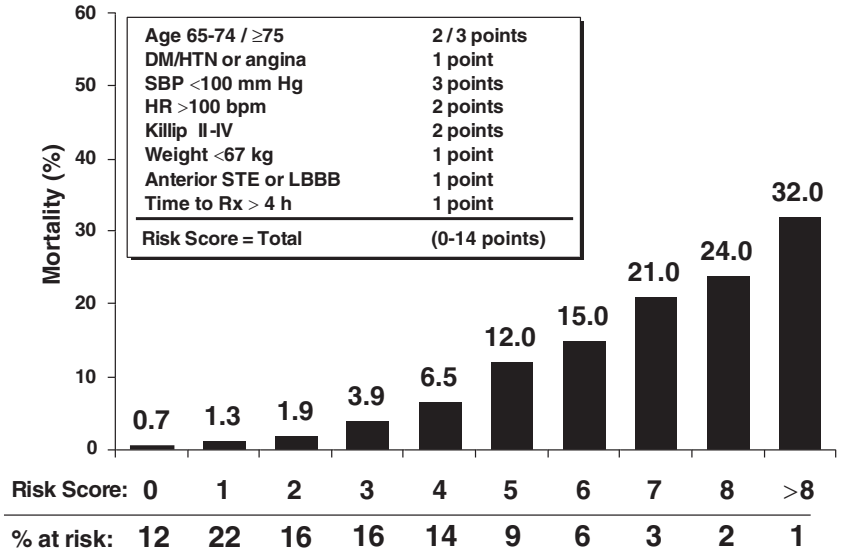

FIGURE 39.4. TIMI risk score for STEMI: a simple, bedside, clinical tool for predicting 30-day mortality. At the high end, a score of more than 5 identified 12% of patients with a mortality risk at least twofold higher than the mean for the population. In contrast, the 12% of patients with a risk score of zero had a mortality rate of less than 1%. Discriminating among the lower risk groups, nearly two-thirds of the population had risk scores of 0 to 3 with a 5.3-fold gradient in mortality over this range where smaller differences in absolute risk may have clinical impact. h/o, history of; HTN, hypertension; LBBB, left bundle branch block; STE, ST-segment elevation; TIMI, Thrombosis in Myocardial Infarction. [Adapted from Morrow DA, Antman EM, Charlesworth A, et al: TIMI risk score for ST-elevation myocardial infarction: a convenient, bedside, clinical score for risk assessment at presentation: an intravenous nPA for treatment of infarcting myocardium early II trial substudy. *Circulation* 102(17):2031–2037, 2000.]

with slow (TIMI grade 2) antegrade flow, and 9.5% in patients with an occluded artery (TIMI grade 0 or 1 flow) [16].

Even among patients who achieve normal (TIMI grade 3) epicardial blood flow in the IRA after reperfusion therapy, however, tissue-level perfusion may be inadequate. Using a number of different diagnostic tools (Table 39.2), investigators have demonstrated that measures of tissue and microvascular perfusion provide prognostic information that is independent of TIMI flow grade [17] (Fig. 39.5). For example, Ito and colleagues, using myocardial contrast echocardiography, found impaired tissue and microvascular perfusion in approximately one-third of patients with TIMI grade 3 blood flow after primary PCI: these patients were at increased risk for the development of CHF and death [18]. Impaired microvascular perfusion assessed with cardiac magnetic resonance imaging also correlates with higher mortality risk. Microvascular dysfunction is thought to occur in the setting of MI as a result of distal embolization of microthrombi, tissue inflammation from myocyte necrosis, and arteriolar spasm caused by tissue injury.

Perhaps the most clinically relevant measure of tissue perfusion is a simple bedside assessment of the degree of resolution of ST-segment elevation on the 12-lead ECG. Greater degrees of ST-segment resolution are associated with a higher probability of achieving a patent IRA and TIMI grade 3 flow [19]. Furthermore, patients who have normal epicardial blood flow, but persistence of ST-segment elevation on the 12-lead ECG, have been shown to have abnormal tissue and microvascular perfusion using a variety of specific imaging modalities such as contrast echocardiography and nuclear SPECT perfusion imaging [20,21]. In addition, persistent ST-segment elevation has been shown to predict poor recovery of infarct zone wall motion and the clinical endpoints of death and heart failure [22]. As a result, ST-segment resolution appears to integrate epicardial and myocardial (microvascular) reperfusion, and as such may actually provide a more clinically useful assessment of reperfusion than coronary angiography [23].

TABLE 39.2

DIAGNOSTIC TOOLS USED TO EVALUATE TISSUE AND MICROVASCULAR PERFUSION IN PATIENTS WITH ST ELEVATION MI[a]

Technique	Finding suggestive of microvascular injury
Myocardial contrast echocardiography	Absence of microbubble contrast uptake in the infarct zone
Doppler flow wire	Abnormal coronary flow reserve; systolic reversal of coronary flow
PET scanning	Impaired regional myocardial blood flow as measured with $^{13}NH_3$
Nuclear SPECT imaging	Absence of tracer uptake into infarct zone
Contrast angiography	Abnormal myocardial "blush," with failure to opacify myocardium or prolonged dye washout from myocardium
MRI	Hypoenhancement of infarct zone following gadolinium contrast injection
ECG	Failure to resolve ST-segment elevation

[a] Assumes that the epicardial infarct artery is patent. These techniques can be presumed to reflect microvascular and tissue perfusion only when the infarct artery has been successfully recanalized.

Time to Reperfusion

Regardless of the choice of reperfusion strategy, several common themes are evident. First, the benefits of reperfusion therapy are time dependent. Patients who receive fibrinolytic therapy within 1 hour from the onset of chest pain have an approximately 50% reduction in mortality, whereas those presenting more than 12 hours after onset of symptoms derive little, if any, benefit. For each hour earlier that a patient is treated, there is an absolute 1% decrease in mortality [24]. Similarly, for primary PCI, the "door-to-balloon" time has been shown to be directly correlated with clinical benefit [25].

Fibrinolytic Therapy

The use of fibrinolytic therapy worldwide has decreased substantially. Nevertheless, fibrinolytic therapy remains the primary approach to reperfusion therapy in some countries and in some regions in the United States where there is no access to experienced centers for timely primary PCI.

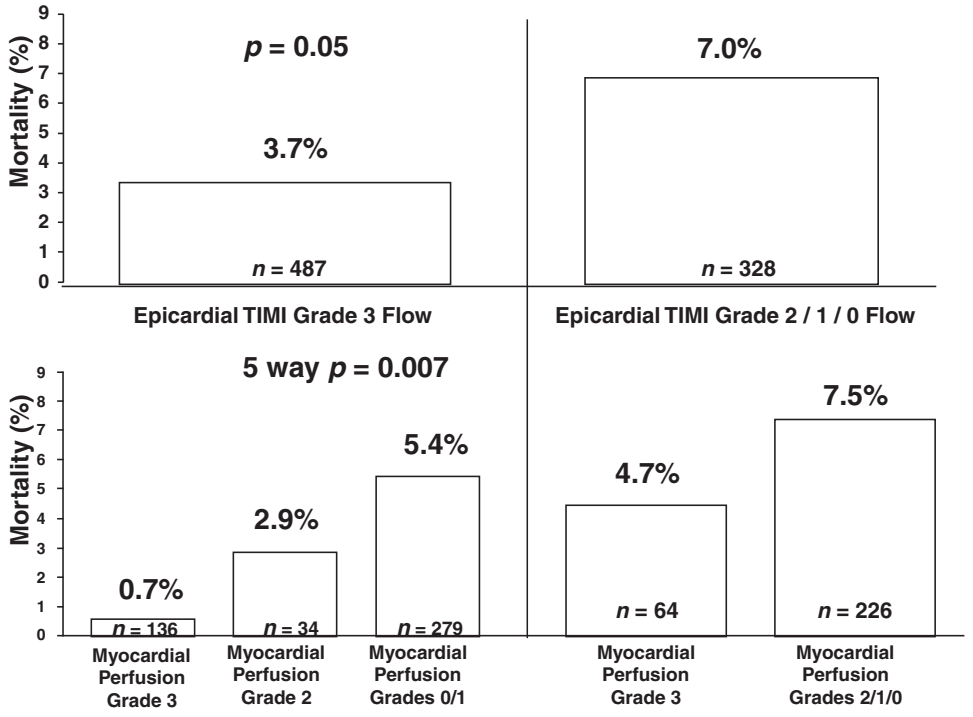

FIGURE 39.5. Relationship between epicardial perfusion, myocardial perfusion, and mortality after fibrinolytic therapy in the TIMI 10B trial. Myocardial perfusion was assessed using the TIMI Myocardial Perfusion Grade, which assesses the degree of microvascular "blush" seen on the routine coronary angiogram. This study found that myocardial perfusion was significantly associated with mortality independent of epicardial blood flow; using these two measures together provided incremental risk prediction. [Adapted from Gibson CM, Cannon CP, Murphy SA, et al; for the TIMI Study Group: The relationship of the TIMI Myocardial Perfusion Grade to mortality after thrombolytic administration. *Circulation* 101:125–130, 2000.]

Placebo-controlled trials using streptokinase, anistreplase (APSAC), and tissue plasminogen activator (tPA) established a clear benefit of fibrinolytic therapy for patients with STEMI. The Fibrinolytic Therapy Trialists' overview of all the large placebo-controlled studies reported a 2.6% absolute reduction in mortality for patients with STEMI treated within the first 12 hours after the onset of symptoms [24]. This benefit has been shown to persist through 10 years of follow-up. Highlights of differences in dosing, pharmacokinetics, recanalization rates, and cost between agents are shown in Table 39.3.

Several mutant forms of tPA have been developed that have a prolonged half-life (to allow bolus administration), as well as increased fibrin specificity and resistance to endogenous inhibitors of plasminogen, such as PAI-1. Bolus administration may minimize the risk for dosing errors, decrease "door to needle" time, and allow for prehospital administration. Reteplase (rPA) is a double-bolus agent that was shown to have similar efficacy and bleeding risk to accelerated tPA in the GUSTO III trial [26]. In the ASSENT II trial, tenecteplase (TNK-tPA)—a single-bolus agent—was shown to be equivalent to tPA in terms of mortality and intracranial hemorrhage (ICH), but was associated with a lower rate of noncerebral bleeding complications [27]. The safety advantage of this agent may be due to its increased fibrin specificity and the fact that the dose is adjusted for body weight.

Although the bolus fibrinolytic agents have not been demonstrated in placebo-controlled trials to reduce mortality or ICH, they are easier to use and have largely replaced tPA for this reason in the United States. Tenecteplase appears to offer a modest advantage in safety over other agents. Readministration of streptokinase or anistreplase should be avoided for at least 4 years (preferably indefinitely) because potentially neutralizing antibodies may develop and because anaphylaxis can occur on reexposure to these drugs.

TABLE 39.3

THROMBOLYTIC AGENTS IN CURRENT CLINICAL USE

	Alteplase	Reteplase	Tenecteplase	Streptokinase
Fibrin selective	+++	++	++++	–
Half-life	5 min	14 min	17 min	20 min
Dose	15 mg bolus; then 0.75 mg/kg over 30 min; then 0.5 mg/kg over 60 min (max 100 mg total dose)	Two 10 unit bolus doses given 30 min apart	0.53 mg/kg as a single bolus	1.5 million units over 30–60 min
Weight adjusted	Partial	No	Yes	No
Adjunctive heparin	Yes	Yes	Yes	Probably
Possible allergy	No	No	No	Yes
TIMI grade 2 or 3 flow (90 min)	80%	80%	80%	60%
TIMI grade 3 flow (90 min)	55%–60%	60%	55%–65%	32%
Efficacy vs. tPA	NA	Similar	Equivalent	1% ↑ mortality
Safety	NA	Similar	Similar ICH ↓ non-ICH bleeding	↓ ICH ↓ overall bleeding

TABLE 39.4

CONTRAINDICATIONS TO FIBRINOLYTIC THERAPY

Absolute contraindications	Relative contraindications
Any prior intracranial hemorrhage	Blood pressure >180/110[a]
Stoke within past year	Any prior stroke or TIA
Recent head trauma	Known bleeding diathesis
Known brain tumor	Proliferative diabetic retinopathy
Active internal bleeding	Prolonged CPR
Suspected aortic dissection	Pregnancy
Major surgery or trauma within 2 wk	

CPR, cardiopulmonary resuscitation; TIA, transient ischemic attack.
[a]Prior recommendations have considered only a *sustained* blood pressure >180/110 a relative contraindication; however, even a single blood pressure greater than this threshold is associated with an increased risk for intracranial hemorrhage.

Current Guidelines for Fibrinolysis

Fibrinolytic therapy is indicated as an option for reperfusion therapy in patients presenting within 12 hours of symptom onset if they have ST-segment elevation or new LBBB and no contraindications to lytic therapy (Table 39.4). Patients who are older than 75 years of age, those who present more than 12 to 24 hours after the onset of acute MI, and those who are hypertensive but present with high-risk MI have a less favorable balance of risk and potential benefit, but may be considered for treatment with a fibrinolytic therapy when primary PCI is not available. Patients should not be given fibrinolytic therapy if the time to treatment is longer than 24 hours or if they present only with ST-segment depression [28].

Limitations of Fibrinolytic Therapy

Current fibrinolytic regimens achieve patency (TIMI grade 2 or 3 flow) in approximately 80% of patients, but complete reperfusion (TIMI grade 3 flow) in only 50% to 60% of cases. In addition, as noted previously in the chapter, approximately one-third of patients with successful epicardial reperfusion have inadequate myocardial and microvascular reperfusion [18]. Finally, even after successful fibrinolysis, a 10% to 20% risk of reocclusion is present. Reocclusion and reinfarction are associated with a two- to threefold increase in mortality [29,30] (Fig. 39.6).

Bleeding is the most common complication of fibrinolytic therapy. Major hemorrhage occurs in 5% to 15% of patients. ICH is the most devastating of the bleeding complications, causing death in the majority of patients affected and almost universal disability in survivors. In major clinical trials, ICH has occurred in 0.5% to 0.9% of patients, but in clinical practice, where patient selection is less rigorous, rates are higher. Patients at particularly high risk for ICH include the elderly (particularly elderly females), patients with low body weight, and those who receive excessive doses of heparin.

Combination Therapy with a GP IIb/IIIa Inhibitor and Reduced-Dose Fibrinolytic

Standard fibrinolytic therapy is directed at the fibrin-rich "red" portion of the coronary thrombus. Activated platelets are the critical component of the white portion of the arterial thrombus. Paradoxically, fibrinolytic agents directly and indirectly promote platelet activation [31], and activated platelets themselves contribute to fibrinolytic resistance by secreting PAI-1 and promoting clot retraction, thereby limiting penetration of the fibrinolytic agent into the thrombus. As a result of these observations, it was hypothesized that potent platelet inhibition with a GP IIb/IIIa inhibitor might augment the efficacy of fibrinolytic therapy.

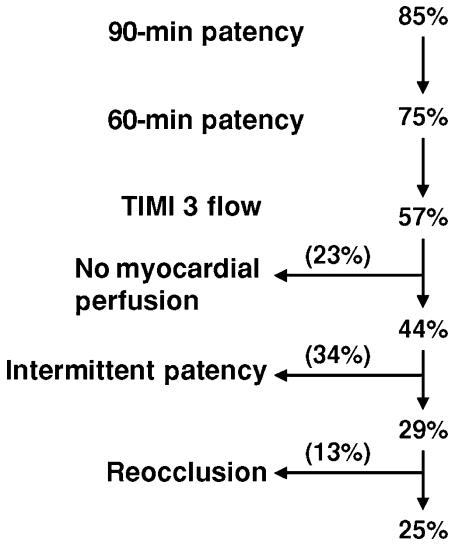

FIGURE 39.6. Limitations of current fibrinolytic regimens. [From Lincoff AM, Topol EJ: Illusion of reperfusion. Does anyone achieve optimal reperfusion during acute myocardial infarction? *Circulation* 87:1792–1805, 1993.]

Although a series of phase II studies comparing standard fibrinolytic therapy with various combinations of GP IIb/IIIa inhibitors and reduced doses of fibrinolytic agents suggested improved TIMI flow grade and ST-segment resolution with the combination regimens [32–35], definitive phase III trials revealed no convincing improvement in outcomes and an increase in ICH in the elderly with combination regimens [36,37]. Thus, despite initial promise, data do *not* support the use of GP IIb/IIIa inhibitor/fibrinolytic combinations as the primary reperfusion strategy for treatment of STEMI.

Rescue Percutaneous Coronary Intervention

Because failure of fibrinolytic therapy is associated with high rates of morbidity and mortality, "rescue" PCI is frequently performed in such patients. Data to support rescue PCI in patients with an occluded infarct artery are limited, as tools to diagnose failed reperfusion are only modestly effective, and clinical trials evaluating rescue PCI have enrolled very slowly. In the MERLIN trial, 307 patients with ECG evidence of failed reperfusion (ST-segment resolution <50% measured 60 minutes after fibrinolytic therapy) were randomized to rescue PCI or conservative therapy. Rescue PCI was performed an average of approximately 90 minutes after the qualifying ECG and was associated with a 26% reduction in the composite endpoint of death, reinfarction, stroke, heart failure, and revascularization at 30 days. However, mortality was not significantly reduced. The most recent study performed was the REACT trial, in which 427 patients with ECG evidence of failed fibrinolysis at 90 minutes were randomized to repeat fibrinolysis, conservative treatment, or rescue PCI. No benefit was observed for repeat fibrinolysis, but rescue PCI reduced the primary

endpoint of death, reinfarction, stroke, or severe heart failure at 6 months by 53%. Mortality was also reduced from 12.8% in the conservative therapy arm to 6.2% in the rescue PCI arm. We recommend urgent catheterization and PCI for all patients with persistent ST-segment elevation and ongoing chest pain 90 minutes after the administration of reperfusion therapy, unless they are at particularly low risk for complications (i.e., a young patient with an uncomplicated inferior MI). For patients who are pain free, but in whom the ST segments remain elevated, urgent catheterization should also be strongly considered, particularly if the patient has high-risk features, such as older age, anterior location of infarction, diabetes, or prior CAD.

Primary Percutaneous Coronary Intervention

In centers with adequate resources, experienced operators, and an institutional commitment to programmatic excellence, immediate or "primary" PCI has become the preferred reperfusion method for patients with STEMI. Randomized trials performed in both referral centers and experienced community hospitals have shown that primary PCI reduces the likelihood of death or MI when compared to fibrinolytic therapy [38]. Moreover, rates of major bleeding and stroke are also significantly lower with primary PCI than with fibrinolytic therapy (Fig. 39.7). The relative benefits of primary PCI are greatest in patients at highest risk, including those with cardiogenic shock, right ventricular infarction, large anterior MI, and increased age (due partly to an increased ICH rate with fibrinolytic therapy). However, as with fibrinolytic therapy, rapid time to treatment is paramount to success [25]. In addition, while operator and institutional experience are critical to realize the full benefit of primary PCI, excellent results with primary PCI have been demonstrated in well-trained community hospitals without on-site cardiac surgery [39]. Current ACC/AHA guidelines recommend primary PCI over fibrinolytic therapy when it can be performed by experienced operators in experienced centers within 90 minutes of presentation. When the door-to-balloon time is expected to be longer than 90 minutes, fibrinolysis is generally preferred for patients presenting within 12 hours of symptom onset unless contraindications are present [28].

Advances in PCI technology have been rapidly translated from elective to emergent PCI. Compared with primary PTCA, primary stenting is associated with similar rates of death and reinfarction, but lower subsequent target vessel revascularization rates [40,41]. Initial fears about stent thrombosis when drug-eluting stents (DES) were placed in the setting of STEMI have not been realized, and recent studies demonstrate that the advantages of DES over bare metal stents (BMS) with regard to in-stent restenosis and target vessel revascularization extend to patients with STEMI [42,43]. One logistical issue merits comment regarding stent choice. It may be difficult in the setting of an evolving STEMI to determine whether a patient is a good candidate for at least 1 year of uninterrupted aspirin and thienopyridine therapy; a BMS would be preferred in situations where the clinician cannot make this determination.

Because of the large thrombus burden in STEMI, distal embolization at the time of PCI is common and may cause additional tissue and microvascular injury. Strategies to prevent distal embolization using embolic protection devices, which are commonly used when PCI is performed in saphenous vein grafts, cause delays in reperfusion and do not appear to improve outcomes when STEMI is due to native vessel obstruction. In contrast, a simpler strategy of thrombus extraction has yielded very promising results. In a randomized trial of 1,071 patients with STEMI, manual thrombus aspiration before PCI was demonstrated to improve TIMI myocardial perfusion grade and ST-segment resolution ($p < 0.001$) [44], as well as 1-year mortality (3.6% vs. 6.7%; $p = 0.02$) [45]. Aspiration thrombectomy is a reasonable option for patients undergoing primary PCI, particularly in patients with large thrombus burden and shorter ischemic times [46].

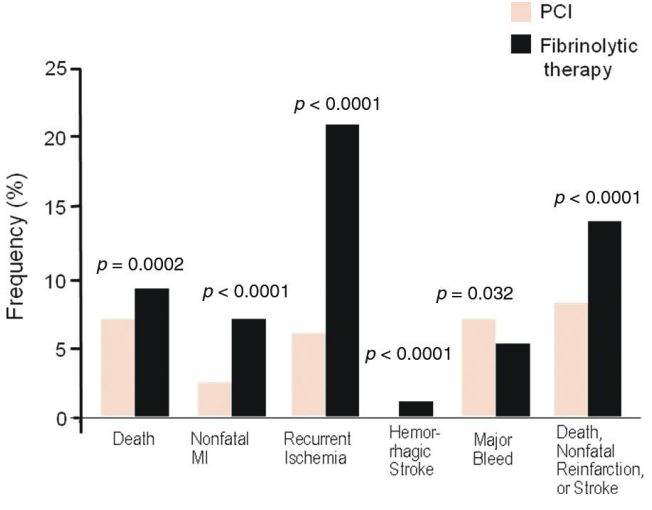

FIGURE 39.7. Short-term (4- to 6-week) outcomes from a meta-analysis of 23 randomized controlled trials comparing fibrinolytic therapy with primary PCI. [Adapted from Keeley EC, Boura JA, Grines CL: Primary angioplasty versus intravenous thrombolytic therapy for acute myocardial infarction: a quantitative review of 23 randomised trials. *Lancet* 361(9351):13–20, 2003.]

Performance Improvement Measures to Improve Door-to-Balloon Times

Considerable attention has been focused on improving door-to-balloon times. A study by Bradley et al. [47] identified key strategies that discriminated hospitals with shorter versus longer door-to-balloon times (Table 39.5). Most of these strategies have been adopted by the Door-to-Balloon (D2B) Alliance, a quality improvement initiative aiming to achieve a door-to-balloon time of 90 minutes or shorter for 75% or more of nontransferred patients with STEMI [48].

TABLE 39.5

PROCESS MEASURES TO IMPROVE DOOR-TO-BALLOON TIMES

- Emergency medicine physician activates the catheterization laboratory
- A single call to a central page operator activates the catheterization laboratory
- A prehospital ECG is used to activate the catheterization laboratory activated while the patient is en route to the hospital
- Expectation that staff will arrive in the catheterization laboratory within 20–30 min (vs. >30 min) after being paged
- An attending cardiologist is always on site (sleeps in hospital)
- Real-time data feedback is provided to emergency department and the catheterization laboratory staff

Transfer for Primary Percutaneous Coronary Intervention

Although primary PCI is the preferred reperfusion option for most patients who present to dedicated centers that can perform interventional procedures quickly and expertly, most patients with STEMI present to centers without primary PCI readily available. In such cases, a decision must be made as to whether immediate pharmacologic reperfusion therapy or transfer for primary PCI (if possible) is the best alternative. For patients in whom a rapid transfer is possible (time from arrival at first hospital to balloon inflation <90 minutes or PCI-associated delay <1 hour), transfer for primary PCI is preferable. Unfortunately, data from the National Registry of Myocardial Infarction (NRMI) through 2002 suggested that only 4% of transferred patients underwent primary PCI with a door-to-balloon time shorter than 90 minutes [49]. More recently, several referral centers or metropolitan areas have initiated regional transfer networks that have achieved door-to-balloon times of 100 to 120 minutes [50–52]. For patients with contraindications to fibrinolytic therapy, evidence of failed fibrinolytic therapy, cardiogenic shock, or presentation more than 12 hours after symptom onset, transfer to a center that can perform emergent PCI is indicated, even if delay times are longer [53].

Several studies have compared strategies of routine transfer of patients eligible for fibrinolytic therapy for primary PCI versus immediate fibrinolysis with or without transfer. Although these studies have reported a lower incidence of adverse cardiac events among those randomized to transfer for primary PCI [54,55], generalizability of the results has been questioned as the very rapid transfer times in these studies are significantly shorter than those typically occur in the United States [49] and the rates of referral for rescue PCI were unusually low in these trials.

Subsequent analyses have helped to define the influence of symptom duration and transfer-related time delay on the benefits of transfer for primary PCI. For example, among the 850 patients enrolled in the PRAGUE-2 study, there was a significant and quantitatively large reduction in mortality (6.0% vs. 15.3%; $p < 0.02$) among those who were randomized more than 3 hours after symptom onset. In contrast, there was no reduction in mortality among patients presenting within 3 hours [56]. Similar findings were observed in the CAPTIM trial in which the control arm received prehospital fibrinolytic [57]. A meta-analysis of randomized studies has suggested that if the delay between immediate administration of a fibrinolytic and initiation of PCI is more than 1 hour, the pharmacologic therapy becomes favored with respect to survival [58] (Fig. 39.8). These data form the basis of the recommendation in the AHA/ACC guidelines that fibrinolysis is generally preferred in eligible patients who present within 3 hours of symptom onset, and more than a 1-hour delay between fibrinolytic and primary PCI is expected (Fig. 39.9).

Pharmacoinvasive Strategies

In light of the deleterious impact of delays to primary PCI on myocardial salvage, an approach in which reperfusion is initiated with a pharmacologic regimen and followed by angiography and PCI is attractive, particularly among patients being transferred for PCI. Nevertheless, there has been considerable controversy as to the role of PCI after apparently successful fibrinolytic therapy. In a series of trials performed in the late 1980s, the TIMI investigators reported no benefit from routine application of an immediate or delayed invasive strategy, compared to a more conservative strategy in which catheterization was reserved for patients with recurrent or provocable ischemia [59,60]. Because these trials were published, dramatic advances in interventional cardiology have taken place, including improvements in catheter and stent technology, careful attention to groin hemostasis, and improvements in adjunctive antiplatelet and antithrombotic regimens; as a result, PCI can be performed effectively and safely early after fibrinolytic therapy [61]. In addition, it is well known that patients who arrive in the catheterization laboratory with a patent IRA prior to "primary" PCI, either due to spontaneous lysis or due to pharmacologic reperfusion, have an extraordinarily low risk for mortality [62].

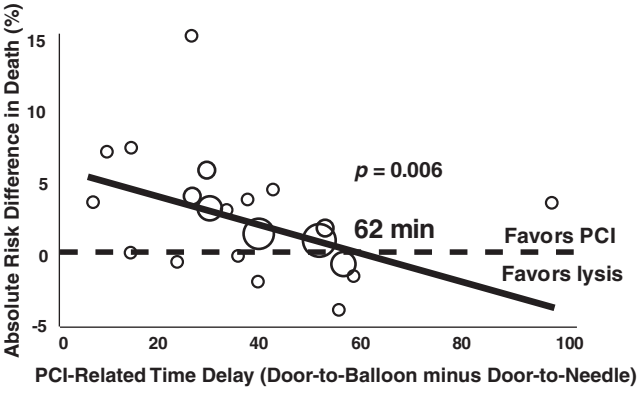

FIGURE 39.8. Metaregression evaluating the association between time delay associated with primary PCI and the absolute benefit of primary PCI over fibrinolytic therapy. Circle sizes represent the sample size of individual studies and the solid line represents the weighted metaregression. For every 10-minute delay to PCI, a 1% reduction in the mortality difference of primary PCI versus lytics was observed. [Adapted from Nallamothu BK, Bates ER: Percutaneous coronary intervention versus fibrinolytic therapy in acute myocardial infarction: is timing (almost) everything? *Am J Cardiol* 92(7):824–826, 2003.]

The term "facilitated" PCI has been coined to signify the administration of a pharmacologic reperfusion regimen en route to the cardiac catheterization laboratory for a planned "primary" PCI. A number of different pharmacologic pretreatment regimens have been proposed, including fibrinolytic agents alone (at full or reduced dose), combinations of GP IIb/IIIa inhibitors and reduced-dose fibrinolytics, and GP IIb/IIIa inhibitors alone. To date, the clinical trial results regarding facilitated PCI using regimens that contain a fibrinolytic have been disappointing: although surrogate measures of early reperfusion are enhanced, no favorable efficacy outcomes have been observed and bleeding rates are clearly increased [63,64]. Moreover, the usefulness of administration of a GP IIb/IIIa inhibitor alone prior to the arrival in the catheterization laboratory is uncertain [46,64].

An alternative pharmacoinvasive strategy that may be logistically attractive for patients presenting to non-PCI centers is to perform initial pharmacologic reperfusion therapy followed by transfer for routine *nonemergent* coronary angiography and revascularization if needed. This pathway has shown favorable results in several relatively small studies [65–67] and more recently in the larger TRANSFER-AMI trial [68]. In TRANSFER-AMI trial, 1,059 high-risk patients with STEMI presenting to hospitals without PCI capability received pharmacologic reperfusion with a regimen that contained tenecteplase and were randomized to standard treatment on site or to immediate transfer and PCI within 6 hours after fibrinolysis. Interestingly, most patients in the standard treatment arm underwent coronary angiography, but this was performed approximately 1 day later than in the transfer arm. The primary endpoint of death, MI, recurrent ischemia, CHF, or cardiogenic shock within 30 days

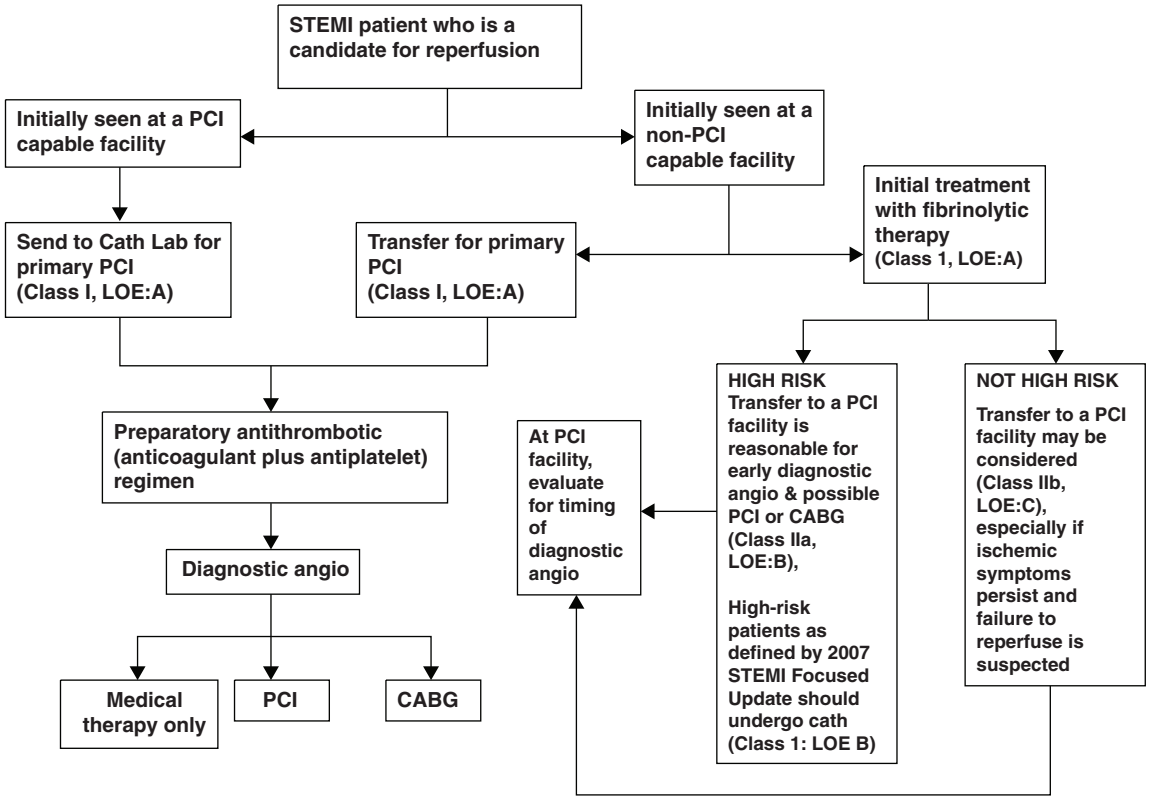

FIGURE 39.9. An algorithm for triage and transfer for primary PCI among patients with ST elevation MI. [Adapted from Kushner FG, Hand M, Smith SC Jr, et al: 2009 Focused Updates: ACC/AHA Guidelines for the Management of Patients With ST-Elevation Myocardial Infarction (updating the 2004 Guideline and 2007 Focused Update) and ACC/AHA/SCAI Guidelines on Percutaneous Coronary Intervention (updating the 2005 Guideline and 2007 Focused Update): a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 120(22):2271–2306, 2009.]

was reduced from 17.2% in the standard treatment arm to 11.0% in the early PCI arm (HR 0.64; $p = 0.004$). For patients who present to hospitals without PCI capability and in whom the door-to-balloon time is expected to be longer than 90 minutes, these data support a strategy of "drip and ship," in which standard pharmacologic reperfusion therapy is administered and the patient transferred for subsequent catheterization and PCI. The timing of the catheterization and PCI remains controversial. Data from studies of facilitated PCI suggest that very early PCI (i.e., within 2 hours) is not helpful and may be harmful. However, the accumulated data described previously suggest favorable outcomes if the PCI is performed between 2 and 24 hours after successful fibrinolytic therapy. An important consideration may be the use of adequate anticoagulant and antiplatelet therapy in the setting of the transient prothrombotic state that may be initiated by the release of fibrin degradation products during fibrinolysis.

ADJUNCTIVE ANTIPLATELET AND ANTITHROMBOTIC THERAPY

Aspirin and Oral P_2Y_{12} Inhibitors

In patients with STEMI, aspirin decreases reocclusion and reinfarction rates by nearly 50% and mortality by approximately 25% [69]. The benefits of aspirin are comparable to those of fibrinolytic therapy, and when used together, aspirin and fibrinolytic therapy provide additive benefit [70]. Aspirin should be initiated at an oral dose of 162 to 325 mg (preferably chewed) at the time the patient is first encountered by medical personnel in the field or emergency department. Following MI, lifelong therapy with aspirin is indicated to prevent recurrent cardiac events. Efficacy appears to be similar at all doses greater than 75 mg, whereas bleeding risk clearly increases with higher aspirin dose. Thus, for most patients, an 81-mg dose of aspirin is preferred for long-term secondary prevention [71].

Clopidogrel is a thienopyridine derivative that inhibits the binding of ADP to the P_2Y_{12} receptor on the platelet surface, thereby decreasing platelet activation and aggregation. The CLARITY trial compared clopidogrel (300-mg loading dose followed by 75 mg per day) with placebo in 3,491 patients with STEMI who were treated with standard pharmacologic reperfusion including fibrinolytic therapy, aspirin, and heparin. The primary composite endpoint of death, MI, or an occluded IRA assessed at the time of protocol-mandated angiography (average 3 to 4 days) was reduced from 21.7% in the placebo arm to 15.0% in the clopidogrel arm ($p < 0.001$; Fig. 39.10). At 30 days, the clinical composite of death, MI, or urgent revascularization was reduced by 20% ($p = 0.03$) [72]. The much larger COMMIT trial was performed in more than 45,000 patients in China and was designed to evaluate the impact of adjunctive clopidogrel (administered at 75 mg per day without a loading dose) on death and major clinical events. Clopidogrel reduced death, reinfarction, or stroke by 9% and death alone by 7%, both of which were statistically significant [73]. In both these trials, the combination of clopidogrel and aspirin showed no excess in bleeding compared to aspirin alone. Using the results of these two trials, clopidogrel should now routinely be added

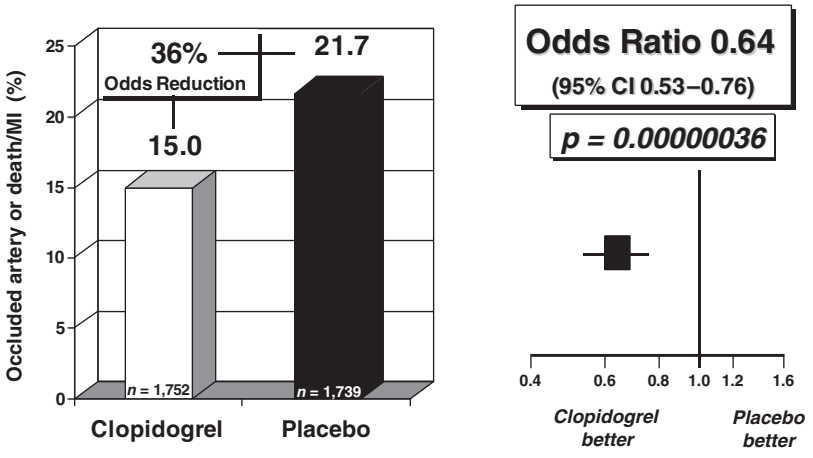

FIGURE 39.10. Influence of clopidogrel on outcomes in patients treated with fibrinolytic therapy for STEMI in the CLARITY trial. The primary endpoint was an occluded infarct-related artery, or death or MI occurring at or before the time of angiography 3 to 8 days after treatment. [Adapted from Sabatine MS, Cannon CP, Gibson CM, et al: Addition of clopidogrel to aspirin and fibrinolytic therapy for myocardial infarction with ST-segment elevation. *N Engl J Med* 352(12):1179–1189, 2005.]

to standard fibrinolytic regimens in patients younger than 75 years [28].

For patients undergoing primary PCI, an oral P_2Y_{12} receptor antagonist should be administered in addition to aspirin: a loading dose followed by a *minimum* of 12 months of maintenance therapy is recommended for patients with STEMI receiving a stent (BMS or DES) [46]. Presently available alternatives include clopidogrel and prasugrel, a novel thienopyridine.

If clopidogrel is used, a loading dose of 300 to 600 mg should be given as early as possible before or at the time of PCI [46]. Recently, higher loading dosages of clopidogrel have been evaluated in the CURRENT/OASIS 7 trial, which compared high-dose (600-mg loading dose, 150 mg per day for 7 days, and then 75 mg per day) with standard-dose (300-mg loading dose and then 75 mg per day) clopidogrel among 24,769 patients with ACS, 17,232 (70%) of whom underwent PCI. The overall result of the trial was neutral. However, in the subgroup of patients who underwent PCI, the higher dose clopidogrel strategy was associated with a lower rate of the primary endpoint of cardiovascular (CV) death, MI, or stroke at 30 days (4.5% vs. 3.9%; HR 0.85; $p = 0.036$). Risk reduction was similar in the STEMI ($n = 6{,}346$) and UA/NSTEMI ($n = 10{,}996$) subgroups; moreover, among patients with STEMI, high-dose clopidogrel was associated with a lower risk for stent thrombosis (4.0% vs. 2.8%). The higher dose clopidogrel regimen was also associated with a higher rate of major bleeding (1.1% vs. 1.6%; $p = 0.006$) [74].

Prasugrel is a novel thienopyridine that is more rapidly acting, more potent, and associated with less response variability than clopidogrel. Prasugrel administered as a loading dose of 60 mg followed by 10 mg daily is an option for patients treated with primary PCI, who do not have a contraindication on the basis of specific risks for increased bleeding (including history of known cerebrovascular disease) [46]. The TRITON-TIMI 38 trial enrolled 13,608 patients with ACS who were scheduled to undergo PCI. Patients were randomized to prasugrel (60-mg loading dose and then 10 mg per day) or clopidogrel (300-mg loading dose and then 75 mg per day): both the drugs were initiated at the time of PCI with no pretreatment given. In the subgroup of patients with STEMI ($n = 3{,}534$), the primary efficacy endpoint of CV death, MI, and stroke at a median of 14.5 months was reduced from 12.4% in the clopidogrel arm to 10.0% in the prasugrel arm (HR 0.79; $p = 0.02$). Stent thrombosis occurred in 2.4% patients randomized to clopidogrel versus 1.2% randomized to prasugrel ($p = 0.008$; Table 39.6). Importantly, in the STEMI subgroup, no significant differences were noted in non-CABG bleeding between treatment arms [75].

Although the absence of clopidogrel pretreatment in TRITON-TIMI 38 has important implications regarding the interpretation of the efficacy advantage of prasugrel in the overall trial, this issue is not relevant in patients with STEMI, who do not have time for pretreatment prior to primary PCI. Indeed, patients with STEMI, who tend to be younger and at lower risk for bleeding than those with UA/NSTEMI, and who may benefit from more rapid and intensive early antiplatelet therapy, may be particularly attractive candidates for prasugrel.

Ticagrelor is a novel direct acting and *reversible* oral antagonist of the P_2Y_{12} receptor. This agent, which as of 2010 was not commercially available, provides more rapid onset (and

	$N = 3{,}534$			$N = 7{,}026$		
Endpoint	Prasugrel	Clopidogrel	HR (95% CI)	Ticagrelor	Clopidogrel	HR (95% CI)
CV death, MI, stroke	10.0%	12.4%	0.79 (0.65–0.97)	8.5%	10.1%	0.84 (0.72–0.98)
Stent thrombosis[a]	1.6%	2.8%	0.58 (0.36–0.93)	2.2%	2.9%	0.75 (0.59–0.95)
Non-CABG TIMI major bleeding[a,b]	2.4%	2.1%	1.11 (0.70–1.77)	4.5%	3.8%	1.19 (1.02–1.38)

[a]The stent thrombosis and bleeding results from PLATO are from the entire study because the specific data for STEMI have not yet been reported.
[b]TIMI major bleeding (non-CABG) was the primary bleeding endpoint in TRITON-TIMI 38 and was an additional bleeding endpoint in PLATO. Note that endpoint assessment was at 15 months in TRITON-TIMI 38 and 12 months in PLATO

offset) of action and a more potent and predictable antiplatelet response than clopidogrel. It does not require activation by the cytochrome p450 system. In the PLATO trial [76], ticagrelor (180-mg loading dose, 90 mg twice daily) was compared to clopidogrel (300- to 600-mg loading dose, 75 mg daily) in 18,624 patients with ACS, 38% of whom had STEMI. At the end of the 12-month follow-up period, the primary endpoint of CV death, MI, and stroke occurred in 11.7% of subjects in the clopidogrel arm versus 9.8% in the ticagrelor arm (HR 0.84; 95% CI 0.77 to 0.92; $p < 0.001$). The risk reduction was similar for UA/NSTEMI (HR 0.83; 95% CI 0.74 to 0.93) and STEMI (HR 0.84; 95% CI 0.72 to 0.98; Table 39.6). Similar to the CURRENT/OASIS 7 and TRITON-TIMI 38 trials, stent thrombosis was reduced significantly with the more potent oral antiplatelet regimen. Also consistent with prior studies, an increase in non-CABG major bleeding was observed in the ticagrelor arm (4.5% vs. 3.8%; $p = 0.03$); however, bleeding rates following CABG were lower with ticagrelor, likely because of the shorter half-life of the drug [76].

Several notable findings were observed with ticagrelor in the PLATO trial. First, a significant 21% relative risk reduction in vascular mortality and a 22% reduction in total mortality (5.9% vs. 4.5%; $p < 0.001$) were observed. This is notable as none of the thienopyridine trials demonstrated a mortality reduction. In addition, several unique side effects have been observed with ticagrelor, which are likely mediated by adenosine. These include transient dyspnea, which occurs in 10% to 15% of patients early after treatment initiation, but is not associated with heart failure and usually terminates within a week. Ventricular pauses may also be triggered by ticagrelor early after treatment initiation, but these also decrease in frequency over time, are rarely symptomatic, and have not required clinical intervention.

GP IIb/IIIa Inhibitors

Although use of GP IIb/IIIa inhibitors in elective PCI has been decreasing, these agents remain useful adjuncts to primary PCI in patients with STEMI when heparin is the anticoagulant used. In a meta-analysis involving 3,266 patients enrolled in four randomized trials comparing abciximab with placebo, patients receiving abciximab had a 46% reduction in 30-day death, reinfarction, and urgent target vessel revascularization compared to those who received placebo [77]. Fewer data are available for the other GP IIb/IIIa inhibitors (tirofiban and eptifibatide) in the primary PCI setting. Current ACC/AHA guidelines recommend selective use of any of these agents at the time of primary PCI (class IIa recommendation), for example, among patients with a large thrombus burden or those who have not received adequate thienopyridine loading [46].

Antithrombin Therapies in Patients Receiving Fibrinolytic Therapy

Using data from angiographic trials showing improved IRA patency rates 5 to 7 days after treatment with intravenous unfractionated heparin (UFH) and subsequent outcomes trials with alternative anticoagulants, the AHA/ACC guidelines recommend administration of an anticoagulant (UFH, enoxaparin, or fondaparinux) as adjunctive therapy in all patients receiving pharmacologic reperfusion therapy with the fibrin-specific agents alteplase, reteplase, or tenecteplase. For UFH, recommended dosing is a 60 U per kg bolus (maximum bolus of 4,000 U) plus an initial infusion of 12 U per kg per hour (with a maximum initial infusion rate of 1,000 U per hour) for up to 48 hours. Data to support antithrombin therapy for patients receiving streptokinase come from trials that evaluated the low-molecular-weight heparins (LMWHs) reviparin and enoxaparin among patients receiving streptokinase compared either to placebo (reviparin) or to UFH (enoxaparin) [78,79]. These trials provide both definitive evidence for the clinical benefit of administering an antithrombin in combination with a fibrinolytic and strong support for their use in conjunction with streptokinase as well as the fibrin-specific agents.

LMWHs represent an attractive alternative to UFH for patients receiving fibrinolytic therapy. Following a series of smaller studies that yielded promising results, the ExTRACT-TIMI 25 trial randomized 20,506 patients treated with standard fibrinolytic regimens to intravenous UFH for 48 hours or to enoxaparin. Enoxaparin was given as a 30-mg IV bolus followed by 1 mg per kg every 12 hours until hospital discharge [79]. The bolus dose was eliminated and the maintenance dose reduced to 0.75 mg per kg for patients older than 75 years, because previous trials had suggested a higher risk of ICH among elderly patients with STEMI who received full-dose enoxaparin [80]. The primary endpoint of death or reinfarction was reduced from 12.0% in the UFH arm to 9.9% in the enoxaparin arm (RR 0.83; $p < 0.001$). Major bleeding occurred in 1.4% of UFH-treated patients versus 2.1% of those treated with enoxaparin ($p < 0.001$), but there was no significant difference in ICH, and the net clinical benefit (death/MI/major bleeding) favored enoxaparin.

Fondaparinux, a novel factor Xa inhibitor, was evaluated in the OASIS 6 trial, a complex trial that included patients treated with both fibrinolytic therapy and primary PCI, and also included patients with and without indications for UFH. Although the rate of death or reinfarction was significantly reduced by 21% with fondaparinux compared with placebo, no difference was observed compared with UFH. No increase in bleeding risk was seen with fondaparinux. Notably, the OASIS 6 trial demonstrated a hazard associated with the use of fondaparinux to support primary PCI [81].

The direct antithrombin agents have also been extensively studied as adjuncts to fibrinolytic therapy, but appear to offer no significant advantage over UFH when given with any of the currently available fibrinolytic agents [82–84]. Thus, of the currently available antithrombin agents, LMWH administered for the duration of the hospitalization (up to 8 days) has been shown to be superior to guidelines-based use of UFH. Fondaparinux is superior to placebo and appears to provide similar efficacy and safety to UFH. Observations from both ExTRACT-TIMI 25 and OASIS 6 indicate that more prolonged administration of an anticoagulant for the duration of the index hospitalization is beneficial compared with administering UFH only for 48 hours. As such, present guidelines recommend that patients managed with fibrinolysis should receive anticoagulant therapy for a minimum of 48 hours and preferably for the duration of the hospitalization after STEMI, up to 8 days [53]. Enoxaparin or fondaparinux are preferred over UFH when administration of an anticoagulant for longer than 48 hours is planned in patients with STEMI treated with a fibrinolytic.

Antithrombin Therapy as an Adjunct to Primary PCI

Until recently, UFH—administered in combination with a GP IIb/IIIa receptor antagonist—has served as the preferred adjunctive regimen to support primary PCI for STEMI. In the HORIZONS-AMI trial [85], 3,602 patients undergoing primary PCI for STEMI were randomized to standard care with heparin plus a GP IIb/IIIa inhibitor or to bivalirudin (a direct-acting antithrombin) alone. The primary outcome, which was

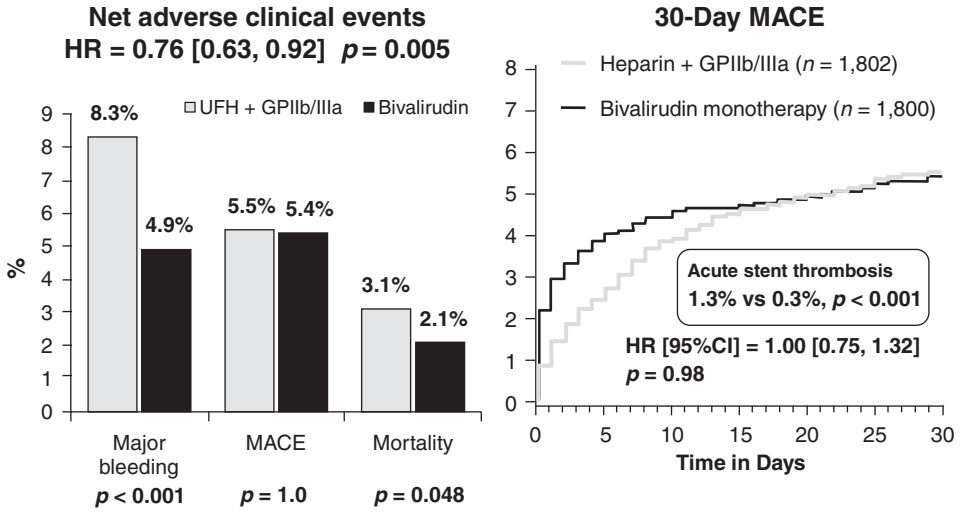

FIGURE 39.11. Results from the HORIZONS-AMI trial. Among patients receiving primary PCI for STEMI, randomization to bivalirudin, as compared to unfractionated heparin plus a GP IIb/IIIa inhibitor, reduced bleeding complications and mortality, but was associated with an increase in early stent thrombosis. [Adapted from Stone GW, Witzenbichler B, Guagliumi G, et al: Bivalirudin during primary PCI in acute myocardial infarction. *N Engl J Med* 358(21):2218–2230, 2008.]

a composite of efficacy and safety endpoints at 30 days, was significantly lower in the bivalirudin versus heparin/GP IIb/IIIa inhibitor arm (9.2% vs. 12.1%; RR 0.76; $p = 0.005$). This was mediated by lower rate of major bleeding with bivalirudin (4.9% vs. 8.3%; RR 0.60; $p < 0.001$) and similar rates of the ischemic outcomes. Total mortality (2.1% vs. 3.1%; $p = 0.05$) and cardiac mortality (1.8% vs. 2.9%; $p = 0.03$) trended lower in the bivalirudin arm (Fig. 39.11). One issue of some concern was an increased risk of stent thrombosis within the first 24 hours in the bivalirudin group. It is possible that this early risk for stent thrombosis may be mitigated by using higher loading doses of clopidogrel [86] or by using more potent novel P_2Y_{12} inhibitors, such as prasugrel. Bivalirudin is a useful alternative to heparin in patients undergoing primary PCI [46].

Warfarin/Oral Anticoagulation

Warfarin monotherapy appears to be at least as effective as aspirin for secondary prevention post-MI. There are several circumstances in which the benefit with warfarin therapy may exceed that of aspirin. First, warfarin is superior to aspirin in preventing systemic emboli in patients with atrial fibrillation. In addition, it reduces systemic emboli in patients with documented LV dysfunction following MI. Because there is a substantial risk of systemic embolization following a large anterior MI, even if thrombus is not visible on echocardiography, many experts recommend 3 to 6 months of warfarin therapy in these patients if they are suitable candidates for anticoagulation [53]. Studies have also evaluated the combination of warfarin and aspirin post-MI. Neither fixed-dose warfarin nor low-dose warfarin titrated to an INR of approximately 1.5 to 2.0 appears to be superior to monotherapy with either agent alone, and the combination is associated with excess bleeding risk [87]. Several studies have shown that the combination of aspirin and warfarin is effective in preventing reocclusion and clinical events when the INR is maintained at a higher level consistently [88–90]. However, these findings are of questionable significance in light of the results of the CLARITY and COMMIT trials, which have demonstrated similar benefit with a simpler regimen of aspirin and clopidogrel. Thus, warfarin plus low-dose aspirin may be a good choice in patients who have another indication for anticoagulation (such as atrial fibrillation or prosthetic valve), provided the bleeding risk is low and a warfarin clinic is available for very careful monitoring.

An increasingly challenging scenario relates to the combination of aspirin, clopidogrel, and warfarin. Emerging evidence suggests that "triple therapy" is associated with substantially increased risks for bleeding. It may be expected that risks will be even higher with combinations that include the newer and more potent antiplatelet agents such as prasugrel and ticagrelor. As such, we recommend attempting to avoid altogether or to minimize the duration of triple therapy. Consideration should be given to using BMS instead of DES, which would allow the duration of clopidogrel to be reduced to 1 month. For patients who require triple therapy, the INR should be maintained at the lowest end of the therapeutic range, aspirin dose should be reduced to 81 mg, and GI prophylaxis with an H_2 antagonist, such as ranitidine, should be considered. For patients with atrial fibrillation, a reevaluation of the risks of bleeding and stroke (using a tool such as the $CHADS_2$ score) should be performed and the threshold to initiate or continue warfarin should be higher among patients on aspirin and clopidogrel [91].

ANTI-ISCHEMIC THERAPY

Beta-Blockers

Beta-blockers were among the first therapeutic interventions used to limit the size of acute MI. Previous trials that excluded patients with heart failure, hypotension, or bradycardia demonstrated that very early administration of a beta-blocker decreases infarct size and prevents recurrent MI and death [92]. The fact that beta-blockers were particularly effective in reducing sudden death and reducing mortality among patients with complex ventricular ectopy at baseline suggests that beta-blockers exert much of their beneficial effect by reducing the frequency and severity of arrhythmias [93]. In addition, they appear to significantly decrease the risk of cardiac rupture. Data from the COMMIT trial in more than 45,000 patients, however, failed to demonstrate benefit from a strategy of immediate intravenous metoprolol followed by 200 mg metoprolol daily on in-hospital outcomes, including death and MI. Although early beta blockade reduced the risks of reinfarction and ventricular fibrillation (VF) compared to placebo, this was counterbalanced by an increased risk of cardiogenic shock during the first few days after admission [94]. Post-hoc analyses indicate that this increased risk was predominantly among patients with indicators of or risk factors for hemodynamic compromise. In addition, the outcome may have been influenced by the high dose of metoprolol used in this study. ACC/AHA guidelines now recommended that beta-blockers be initiated

orally, within the first 24 hours, once it has been determined that the hemodynamic status is stable and there is no evidence of heart failure. Parenteral beta-blockers should be used only if there is a clear indication such as ongoing chest pain or an atrial tachyarrhythmia with normal or elevated blood pressure [28].

When given long term following MI, beta-blockers significantly reduce the incidence of nonfatal reinfarction and mortality, an effect that extends to most members of this class of agents [93]. The CAPRICORN trial examined the incremental effect of beta blockade to angiotensin-converting enzyme (ACE) inhibition in post-MI in patients with LV dysfunction but no clinical heart failure. Over a mean follow-up of 1.3 years, the composite of death and myocardial infarction was reduced from 20% in the placebo arm to 14% in the carvedilol arm, a 29% relative reduction. On the basis of robust clinical data and a very favorable cost-to-benefit ratio, long-term oral beta blockade should be continued indefinitely following MI.

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors are routinely used following STEMI to prevent adverse LV chamber remodeling, a gradual process by which the left ventricle assumes a more globular shape and dilates; remodeling is associated with an increased risk for CHF and death. A large overview of almost 100,000 patients found a 7% reduction in 30-day mortality when ACE inhibitors were given to all patients with acute MI, with most of the benefit observed in the first week. The benefit was greatest in high-risk groups, such as those in Killip class II or III, those with LV dysfunction, and those with an anterior MI [95]. In addition to preventing remodeling and CHF, ACE inhibitors also prevent recurrent ischemic events after MI [96]. As opposed to aspirin and reperfusion therapy, it is not crucial to introduce the ACE inhibitor in the hyperacute phase of acute MI.

Angiotensin receptor blockers (ARBs) are effective alternatives to ACE inhibitors in patients with LV dysfunction or heart failure following acute MI, and provide similar long-term outcomes [97]. However, combination therapy with ACE inhibitors and ARBs is not effective post-MI [97]. Because of the larger evidence base and lower cost of ACE inhibitors, they are preferred over ARBs unless side effects to ACE inhibitors develop.

Aldosterone antagonists should also be considered for use in appropriate high-risk patients following STEMI, who are receiving adequate doses of ACE inhibitors. In the EPHESUS trial, which included patients with an LV ejection fraction <40% following an MI and either heart failure symptoms or diabetes, eplerenone treatment (compared to placebo) was associated with a 15% reduction in the risk for mortality [98]. Because of its much lower cost, spironolactone may be considered as an alternative to eplerenone. Aldosterone antagonists should be avoided in patients with hyperkalemia or significant renal dysfunction.

Nitrates

Nitrates dilate large coronary arteries and arterioles, peripheral veins, and to a lesser extent, peripheral arterioles. Venodilation decreases preload, thus reducing both myocardial oxygen demand and symptoms of pulmonary congestion that may complicate MI. The GISSI-3 [99] and ISIS-4 [100] trials collectively enrolled almost 80,000 patients and evaluated the role of long-term (4- to 6-week) nitrate therapy post-MI. Neither study found a significant reduction in mortality with nitrates, although the power to detect such a difference may have been reduced because more than 50% of patients received off-protocol nitrates. Although evidence from randomized clinical trials does not support routine long-term nitrate therapy for patients with uncomplicated MI, it is reasonable to give intravenous nitroglycerin for the first 24 to 48 hours in patients with acute MI who have CHF, recurrent ischemia, or hypertension. Intravenous therapy is preferred in the early phases of MI due its immediate onset of action and ease of titration.

Calcium Channel Blockers

The calcium channel blockers in current use block the entry of calcium into cells via voltage-sensitive calcium channels. In vascular smooth muscle cells, this causes coronary and peripheral vasodilation, whereas in cardiac tissue, it leads to depression of myocardial contractility, sinus rate, and atrioventricular (AV) nodal conduction. The dihydropyridine calcium channel antagonists, of which nifedipine is the prototype, cause coronary and peripheral artery dilation without blocking sinus or AV nodal function. As a result, the potential benefit of these agents is counterbalanced by reflex tachycardia. The short-acting preparations of nifedipine, in particular, appear to be dangerous in the setting of acute MI, as they may cause rapid hemodynamic fluctuations. Sustained-release preparations of nifedipine, on the other hand, can be used safely in combination with a beta-blocker. Amlodipine is a third-generation agent that causes less reflex tachycardia than other dihydropyridines, but as with other calcium channel blockers, there is no documented benefit of this agent following MI, so it should only be used in patients who remain hypertensive after full-dose beta blockade and ACE inhibition.

Diltiazem and verapamil slow the heart rate and modestly reduce myocardial contractility, thereby decreasing myocardial oxygen demand. Of the two agents, verapamil has greater negative inotropic and chronotropic effects. These agents have been given to patients as secondary prevention after stabilization of an index MI. A pooled analysis indicated that verapamil and diltiazem had no effect on mortality following acute MI, but that they did significantly reduce the rate of reinfarction (6.0% vs. 7.5%; $p < 0.01$) [101]. Despite an overall neutral effect of these agents on mortality, among patients with depressed LV function or evidence of CHF, mortality is increased in patients treated with diltiazem or verapamil.

It should be emphasized that there have not been studies comparing the efficacy of verapamil or diltiazem to a beta-blocker. Beta-blockers consistently reduce both mortality and reinfarction and should be recommended for all patients who can tolerate them. Verapamil or diltiazem may be a reasonable alternative for patients who cannot tolerate a beta-blocker, provided LV function is normal, but they should not be given routinely following MI.

ARRHYTHMIAS COMPLICATING ST ELEVATION MYOCARDIAL INFARCTION (Table 39.7)

Ventricular Arrhythmias

Ventricular tachycardia (VT) occurs frequently during the first few days after MI, but does not appear to increase the risk for subsequent mortality if the arrhythmia is rapidly terminated. VT occurring after 24 to 48 hours, however, is associated with a marked increase in mortality. *Monomorphic* VT is usually due to a reentrant focus around a scar, whereas *polymorphic* VT is more commonly a function of underlying ischemia, electrolyte abnormalities, or drug effects.

TABLE 39.7

ELECTRICAL COMPLICATIONS OF ACUTE MI

Complication	Prognosis	Treatment
Ventricular tachycardia/fibrillation		
Within first 24–48 h	Good	Immediate cardioversion; amiodarone or lidocaine; beta-blockers
After 48 h	Poor	Immediate cardioversion; electrophysiology study/implantable defibrillator; amiodarone
Sinus bradycardia	Excellent	Atropine for hypotension or symptoms
Second-degree heart block		
Mobitz type I (Wenckebach)	Excellent	Atropine for hypotension or symptoms
Mobitz type II	Guarded	Temporary pacemaker
Complete heart block		
Inferior MI	Good	Temporary pacemaker
Anterior MI	Poor	Temporary pacemaker followed by permanent pacemaker

VF is the primary mechanism of arrhythmic sudden death. In patients with acute MI, most episodes of VF occur early (<4 to 12 hours) after infarction. As with sustained VT, *late* VF occurs more frequently in patients with severe LV dysfunction or CHF, and is a poor prognostic marker. Patients with VF, or sustained VT associated with symptoms or hemodynamic compromise, should be cardioverted emergently. Underlying metabolic and electrolyte abnormalities must be corrected, and ongoing ischemia should be addressed. We aim to maintain the serum potassium level to 4.5 mEq per L or greater and serum magnesium level 2 mEq per L or more. Intravenous amiodarone is a particularly effective antiarrhythmic agent in patients with acute MI, because it lowers heart rate. Lidocaine remains an effective alternative if amiodarone is not tolerated or is unsuccessful in controlling the arrhythmia. Prophylactic use of antiarrhythmic agents, other than beta-blockers, is not indicated.

Bradyarrhythmias

The usual cause of bradycardia is increased vagal tone or ischemia/infarction of conduction tissue. Sinus bradycardia is typically due to irritation of cardiac vagal receptors, which are located most prominently on the inferior surface of the left ventricle. Thus, this arrhythmia is usually seen with inferior MI. If the heart rate is extremely low (<40 to 50) and is associated with hypotension, intravenous atropine should be given.

Mobitz type I (Wenckebach) second-degree AV block is also very common in patients with inferior wall MI, and may be due to ischemia or infarction of the AV node or to increased vagal tone. The level of conduction block is usually located within the AV node, and therefore the QRS complex is narrow and the risk for progression to complete heart block is low. Atropine should be reserved for patients with hypotension or symptoms, and temporary pacing is rarely required. Mobitz type II block is observed much less often than Mobitz type I block in acute MI. As opposed to Mobitz type I block, Mobitz type II block is more frequently associated with anterior MI, an infranodal lesion, and a wide QRS complex. Because Mobitz type II block can progress suddenly to complete heart block, a temporary pacemaker is indicated.

Although compete heart block may occur with either inferior or anterior MI, the implications differ markedly depending on the location of the infarct. With inferior MI, heart block often progresses from first-(or Wenckebach) to third-degree AV block (see Fig. 39.2). The level of block is usually within or above the level of the AV node, the escape rhythm is often stable, and the effect is transient. Although temporary pacing is often indicated, a permanent pacemaker is rarely required.

TABLE 39.8

SUMMARY OF ADVANCES IN MANAGING STEMI BASED ON RANDOMIZED CONTROLLED CLINICAL TRIALS

- Performance of a prehospital ECG reduces reperfusion times in STEMI [5]
- Fibrinolytic therapy reduces mortality vs. placebo if administered within 12 h of symptom onset, but is associated with a small risk of intracranial hemorrhage [24]
- Aspirin reduces mortality to a similar extent as fibrinolytics [70]
- Primary PCI is superior to fibrinolytic therapy for patients who can be treated within 90 min of presentation in a high-volume center [38]
- Transfer to another facility for early nonemergent PCI should be considered following successful fibrinolytic therapy [68]
- The addition of clopidogrel to aspirin, antithrombins, and fibrinolytic therapy reduces recurrent MI and mortality [72,73]
- Prasugrel and ticagrelor represent alternatives to clopidogrel that reduce stent thrombosis and recurrent ischemic events, but at an increased risk for bleeding [75,76]
- Enoxaparin is superior to unfractionated heparin as an adjunct to fibrinolytic therapy, but is associated with slightly more bleeding [79]
- Beta-blockers improve long-term outcomes following STEMI, but may increase risk when given early to unstable patients [93,94]
- ACE inhibitors prevent adverse remodeling after STEMI and reduce death and heart failure events [95]
- Aldosterone antagonists reduce mortality in patients with LV dysfunction or heart failure following MI, but should be used in caution in individuals with renal dysfunction [98]
- Nitrates and calcium blockers are indicated in selected patients, but not routinely [100,101]

With anterior MI, complete heart block is usually a result of extensive infarction involving the bundle branches. The escape rhythm is usually unstable and the AV block permanent. Mortality is extremely high, and permanent pacing is almost always required in survivors.

Supraventricular Arrhythmias

Atrial fibrillation may occur in up to 15% of patients early after MI, but atrial flutter and paroxysmal supraventricular tachycardia are not commonly seen. Ischemia itself rarely causes atrial fibrillation, except in rare cases of atrial infarction: more common precipitants include heart failure and pericarditis. Although atrial fibrillation is usually transient, it is a marker for increased morbidity and mortality, probably because it is associated with other adverse risk predictors such as LV dysfunction and CHF. Management of supraventricular arrhythmias in the setting of acute MI is similar to management in other settings; however, there should be a lower threshold for cardioversion and ventricular rate should be more aggressively controlled (Table 39.8). Because of their beneficial effects in acute MI, beta-blockers are the agents of choice to control rate. Diltiazem or verapamil may serve as alternatives in patients without significant CHF or LV dysfunction, whereas digoxin should be reserved for patients with concomitant LV dysfunction. Of the antiarrhythmic agents available, amiodarone is safest in patients with recent MI, because it has a low risk for proarrhythmia.

CHAPTER 40 ■ MECHANICAL COMPLICATIONS OF MYOCARDIAL INFARCTION

ANNABEL A. CHEN-TOURNOUX AND MICHAEL A. FIFER

PATHOPHYSIOLOGY UNDERLYING MYOCARDIAL STUNNING AND ITS TIME COURSE FOLLOWING ISCHEMIA AND REPERFUSION

Within 8 to 10 seconds after occlusion of an epicardial coronary artery, myocardial oxygen supply is exhausted, resulting in a shift from aerobic to anaerobic metabolism. High-energy phosphates (creatine phosphate and adenosine triphosphate [ATP]) become depleted, whereas hydrogen ions, lactate, and other metabolic products accumulate, causing intracellular pH to fall to 5.8 to 6.0 within 10 minutes of the onset of ischemia [1]. In addition, adenosine monophosphate (AMP) is degraded to adenosine, which diffuses into extracellular fluid, depleting the intracellular adenine nucleotide pool. The ischemic myocardium stretches instead of shortens during systole, corresponding to regional wall motion abnormalities observed with imaging modalities, such as echocardiography. Electrocardiogram (ECG) changes appear as well. Disruption of the cell membrane allows protein leakage out of the cell, producing serologic evidence of myocyte injury. If blood flow is restored within 15 minutes of coronary occlusion, myocyte injury is reversible. Glycolysis ceases after approximately 40 minutes of severe ischemia, after which time injury becomes irreversible and myocytes are not salvageable by reperfusion. Even with earlier restoration of blood flow, however, a phenomenon called myocardial stunning is observed.

First described in a dog model by Heyndrickx et al. [2] in 1975, stunning is defined as prolonged contractile dysfunction occurring after relief of a discrete episode or episodes of ischemia. Importantly, the dysfunction associated with stunning is completely reversible. By definition, myocardial perfusion must be restored to normal or near normal to distinguish stunning from myocardial dysfunction due to continued ischemia (hibernation). The severity and duration of stunning depend on

multiple factors, such as the extent of the original ischemic insult, the adequacy of restored flow, the presence of preexisting collateral vessels, and prior ischemic preconditioning. In general, the myocardium is stunned for a period longer than that of the ischemic insult, often requiring hours to days to regain function [3].

Although early restoration of flow is necessary for myocardial survival, reperfusion is also thought to underlie the pathogenesis of stunning, through the development of oxidative stress and/or impaired calcium homeostasis [4]. In the first 5 minutes of reperfusion, there is marked hyperemia, with a 400% to 600% increase in flow, returning to the baseline level after 15 to 20 minutes. Because levels of oxygen-free radicals peak at 4 to 7 minutes, most of the free radical-induced injury responsible for stunning is thought to occur in the initial moments following reperfusion. Blunted calcium transients and dysfunction of the ryanodine receptor and the sarcoplasmic reticulum calcium ATPase (SERCA-2), which would lead to impaired myocyte excitation–contraction coupling, have also been described following ischemia–reperfusion. Other possible mechanisms of reperfusion injury involved in myocardial stunning include microvascular injury, endothelial cell dysfunction, and activation of neutrophils, platelets, and the complement system.

Stunning is observed in clinical scenarios in which the heart is reperfused after transient ischemia, whether it be global, as with cardioplegia during cardiac surgery or transplant harvest, or regional, as with acute coronary syndromes, percutaneous coronary interventions (PCI), or exercise-induced angina. In patients with coronary disease, stunning from repeated episodes of demand ischemia may lead to chronic left ventricular (LV) dysfunction.

Stunned, but viable, myocardium may be identified by echocardiographic, scintigraphic, and magnetic resonance imaging techniques [5]. Because ischemic myocytes have different rates of injury and recovery, the timing of improvement after acute myocardial infarction (MI) is variable and often unpredictable. The major clinical implication of stunning is that even brief periods of ischemia may be associated with prolonged contractile dysfunction. Moreover, because this dysfunction may be fully reversible, continued hemodynamic support, with intra-aortic balloon counterpulsation and/or inotropic agents such as catecholamines or phosphodiesterase inhibitors, may be indicated. Importantly, inotropic stimulation does not appear to worsen cell injury as long as the reperfused artery is patent. Finally, myocardial stunning has implications for the timing of evaluation of LV function to guide therapeutic decisions after MI. For example, LV ejection fraction assessment for implantable cardiac defibrillator implantation is generally deferred for at least 1 month following MI.

DIAGNOSIS, TREATMENT, AND OUTCOME OF SHOCK DUE TO LEFT VENTRICULAR PUMP FAILURE

Approximately 5% to 8% of patients with ST-segment elevation MI (STEMI) and 2.5% of patients with non–ST-segment elevation MI develop cardiogenic shock (CS), the leading cause of death in patients hospitalized with MI (Table 40.1). CS is broadly defined as a state of end-organ hypoperfusion due to cardiac failure. Clinical evidence of systemic hypoperfusion includes altered mental status, cold clammy skin, and oliguria. Hemodynamic parameters of CS include persistent (≥1 hour) hypotension (systolic blood pressure <80 to 90 mm Hg or mean arterial pressure 30 mm Hg lower than baseline) not responsive to fluid or requiring inotropic or vasopressor support to be maintained; low cardiac index (<1.8 L per minute per m^2 without support or 2.0 to 2.2 L per minute per m^2 with support); and adequate or elevated filling pressures (LV end-diastolic pressure >15 mm Hg or right ventricular [RV] end-diastolic pressure >10 to 15 mm Hg).

In the absence of mechanical complications, the primary insult in CS associated with MI is LV dysfunction due to extensive infarction or ischemia. Although the magnitude of myocardial insult does not correlate perfectly with the development of CS [6], LV function nevertheless remains a prognostic factor in CS [7].

The observation of normal to low systemic vascular resistance among many patients with CS [8] suggests an important role for inappropriate vasodilation in CS. Indeed, neurohormonal and cytokine abnormalities consistent with the systemic inflammatory response syndrome (SIRS) have been observed (Fig. 40.1) [6]. For example, cytokines with myocardial depressant activity, such as tumor necrosis factor (TNF)-α and interleukin (IL)-6, increase over 24 to 72 hours after MI. MI is also associated with abnormal NO metabolism [9] and increased expression of inducible nitric oxide (NO) synthase; NO excess causes vasodilation, depressed myocardial contractility, and interference with catecholamine action in CS. Despite the

TABLE 40.1

NATIONAL REGISTRY OF MYOCARDIAL INFARCTION: ALL-CAUSE IN-HOSPITAL MORTALITY FOR PATIENTS WITH ACUTE MYOCARDIAL INFARCTION

Cause of death	All MI patients (359,755) (%, *n*)	No fibrinolytic therapy (228,512) (%, *n*)	Fibrinolytic therapy (91,218) (%, *n*)	*p*-value

growing recognition of SIRS associated with CS, therapies targeting it remain unproven at this time.

Most cases of CS after acute coronary syndrome develop after hospital presentation, with a median time of 10 to 11 hours (STEMI) and 76 hours (non–ST-segment elevation MI) [10]. Predictors for CS have varied among different studies over time and include older age; prior MI, heart failure, diabetes, hypertension, or cerebrovascular disease; failed reperfusion; lower blood pressure and glomerular filtration rate; and higher heart rate and serum glucose at presentation [6,11]. The only way to prevent CS appears to be very early reperfusion therapy for MI, whether through PCI or thrombolysis.

Outcome in CS is closely related to the patency of the infarct-related artery, in both retrospective analyses [12] and the prospective, randomized SHOCK (*sh*ould we emergently revascularize *o*ccluded *c*oronaries in cardiogenic sho*ck*) trial. In this multicenter study, patients with acute MI and CS were randomly assigned to early (within 6 hours) percutaneous or surgical revascularization (152 patients) or initial medical stabilization with subsequent revascularization permitted 54 hours after randomization (150 patients) [13,14]. Fibrinolysis was recommended in the initial medical stabilization group, and intra-aortic balloon counterpulsation was recommended in both treatment groups. Although there was an excess of death in the early revascularization group in the first 5 days, likely related to procedural complications, early revascularization improved survival at 6 months and 1 year (46.7% vs. 33.6%; $p < 0.03$), a benefit that remained stable at 3 and 6 years [15]. Although the benefit of revascularization increases the earlier it is achieved, there is a survival benefit as long as 48 hours after MI and 18 hours after shock onset. The benefit of early revascularization is similar for different subgroups (patients with diabetes, women, patients with prior MI, early vs. late shock) and whether revascularization is achieved with PCI or coronary artery bypass graft surgery [16]. Among patients undergoing PCI, registry data indicate that stenting and glycoprotein IIb/IIIa inhibitors are independently associated with improved outcomes [17]. On the basis of these results, emergency revascularization is recommended (class I) for patients younger than 75 years with MI and CS, who are determined to be suitable candidates [18]. If revascularization is not available, fibrinolysis and intra-aortic balloon pump placement followed by transfer to another facility is recommended.

In the SHOCK trial, lack of benefit with early revascularization was noted for patients 75 years and older, possibly due to imbalances in baseline ejection fraction. Later studies, including the SHOCK registry [19], have shown a consistent benefit of revascularization in elderly patients selected for it. Thus, an individualized approach weighing the risks and benefits of an aggressive revascularization strategy is warranted for elderly patients.

Multivessel or left main disease is extremely common in patients with MI and CS. Coronary bypass surgery is recommended for extensive disease [18], although PCI of the infarct-related artery may be initially necessary to stabilize the patient.

In addition to early revascularization, supportive therapy with inotropic agents and vasopressors (and avoidance of negative inotropes and vasodilators) is critical. Diuretics or intravenous fluids may be required, depending on the intravascular volume status. Routine antithrombotic therapy for MI includes aspirin, heparin, and if immediate surgery is unlikely, clopidogrel. Oxygen supplementation is standard and mechanical ventilation may be necessary. Intensive insulin therapy is also recommended in critically ill patients [18].

Hemodynamic management of CS may be guided by pulmonary artery catheter monitoring and echocardiography. Such monitoring also allows detection of mechanical complications such as papillary muscle or ventricular septal rupture (VSR).

The principal mechanical therapy for CS is intra-aortic balloon counterpulsation, which augments coronary perfusion and reduces cardiac afterload. For some patients who require a bridge to recovery or subsequent transplantation, short-term support may be offered in the form of LV assist device (LVAD) or extracorporeal life support [20]. Comparisons of percutaneous LVAD to intra-aortic balloon counterpulsation (IABP) have shown similar mortality rates [21–23].

Independent predictors of mortality in CS have varied in different studies over time, and include older age; history of hypertension, MI, or heart failure; lower blood pressure and worse renal function on presentation; failed reperfusion; and low LV ejection fraction [7,11,12,15]. Revascularization provides benefit at every level of risk, and registry studies in the United States and Europe have indicated significant decline (approximately 60% to 48%) in mortality from CS in recent years, in parallel with increasing revascularization with PCI [11,24,25].

RIGHT VENTRICULAR INFARCTION

Right ventricular infarction (RVI) has been recognized as a distinct entity since the initial description of its unique clinical and hemodynamic features in 1974 [26]. Most cases of RVI are due to proximal occlusion of a dominant right coronary artery, and RVI has been described in up to 50% of patients with inferior MI. (Very rarely, RVI may accompany anteroseptal MI due to a culprit left anterior descending artery lesion.) RVI leads to RV hypokinesis and decreased delivery of LV preload across the pulmonary vasculature. In addition, acute RV dilation in the face of the restraining effects of the pericardium leads to elevated intrapericardial pressure and leftward shifting of the interventricular septum, further compromising LV filling [27].

Early recognition of RVI is crucial because of its implications for management and prognosis, so that involvement of the RV should be considered in all patients with inferior MI. Clinical indicators of RVI include hypotension in the setting of clear lungs and elevated jugular venous pressure, although the latter may not be evident if the patient is relatively hypovolemic. Conversely, a volume-depleted patient may exhibit sensitivity to preload reduction, such as with the use of nitrates or diuretics. Patients may also display evidence of interventricular dependence, such as Kussmaul's sign (distention of jugular veins during inspiration), more classically associated with pericardial disease.

Several ECG signs indicate RV involvement: ST-segment elevation in lead 3 greater than in lead 2, ST-segment elevation in lead V_1, and ST-segment elevation in right-sided precordial lead V_{4R}, the latter being the most predictive [28] (Fig. 40.2). These ECG abnormalities may resolve quickly (50% within 10 hours) [29], underscoring the importance of obtaining a right-sided ECG on presentation for all patients with inferior MI. RVI may be associated with bradyarrhythmias (sinoatrial or atrioventricular [AV] block) and tachyarrhythmias (atrial fibrillation and ventricular tachyarrhythmias). Echocardiography reveals RV dilation and hypokinesis and abnormal septal motion, along with inferior LV hypokinesis, and possibly other complications of RVI, such as tricuspid regurgitation, VSR, RV mural thrombus and pulmonary embolism, and right-to-left shunting across a patent foramen ovale. A small study suggests that late-enhancement magnetic resonance imaging has superior sensitivity to detect RVI compared with physical examination, ECG, and echocardiography [30]. Finally, right heart catheterization demonstrating a right atrial pressure equal or greater than 10 mm Hg or greater than 80% of the pulmonary capillary wedge pressure supports the diagnosis of RVI [26].

Treatment of RVI should emphasize urgent reperfusion, whether by thrombolysis or PCI. Successful reperfusion is associated with significantly improved RV function and clinical outcome [31–33]. Supportive measures are critical as well. Intravenous fluid should be judiciously administered to maintain optimal RV preload. A cautious challenge of 1 to 2 L is a reasonable start. Central venous pressure (CVP) monitoring may be helpful in avoiding RV volume overload (CVP exceeding 10 to 14 mm Hg), which may compromise LV preload via ventricular interdependence [34]. Because right atrial contraction is an important contributor to right-sided output, AV synchrony should be maintained, with AV sequential pacing in the case of complete heart block or conversion to sinus rhythm in the case of atrial fibrillation. In cases where right coronary artery occlusion is proximal to the atrial branches, resulting in right atrial ischemia, the CVP tracing may demonstrate depressed A-waves and right atrial pacing may fail to capture. Inotropic support and LV afterload reduction with intra-aortic balloon counterpulsation may also be necessary. Pure α-adrenergic agonists should be avoided because they may increase pulmonary vascular resistance, to which the compromised RV is particularly sensitive. Although tricuspid regurgitation usually remits as RV function recovers, patients with papillary muscle rupture (PMR) or severe papillary muscle dysfunction and a dilated annulus require surgical repair. Pericardiectomy and creation of atrial septal defects may be attempted in extreme cases of hemodynamic compromise.

Hemodynamic instability associated with RVI represents only 5% of cases of CS complicating MI but portends a high in-hospital mortality, ranging from 23% in one report [35] to 53% in the SHOCK trial registry [36]. Although RVI is associated with substantial in-hospital and first-year mortality, patients surviving the acute insult generally have a good prognosis [37]. Most patients demonstrate recovery of RV function in the weeks following RVI. The resilience of the RV after ischemic injury has been attributed to the more favorable balance between myocardial oxygen demand and coronary perfusion as compared with the LV. The positive long-term course of patients after RVI highlights the importance of early diagnosis, early reperfusion, and intensive hemodynamic support.

MYOCARDIAL RUPTURE

Myocardial rupture is a rare, but immediately life-threatening, complication of MI, accounting for 10% to 15% of deaths. Transmural necrosis or myocardial hemorrhage is found at the site of rupture. In the National Registry of Myocardial Infarction, older age, female gender, and fibrinolysis were independent predictors of myocardial rupture [38].

Myocardial rupture may occur despite a limited infarct area and relatively preserved systolic function because of increased shear stress in the necrotic area or its ischemic boundaries. Rupture is possible at three sites: the ventricular free wall (85%), the ventricular septum (10%), or a papillary muscle (5%). The specific presentations and sequelae depend on the location of the defect(s) (Table 40.2), but in all cases, prompt diagnosis and definitive surgical therapy are critical.

Papillary Muscle Rupture

PMR involves the posteromedial papillary muscle (75%) more often than the anterolateral papillary muscle (25%) because of the single vascular supply of the former (right coronary or left circumflex artery, depending on dominance). In contrast, the anterolateral papillary muscle has a dual vascular supply, from the left anterior descending and circumflex arteries. The posteromedial papillary muscle consists of one or two trunks and multiple heads, all of which extend chordae to both mitral valve leaflets. Complete or partial rupture of a trunk or head leads to varying degrees of mitral regurgitation. (Severe mitral regurgitation may also occur with leaflet prolapse due to reduced tethering by an infarcted, but nonruptured, papillary muscle.)

Because PMR may occur despite a limited territory of infarction, it is not uncommon for patients to have relatively preserved LV function in comparison to the degree of heart failure and CS at presentation [39,40]. Patients present with acute dyspnea due to pulmonary congestion. Physical examination may include a systolic murmur, though this may be absent due to equalization of left atrial (LA) and LV pressures. Therefore, a heightened index of suspicion is necessary to distinguish PMR from pure LV dysfunction.

PMR is suggested by the presence of large V-waves in the pulmonary capillary wedge pressure tracing, although this

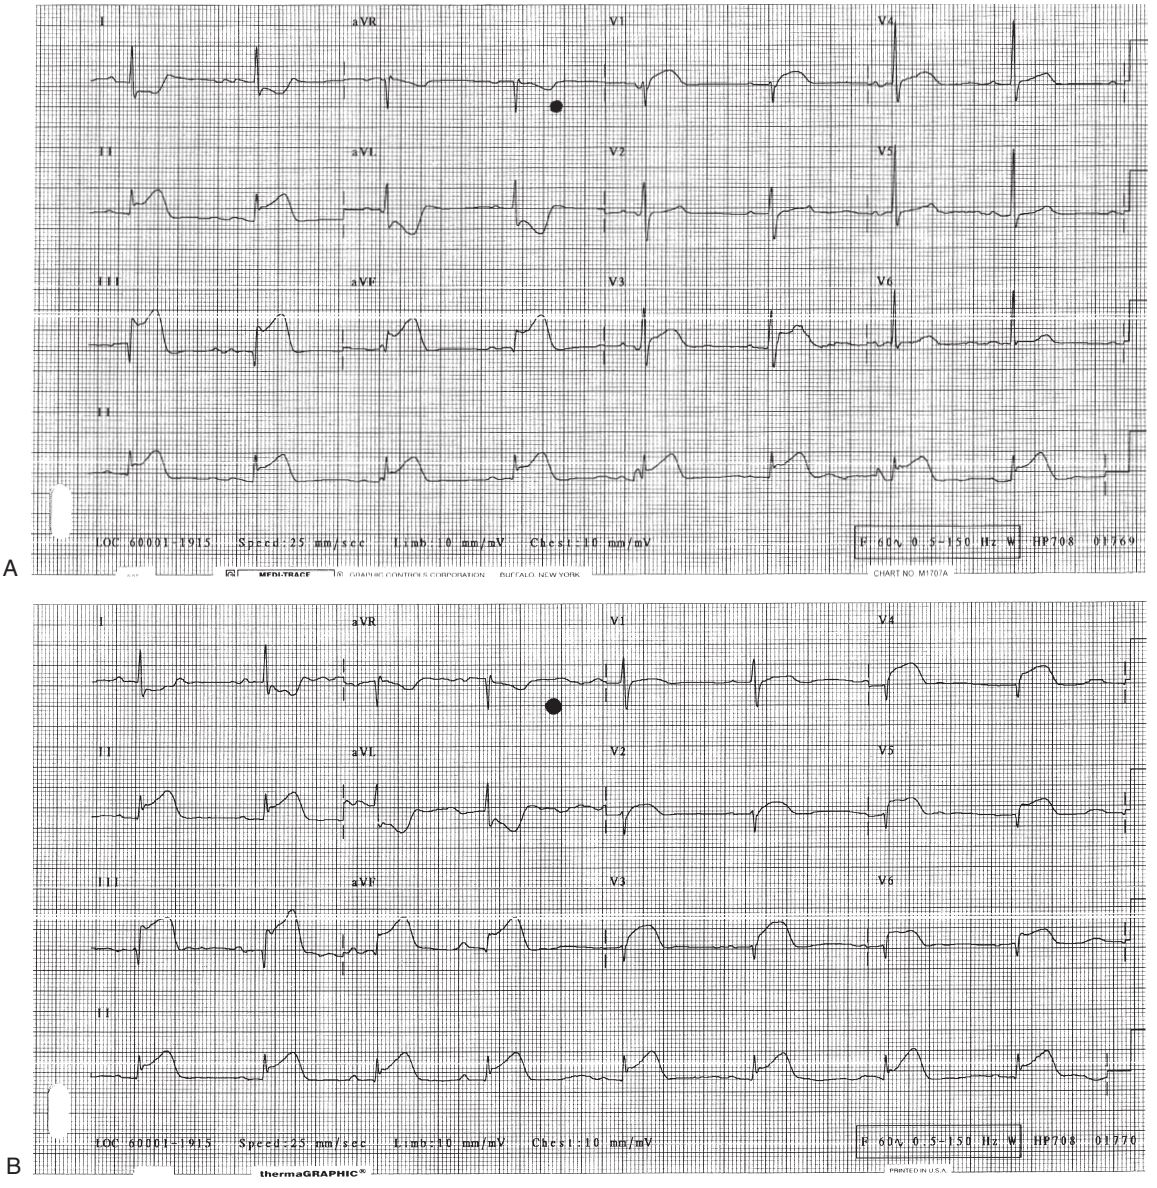

FIGURE 40.2. A: ECG of patient with inferior STEMI and sinus bradycardia showing ST-segment elevation in lead 3 greater than in lead 2 and ST-segment elevation in lead V_1, suggesting RV involvement. **B:** Right-sided placement of precordial leads demonstrates ST-segment elevation in lead V_{4R}, confirming RVI. In this figure, lead V_1 is V_{1R}, V_2 is V_{2R}, V_3 is V_{3R}, V_4 is V_{4R}, V_5 is V_{5R}, and V_6 is V_{6R}.

finding may also be seen with severe LV dysfunction, VSR, or other causes of mitral regurgitation. The diagnosis of PMR is made more definitively by echocardiography, on visualization of a flail portion of a mitral valve leaflet or a ruptured papillary muscle head prolapsing into the left atrium, along with color Doppler evidence of mitral regurgitation.

Stabilization may be accomplished with the use of inotropic agents, afterload reduction if possible, and insertion of an intra-aortic balloon pump. However, with an in-hospital mortality of up to 80% and a long-term survival rate of approximately 6% with medical therapy alone [39,40], urgent surgical repair is indicated. This may consist of chordal-sparing mitral valve replacement or, if necrosis is limited, papillary muscle reimplantation with or without ring annuloplasty. Coronary angiography should be performed so that necessary revascularization may be performed at the time of surgery. Although perioperative mortality (10% to 24%) remains significant, it is reduced with concomitant coronary artery bypass grafting [41,42]. Long-term survival after surgery ranges from 60% to 80%, and is similar to that of matched patients with MI, but no PMR [42].

Ventricular Septal Rupture

The presentation of VSR has changed as treatment for acute MI has evolved to include fibrinolysis and primary PCI. Before the advent of fibrinolytic and percutaneous reperfusion therapies, VSR occurred in 1% to 2% of patients with acute MI, with a mean onset of 3 to 5 days after infarction. In the thrombolytic era, the incidence is approximately 0.2%, with a median onset in the first 24 hours after MI [38,43,44]. Approximately two thirds of VSR cases occur in the mid- to distal septum in association with anterior MI; the remainder occur in

TABLE 40.2

CHARACTERISTICS OF MYOCARDIAL RUPTURE

Characteristic	Ventricular septal rupture	Free wall rupture	Papillary muscle rupture
Incidence	1%–3% without reperfusion therapy; 0.2%–0.34% with fibrinolysis; 3.9% in patients with cardiogenic shock	0.8%–6.2%; primary angioplasty, but not fibrinolysis, appears to reduce risk	1%; posteromedial more frequent than anterolateral papillary muscle
Time course	Bimodal peak: <24 h and 3–5 d; range 1–14 d	Bimodal peak: <24 h and 3–5 d; range 1–14 d	Bimodal peak: <24 h and 3–5 d; range 1–14 d
Clinical manifestations	Chest pain, dyspnea, hypotension	Anginal, pleuritic, or pericardial chest pain; syncope, hypotension, arrhythmia, nausea, restlessness, hypotension, sudden death	Abrupt onset of dyspnea due to pulmonary edema; hypotension
Physical findings	Harsh holosystolic murmur, thrill, accentuated S_2, S_3, pulmonary edema, RV and LV failure, cardiogenic shock	Jugular venous distention, pulsus paradoxus, electromechanical dissociation, cardiogenic shock	Soft murmur in some cases, no thrill, variable signs of RV overload, severe pulmonary edema (may be asymmetric), cardiogenic shock
Echocardiographic findings	VSR, color Doppler left-to-right shunt across septum, RV dilation, and hypokinesis	Myocardial tear, >5 mm pericardial effusion not always visualized; clot within pericardial space, tamponade	Hypercontractile LV, torn papillary muscle or chordae tendineae, flail leaflet, severe MR by color Doppler
Cardiac catheterization	Oxygen saturation step up from RA to RV, large V-waves	Ventriculography insensitive; equalization of diastolic pressures	No oxygen saturation step up from RA to RV (may occur from RV to PA); large V-waves, high PCWP

LV, left ventricle; MR, mitral regurgitation; PA, pulmonary artery; PCWP, pulmonary capillary wedge pressure; RA, right atrial; RV, right ventricle; VSR, ventricular septal rupture.
Adapted from Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Revise the 1999 Guidelines for the Management of Patients With Acute Myocardial Infarction). Available at www.acc.org/clinical/guidelines/stemi/index.pdf.

the basal septum in association with inferior MI. On the basis of the anatomy of the rupture track, VSR may be classified as simple (directly through and through) or complex (serpiginous, with an exit site remote from the entry site); complex VSRs are more frequently noted with inferior MI. Five percent to 10% of patients have multiple defects. VSR is typically associated with total occlusion of the infarct-related artery with little or no collateral flow. Risk factors for VSR include advanced age, female sex, anterior MI, and no previous smoking [44]. In addition, in patients with anterior MI, the presence of ST-segment elevation or Q-waves in the inferior leads, indicating a "wrap-around" left anterior descending artery supplying both the anterior and inferior LV walls, may identify patients at risk for VSR [45].

VSR causes sudden shunting of flow from the LV to the pulmonary circulation. This results in impaired forward cardiac output. There is acute pressure overload of the RV and volume overload of the pulmonary circulation and LV, which become evident clinically as right heart failure, pulmonary congestion, and CS. The degree of shunting depends on the rupture size, the relative resistance of the pulmonary and systemic circulations, and the relative function of the RV and LV. As the LV fails and systolic pressure decreases, left-to-right shunting decreases. If RV pressures exceed those on the left, right-to-left shunting occurs, resulting in hypoxemia.

Symptoms of VSR include chest pain and dyspnea. In contrast to patients with PMR, those with VSR have a harsh pansystolic murmur at the left sternal border, with a left parasternal thrill in 50%. Signs of RV failure are also present, including jugular venous distention and peripheral edema. ECG findings include persistent ST-segment elevation and AV nodal or infranodal conduction abnormalities.

The diagnosis of VSR can be made by right heart catheterization demonstrating a step up in the oxygen saturation (>8%) in the RV, to be distinguished from a step up in the pulmonary artery, which is occasionally observed in patients with severe mitral regurgitation. In addition, catheterization reveals increased pulmonary-to-systemic flow ratios ($\dot{Q}_p/\dot{Q}_s$ >1.4), increased right-sided pressures, and large V-waves in the pulmonary capillary wedge tracing; left ventriculography may identify the rupture site. Echocardiography with color Doppler imaging is commonly used for both diagnosis and surgical planning. A visible defect may be seen in association with the corresponding anterior or inferior wall motion abnormality. Continuous wave Doppler interrogation of flow at this site demonstrates dense, high-velocity flow from LV to RV. Echocardiography also provides information about LV and RV function and concomitant mitral valve pathology.

Nonsurgical therapy, such as afterload reduction, diuretics, and inotropic and intra-aortic balloon pump support, is purely temporizing and alone is associated with greater than 90% mortality. Surgical repair of the VSR, first performed in 1957, is definitive. Some have used biventricular mechanical support as a means to restore hemodynamic stability and avoid surgery on freshly infarcted tissue, before definitive surgical repair [46]. Surgical repair has improved 30-day mortality from VSR to 10% to 15% in cases of anterior MI and 30% to 35% in cases of inferior MI. As mortality is higher in patients with complex VSR and in those with RVI [47], the increased mortality with inferior VSRs has been attributed to the more challenging surgical repair due to complex anatomy and basal location and the possibility of concomitant RV infarction. CS at the time of surgical intervention and incomplete coronary

revascularization have also been shown to be strong predictors of 30-day and long-term mortality [48]. Patients who survive the perioperative period have been reported to have a long-term survival rate of approximately 60% to 80%.

Recently, percutaneous transcatheter closure of VSR has been reported in a limited number of patients; appropriate patient selection, technical aspects of device selection and placement, durability of occlusion, and long-term outcome are unknown.

Free Wall Rupture

LV free wall rupture is by far the most common of all ruptures and usually results in sudden death. The temporal pattern of rupture has two peaks, the first within 24 hours and the second between 3 and 5 days after acute MI [49]. Risk factors for free wall rupture are similar to those for VSR, whereas successful early reperfusion and presence of collateral flow are important preventive factors. Pericardial tamponade and electromechanical dissociation often develop quickly, in which case death is inevitable without treatment.

LV pseudoaneurysm develops if free wall rupture is contained by adherent pericardium or clot formation, thus preventing immediate pericardial tamponade and death. Symptoms of contained rupture include recurrent chest pain or pleurisy, emesis without preceding nausea, unexplained restlessness, and syncope. Hypotension may be accompanied by "inappropriate" bradycardia. New ST-segment elevation or T-wave abnormalities may be evident. Pseudoaneurysms can be diagnosed by echocardiography, contrast or radionuclide ventriculography, or magnetic resonance imaging. Diagnostic pericardiocentesis may yield blood; therapeutic pericardiocentesis may destabilize a contained effusion and result in death. Surgical repair is usually necessary, although survival with pericardiocentesis and supportive medical therapy has been reported in selected patients [50].

LEFT VENTRICULAR REMODELING: PATHOPHYSIOLOGY, CONTEXT, PREVENTION, AND NATURAL HISTORY

Injuries to the LV that decrease systolic performance, such as acute MI, trigger a sequence of histopathologic events that lead to changes in LV size, shape, and function. This process of remodeling is initially compensatory but becomes maladaptive, with progressive hypertrophy, dilation, spherical distortion, and impairment of contractile function, and is associated with heart failure progression and poor clinical outcome.

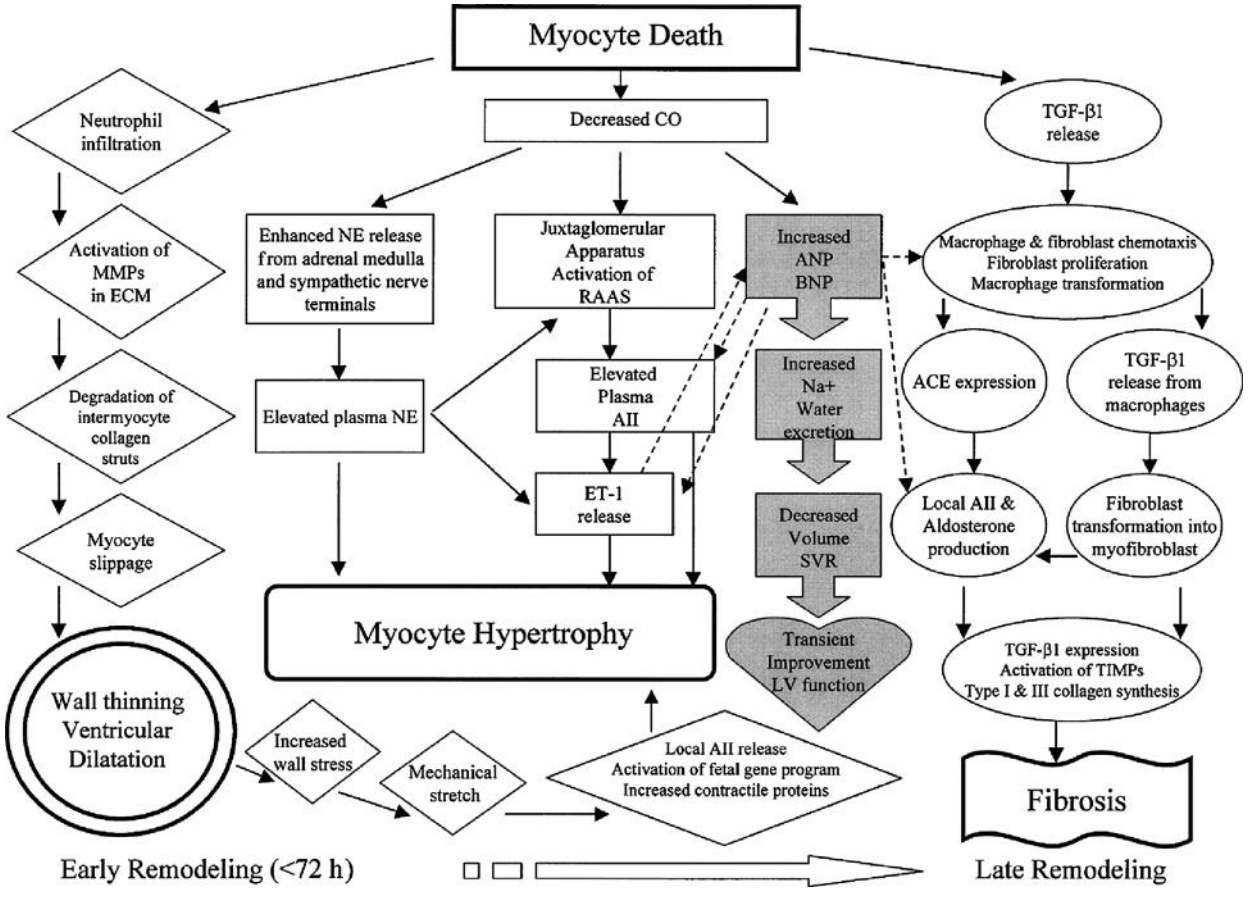

FIGURE 40.3. Ventricular remodeling after MI. AII, angiotensin II; ACE, angiotensin-converting enzyme; ANP, atrial natriuretic peptide; BNP, brain natriuretic peptide; CO, cardiac output; ECM, extracellular matrix; ET, endothelin; MMP, matrix metalloproteinase; NE, norepinephrine; RAAS, renin–angiotensin–aldosterone system; TGF, transforming growth factor; TIMP, tissue inhibitor of metalloproteinase. [From Sutton MG, Sharpe N: Left ventricular remodeling after myocardial infarction: pathophysiology and therapy. *Circulation* 101:2981–2988, 2000, with permission.]

Because LV remodeling is concordant with clinical outcomes over the natural history of heart failure, its prevention has been accepted as a reasonable therapeutic target.

The early phase of remodeling begins within 3 hours of MI and consists of infarct expansion due to collagen degradation by serine proteases and matrix metalloproteinases [51]. The resultant wall thinning and ventricular dilatation increase ventricular wall stress, thus promoting later remodeling, which includes collagen scar formation, fibrosis, and myocyte hypertrophy. The abnormal stresses related to mitral regurgitation [52] or ventricular mechanical dyssynchrony [53] resulting from the MI, if present, further promote remodeling.

The renin–angiotensin–aldosterone (RAAS) and sympathetic nervous systems are central mediators of remodeling [51,54] (Fig. 40.3). Myocyte stretch from increased wall stress stimulates the local production of angiotensin II, which in turn promotes myocyte hypertrophy, fibroblast proliferation, and collagen production. Adrenergic stimulation, in response to myocardial injury and/or hemodynamic compromise, leads to myocardial production of cytokines, such as TNF-α, IL-1β, and IL-6, which mediate myocyte hypertrophy, apoptosis, and changes in the extracellular matrix. Furthermore, adrenergic stimulation enhances the activity of the RAAS. Finally, there is growing evidence that oxidative stress after MI plays a role in the apoptosis, inflammation, fibrosis, and hypertrophy processes of myocardial remodeling.

Therapies to prevent or reduce postinfarction remodeling have focused on limiting infarct expansion and moderating the neurohormonal axes. Infarct expansion and remodeling are influenced by the size and location of the original infarct, patency of the infarct-related artery, presence of collateral flow, regional wall thickness, and radius of curvature. Reperfusion of the infarct-related artery restores stunned myocardium in the infarct border zone, reduces infarct size, and improves ventricular function and long-term prognosis.

Blockade of the RAAS and sympathetic nervous system is the cornerstone of pharmacologic therapy directed at interrupting remodeling and improving long-term outcome. The mechanisms of action of angiotensin-converting enzyme (ACE) inhibitors include beneficial effects on hemodynamics and loading conditions, as well as direct effects on remodeling. ACE inhibition attenuates the increase in LV volume occurring after MI and earlier commencement of ACE inhibition appears to produce greater benefit. This translates into a survival benefit in all patients with MI, including those with evidence of LV dysfunction, as demonstrated in the Survival and Ventricular Enlargement (SAVE) and Acute Infarction Ramipril Efficacy (AIRE) studies [55–57]. It is recommended that all patients without contraindications such as hyperkalemia or azotemia be treated with ACE inhibitors after STEMI. Patients who are intolerant of ACE inhibitors appear to derive similar benefit from angiotensin receptor blockers (ARB) [58]. Aldosterone blockade in patients without contraindication has also been shown to improve survival in patients with LV dysfunction after MI [59].

There are several potential mechanisms of benefit from beta-blockade. Beta-blockers reduce myocyte apoptosis, collagen deposition, and hypertrophy; they reduce myocardial oxygen demand by reducing heart rate and blood pressure, which may be especially beneficial for hibernating myocardium; and they directly oppose catecholamine stimulation of myocytes. Specific agents may have additional effects, such as the antioxidant and anti-inflammatory properties of carvedilol. Evidence of the benefit of beta-blockade includes early studies showing reduced remodeling in patients not receiving ACE inhibitors. The Carvedilol Post-Infarct Survival Control in LV Dysfunction (CAPRICORN) study demonstrated that beta-blockade with carvedilol after MI improved all-cause mortality and ventricular remodeling in patients already receiving standard ACE inhibitor treatment [60,61]. The survival benefit of beta-blockers is greatest in patients at highest risk for adverse events, such as those with LV dysfunction, ventricular arrhythmias, and no reperfusion.

Finally, patients with MI should be followed to determine whether they would benefit from cardiac resynchronization therapy for mechanical dyssynchrony [62] or intervention for mitral regurgitation [63].

Recommendations for the management of the mechanical complications of MI on the basis of randomized controlled trials are summarized in Table 40.3.

TABLE 40.3

SUMMARY OF RECOMMENDATIONS BASED ON RANDOMIZED CONTROLLED CLINICAL TRIALS

- Cardiogenic shock: Early revascularization by PCI or CABG in patients younger than 75 years who are otherwise suitable candidates reduces 1-year mortality. Patients older than 75 years may also benefit from early revascularization and an individualized treatment strategy is recommended [18]
- Remodeling: ACE inhibition or angiotensin-receptor blockade in patients with evidence of LV dysfunction after MI attenuates LV remodeling and improves survival [55–58]
- Remodeling: Beta-blockade in patients with evidence of LV dysfunction after MI attenuates LV remodeling and improves survival and LV remodeling [60,61]

ACE, angiotensin-converting enzyme; CABG, coronary artery bypass graft; LV, left ventricle; MI, myocardial infarction; PCI, percutaneous coronary intervention.

CHAPTER 41 ■ VENTRICULAR TACHYCARDIA

MELANIE MAYTIN AND BRUCE A. KOPLAN

INTRODUCTION

Ventricular tachycardia (VT) is defined as a wide QRS complex tachycardia (QRS width ≥0.12 second) of three or more consecutive beats at a rate faster than 100 per minute. VT arises from either reentry or automaticity in the ventricular myocardium or Purkinje system below the level of the His bundle. One of the common ways in which VT is classified is whether it is sustained or not. Nonsustained VT (NSVT) is that which terminates spontaneously within 30 seconds without causing severe symptoms. Spontaneous sustained VT requires an intervention, such as cardioversion or antiarrhythmic drug (AAD) administration for termination, or produces severe symptoms, such as syncope, prior to termination. VTs lasting longer than 30 seconds are usually designated as sustained.

Another way to classify VT is based on the QRS morphology (Fig. 41.1). Morphologic classifications include *monomorphic VT* (the same morphology from beat to beat), *polymorphic VT* (PMVT, varying morphologies from beat to beat), and *sinusoidal VT* (when the QRS has a duration similar to that of diastole). Torsades de pointes (TDP) is a unique subcategory of PMVT associated with QT prolongation.

VT can also be classified on the basis of its hemodynamic effects that are largely dependent on the rate of the tachycardia and the presence of underlying myocardial dysfunction. Indeed, for all sustained wide QRS tachycardias the first priority is to determine whether the patient is hemodynamically stable, with adequate blood pressure and perfusion. Pulseless VT is associated with no significant cardiac output and is approached in a similar manner as ventricular fibrillation (VF). VT can also be hemodynamically stable. This hemodynamic classification may be the most relevant classification system for initial management. Continuous electrocardiograph (ECG) monitoring should be implemented and a defibrillator should be at the patient's bedside for immediate use, even if the patient is hemodynamically stable. If the patient is pulseless and has impaired consciousness, angina, or severe pulmonary edema, prompt electrical cardioversion is warranted. Further therapy after cardioversion is determined by the type of tachycardia and underlying heart disease.

If the patient is hemodynamically stable, a brief history and a 12-lead ECG should be immediately obtained. The immediate history should include determination of known heart disease, in particular prior myocardial infarction, present medications, history of prior arrhythmias, whether the patient has an implanted defibrillator or pacemaker, and drug allergies. A limited initial physical examination should include the cardiovascular system and lungs. A 12-lead ECG should also be obtained following conversion of the tachycardia to compare the tachycardia QRS to that during sinus rhythm, as well as to evaluate underlying events, such as myocardial infarction, and QT interval prolongation, or other changes suggestive of electrolyte abnormalities. Previous ECGs are also helpful in this regard.

WIDE QRS MONOMORPHIC TACHYCARDIA

Monomorphic tachycardias have the same QRS configuration from beat to beat (Figs. 41.1A and 41.2). The differential diagnosis of this type of wide QRS complex tachycardia includes VT, supraventricular tachycardia (SVT) with aberrant interventricular conduction (bundle branch block; Fig. 41.3), and pre-excited SVT due to antegrade conduction from atrium to ventricle through an accessory pathway (Fig. 41.4B), or pre-excited QRS complexes during atrial fibrillation (AF) or atrial flutter (Fig. 41.3C). The differentiation is critical for prognosis and long-term management.

Initial Evaluation

Hemodynamic instability is an indication for electrical cardioversion. If the patient is hemodynamically stable, a limited history and physical examination should be performed and a 12-lead ECG obtained. The presence of hemodynamic stability does not indicate that the tachycardia is supraventricular. Hemodynamic stability is dependent on the rate of the tachycardia, underlying ventricular function, and the sympathetic nervous system response to tachycardia. VT can be hemodynamically stable, SVT may cause hemodynamic collapse, and vice versa. Wide QRS tachycardias should be managed as VT unless the diagnosis of SVT can be confirmed. Patients with a history of structural heart disease are more likely to have VT, whereas the absence of structural heart disease favors the diagnosis of SVT. Wide QRS tachycardia in patients with a history of myocardial infarction can be assumed to VT with greater than 95% certainty [1].

The physical examination is occasionally helpful in detecting the presence of dissociation between atrium and ventricle (AV dissociation) confirming VT as the diagnosis. Cannon "a"-waves in the jugular venous pulse occurring intermittently and irregularly during VT indicate periodic contraction of the right atrium against a closed tricuspid valve. AV dissociation may also cause variability in the intensity of the first heart sound and beat-to-beat variability in systolic blood pressure due to the variable contribution of atrial contraction to left ventricular filling. The absence of evidence of AV dissociation does not exclude the diagnosis of VT. Some patients have conduction from ventricle retrogradely over the His-Purkinje system and AV node to the atrium (VA conduction) during VT. Each ventricular beat is accompanied by a cannon "a-wave," a finding that is also seen in some SVTs (Table 41.1).

Electrocardiogram

VT can be somewhat irregular at its initiation, but persistence of an irregularly irregular wide QRS suggests AF with bundle

FIGURE 41.1. Three different wide QRS tachycardias are shown. **A:** monomorphic VT; **B:** polymorphic VT; and **C:** sinusoidal VT due to hyperkalemia. VT, ventricular tachycardia.

branch block or conduction over an accessory pathway rather than VT (Fig. 41.4). Comparing the QRS complex morphology during tachycardia with that of sinus rhythm on an old ECG or following cardioversion can be helpful. An identical QRS morphology during tachycardia and sinus rhythm suggests SVT [2] (with the uncommon exception of bundle branch reentry described later in the chapter). An old ECG may also reveal a short PR interval with δ-waves (Fig. 41.3A) that suggests Wolff–Parkinson–White (WPW) syndrome with an accessory pathway–mediated wide complex tachycardia (WCT; Fig. 41.3B). When the onset of tachycardia is recorded, initiation by a premature P-wave suggests SVT.

The following ECG criteria applied in a stepwise approach provide reasonable sensitivity and specificity to differentiate SVT from VT (Figs. 41.5 and 41.6) [3].

1. *AV dissociation:* Dissociation of P-waves (if identifiable) and QRS complexes suggests VT (Fig. 41.2). Because they may be partially buried in the QRS complex, or T-wave, the P-waves may be difficult to identify. Comparison of the contour of QRS and T-waves from beat to beat may be helpful; P-waves may be evident as a slight deflection occurring at regular intervals independent of QRS complexes. AV dissociation is probably the most reliable clue to the diagnosis of VT, especially if a nonsustained run of wide WCT is caught only on a telemetry rhythm strip.

   AV dissociation is also indicated by QRS fusion or capture beats. *Fusion beats* occur when a supraventricular impulse conducts over the AV node and depolarizes a portion of the ventricle simultaneously with excitation from the tachycardia focus. They occur if AV dissociation is present

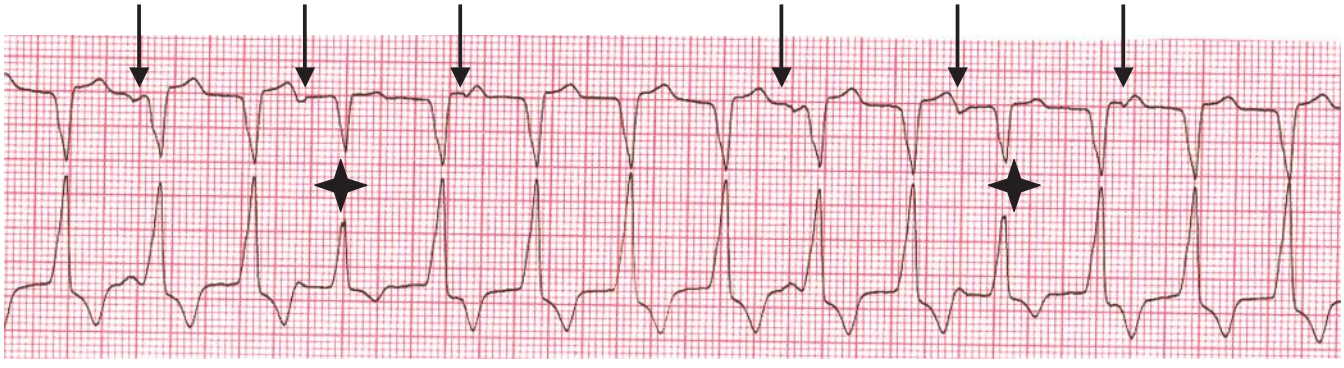

FIGURE 41.2. Sustained monomorphic ventricular tachycardia is present. Dissociated P-waves can be seen (*arrows*) with occasional fusion beats (*stars*) that occur when a sinus P-wave occurs with timing appropriate to conduct to the ventricle.

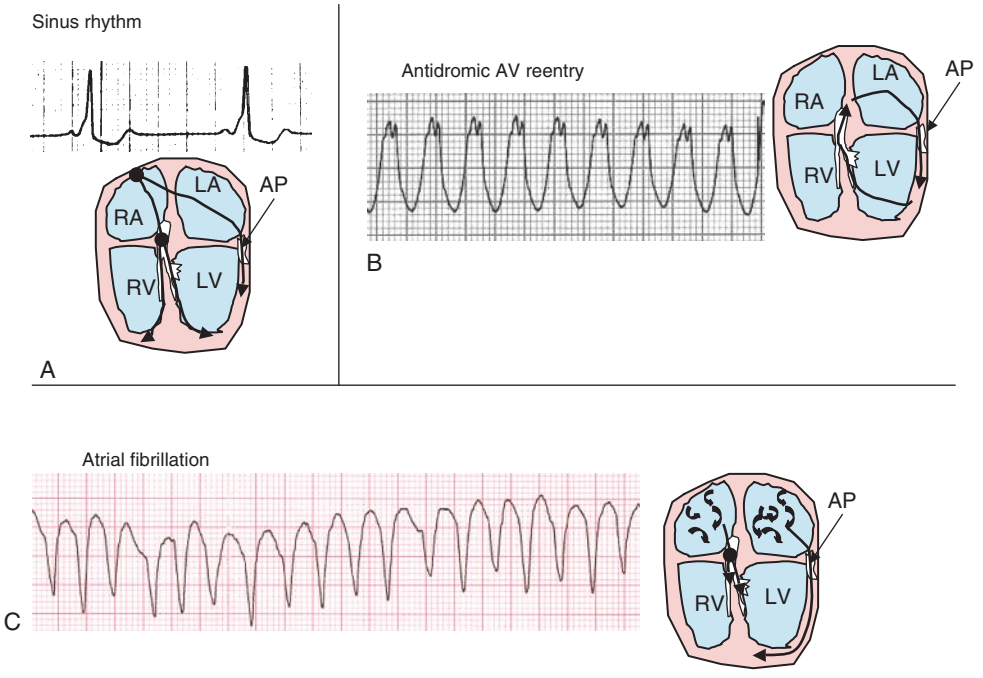

FIGURE 41.3. Features of the Wolff–Parkinson–White syndrome leading to pre-excited tachycardias are shown. **A:** sinus rhythm is shown. The ECG shows a short PR interval and δ-wave. The mechanism is shown in the schematic. Conduction of the sinus impulse (*arrows*) propagates over the AV node to the ventricles and over the accessory pathway (AP) to the ventricles. Conduction through the accessory pathway is faster than the AV node, producing the δ-wave. **B:** antidromic AV reentry is present. Tachycardia is due to circulation of the reentry wave front from atrium to ventricle over the accessory pathway, through the ventricle, and retrograde up the AV node to the atrium. Pre-excited antidromic tachycardia is often indistinguishable from ventricular tachycardia. **C:** atrial fibrillation with rapid conduction over an accessory pathway is shown. Tachycardia is irregular, although at the very rapid rate, the irregularity can be difficult to appreciate.

FIGURE 41.4. A: A wide QRS tachycardia with a left bundle branch block configuration. **B:** Following administration of drugs to slow down atrioventricular (AV) conduction atrial flutter is present with a narrow QRS configuration. Thus, **A** shows atrial flutter with aberrant conduction.

TABLE 41.1

SUPRAVENTRICULAR TACHYCARDIA VERSUS VENTRICULAR TACHYCARDIA

Findings suggesting ventricular tachycardia
AV dissociation
  Electrocardiogram
    Dissociated P-waves
    Fusion beats, capture beats—indicate conduction of a fortuitously timed P-wave from atrium to ventricle before the ventricle is completely depolarized from the VT focus or circuit
  AV dissociation on physical examination
    Intermittent cannon *a*-waves in jugular venous pulse
    Beat-to-beat variability in S_1 and systolic blood pressure

ECG leads V_1–V_6
  QRS concordance: The absence of an rS or Rs complex in any precordial lead
  RS >100 ms: An interval between the onset of the R and the nadir of the S-wave >100 ms in any precordial lead

Left bundle branch block VT
  Initial R-wave in lead V_1 >30 ms in duration
  Interval from onset of R to nadir of S in V_1 >60 ms
  Notching in the downstroke of the S-wave in lead V_1
  In V_6, a QS or QR pattern

Right bundle branch block VT
  V_1: A monophasic R, QR, or RS pattern
  V_6: An R to S <1 or a QS or a QR pattern

and the VT is not particularly fast. Fusion beats have a QRS morphology that is typically intermediate between that of a supraventricular beat and a ventricular beat. *Capture beats* have a similar significance to fusion beats. They occur when a supraventricular beat is able to conduct to the ventricles, depolarizing the ventricle in advance of the next tachycardia beat. These beats are morphologically identical to the QRS complex seen in sinus rhythm but occur in the midst of a wide QRS complex tachycardia.

2. *QRS concordance:* The absence of an rS or Rs complex in any precordial lead (V_1 to V_6) suggests VT.
3. *RS >100 ms:* An interval between the onset of the R and the nadir of the S-wave greater than 100 ms in any precordial lead (V_1 to V_6) favors VT.

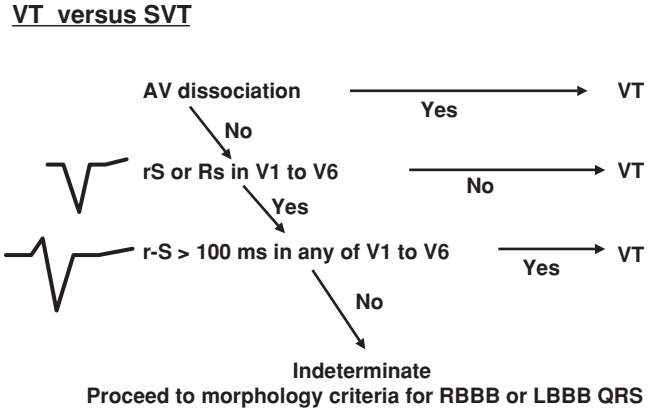

FIGURE 41.5. The schematic for an algorithm for ECG diagnosis of VT is shown. LBBB, left bundle branch block; RBBB, right bundle branch block; SVT, supraventricular tachycardia, VT, ventricular tachycardia.

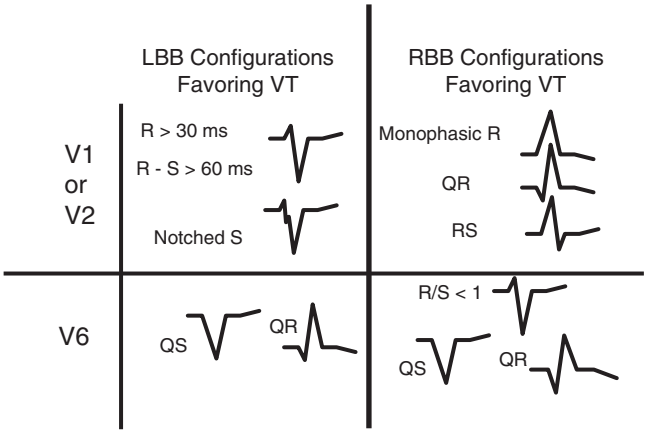

FIGURE 41.6. Electrocardiogram findings indicative of ventricular tachycardia (VT) or supraventricular tachycardia with aberrant conduction are shown. LBB, left bundle branch; RBB, right bundle branch.

If the diagnosis cannot be made after assessment for these features, a more thorough evaluation of the QRS morphology on the 12-lead ECG can be helpful (Fig. 41.6) [3]. For left bundle branch block morphology tachycardias, an initial R-wave in lead V_1 of greater than 30 ms in duration or a duration of greater than 60 ms from the onset of the R-wave to the nadir of the S-wave in V_1 suggests VT. Notching in the downstroke of the S-wave in lead V_1 also suggests VT. In V_6, a QS or QR pattern suggests VT. For right bundle branch block (RBBB) morphology tachycardias, a monophasic R, QR, or RS pattern in V_1 suggests VT. In V_6, an R-to-S amplitude ratio of less than 1 or QS or QR patterns suggests VT.

Electrocardiographic Artifacts that Mimic Wide Complex Tachycardia

Misinterpreting an electrocardiographic artifact, such as the one shown in Figure 41.7, as VT is a common error that has led to inappropriate and invasive procedures including cardiac catheterization, implantation of defibrillators, and even the occasional precordial thump [4]. Normal QRS complexes are often visible marching through the artifact at the sinus rate (arrows in Fig. 41.7). One author has referred to this as the "notches sign" because only small notches may be seen that march through the artifact at intervals that are the same as the RR intervals preceding the onset of tachycardia [5]. The history of the patient's activity at the time of the recording is often helpful in suggesting artifact. The recording in Figure 41.7 was performed during toothbrushing. Artifacts are also commonly caused by tremors, shivering, and electrical noise. The absence of symptoms or hemodynamic instability during the event (especially if the recording suggested a very fast heart rate) also suggests artifact.

ACUTE TREATMENT OF WIDE COMPLEX TACHYCARDIA

The misdiagnosis of VT as SVT followed by delivery of an inappropriate therapy is common in patients with wide QRS tachycardias [6]. As a general rule, wide QRS tachycardia should be treated as VT unless the diagnosis of SVT can be confirmed.

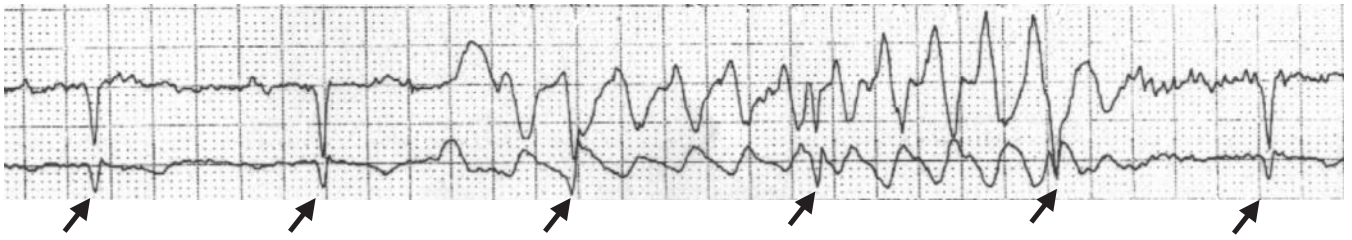

FIGURE 41.7. Apparent nonsustained ventricular tachycardia is actually artifact. Arrows indicate the sinus rhythm QRS complexes that "march through" the artifact.

MANAGEMENT OF HEMODYNAMICALLY UNSTABLE VT/VF

Figure 41.8 provides an algorithm for the management of hemodynamically unstable VT or VF. Hemodynamically unstable wide QRS tachycardia that is not due to sinus tachycardia with bundle branch block or artifact requires immediate electrical cardioversion. Both good basic life support (BLS) with prompt and efficient cardiopulmonary resuscitation (CPR) and rapid defibrillation are the most important measures to improve survival in unstable VT/VF [7]. Survival from VT/VF arrest diminishes by 7% to 10% per minute between collapse and defibrillation if CPR is not performed [8]. In fact, several studies have shown that survival from VT/VF arrest can be doubled or tripled if CPR is provided [9,10]. In keeping with these data, the most recent American Heart Association guidelines for cardiopulmonary resuscitation emphasize an integrated strategy of combined CPR and defibrillation [7]. If pulseless VT/VF persists after defibrillation, CPR should be promptly resumed and five cycles completed prior to additional therapy. When VT/VF is revealed during a rhythm check, CPR should be provided while the defibrillator is charging and resumed immediately following shock delivery. The algorithm for VF/pulseless VT should be followed (Fig. 41.8). Either epinephrine or vasopressin can be used as a first-line vasopressor agent if CPR continues to be required after two unsuccessful attempts at cardioversion [7]. If vasopressin is used, a one-time dose is appropriate as it has a half-life of 20 to 30 minutes. Epinephrine can be administered in 1-mg doses every 3 to 5 minutes.

Although definitive evidence of a long-term mortality benefit of any AADs for acute management of VT/VF is lacking, these agents should be used when initial attempts of electrical cardioversion are not successful [11,12]. When VF/pulseless VT persists after three shocks plus CPR and administration of a vasopressor, consider administering an antiarrhythmic, such as amiodarone. If amiodarone is unavailable, lidocaine may be considered. Magnesium should also be considered for TDP associated with a long QT interval [7]. In a trial of 504 patients

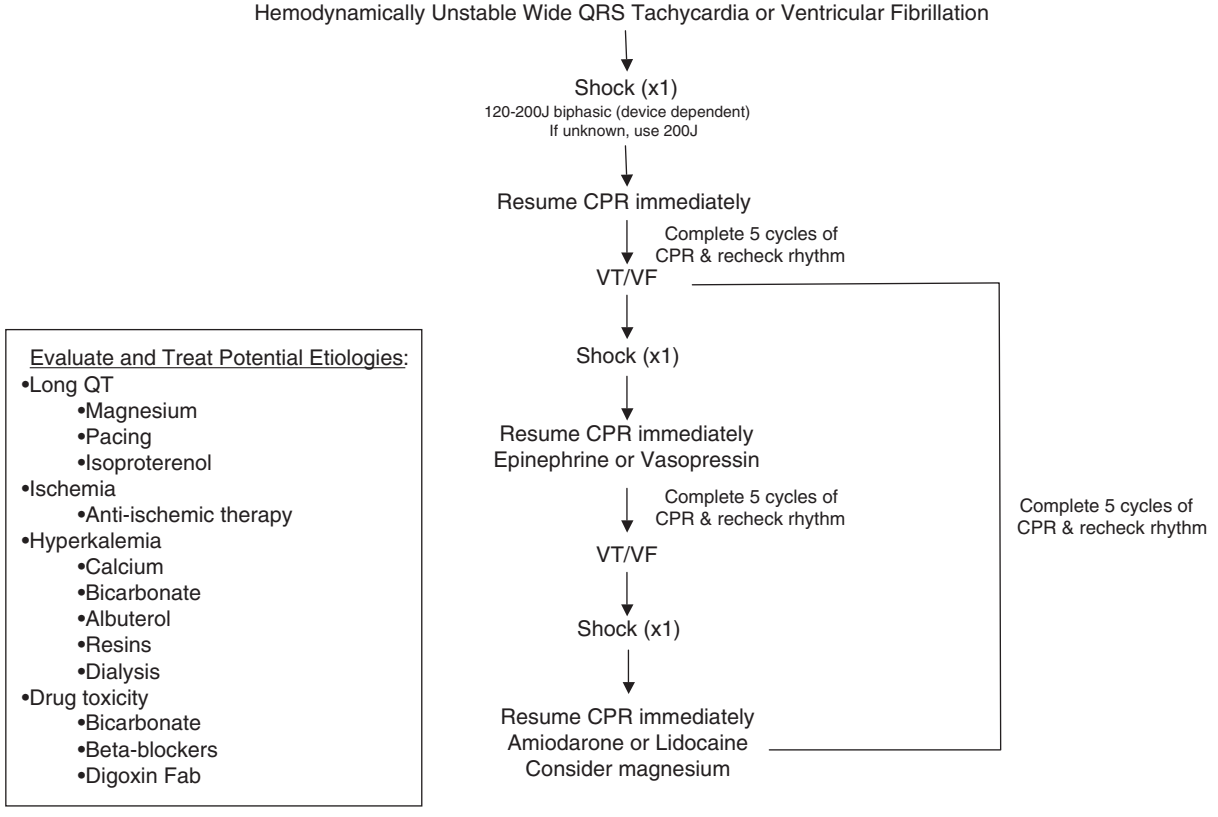

FIGURE 41.8. The algorithm for management of hemodynamically unstable ventricular tachycardia (VT) or ventricular fibrillation (VF) is shown.

with out-of-hospital VF or pulseless VT who failed three attempted cardioversions, administration of 300 mg of intravenous (IV) amiodarone was more effective than placebo for restoration of circulation and survival to hospital admission (44% of treated patients vs. 34% of untreated patients). Survival to hospital discharge was not improved and more patients who received amiodarone had hypotension (59% vs. 48%) or bradycardia (41% vs. 25%) [7,13,14]. Administration of IV procainamide can be considered as an alternative agent, but the data supporting its efficacy are limited [15]. Administration of IV lidocaine is most appropriate in the management of unstable VT/VF during suspected acute myocardial ischemia or infarct [16–18].

Although bretylium is an acceptable alternate antiarrhythmic agent for VT, it has been removed from advanced cardiac life support (ACLS) guidelines due to a combination of global supply shortage and lack of evidence showing its superiority over any of the previously mentioned AADs. Bretylium has similar efficacy to amiodarone for treatment of hemodynamically destabilizing VT that has failed cardioversion, but is associated with a greater incidence of hypotension compared to IV administration of amiodarone [7,18].

MANAGEMENT OF HEMODYNAMICALLY STABLE WIDE QRS TACHYCARDIA

In the absence of signs or symptoms of impaired consciousness or tissue hypoperfusion, a 12-lead ECG should be obtained to attempt to differentiate VT from SVT [7]. In patients in whom the diagnosis of SVT with aberrancy is suspected, the response to vagal maneuvers or adenosine administration while recording the ECG may also elucidate the diagnosis (Fig. 41.4). Vagotonic maneuvers and administration of IV adenosine often terminate or expose SVT and usually have no effect on VT. Close monitoring is required during these maneuvers; hypotension or precipitation of VF can rarely occur.

If the diagnosis remains unknown, the choice of initial antiarrhythmic agent should be influenced by the hemodynamic stability and rhythm analysis (Fig. 41.9). Administration of multiple antiarrhythmic agents should be avoided as polypharmacy increases the risk of precipitating incessant, although usually slower VT or new VTs, such as TDP (see later in the chapter). If the initial agent selected is ineffective, cardioversion is usually warranted.

First-line antiarrhythmic agents for stable wide QRS tachycardia of uncertain origin include procainamide, amiodarone, and in some circumstances, lidocaine. It is also appropriate to use electrical cardioversion as the initial therapy for stable tachycardia if appropriate sedation is available and can be safely achieved. Current ACLS guidelines state that IV administration of amiodarone, procainamide, sotalol (not available in IV form in the United States), and beta-blockers are preferable to lidocaine. Lidocaine is usually ineffective for treatment of sustained VT that is not due to acute myocardial ischemia or infarction [7,19]; procainamide and sotalol both have been shown to be more efficacious in this setting [20,21]. Procainamide and sotalol have negative inotropic effects and can induce hypotension. These agents should be avoided in patients with significantly impaired ventricular function (left ventricular ejection fraction <0.40) in favor of IV amiodarone [18,22,23]. Procainamide is acetylated to *n*-acetylprocainamide (NAPA). NAPA is a class III AAD that can cause TDP and is excreted entirely by the kidney; therefore, procainamide should also be avoided in patients with significant renal dysfunction. Each of these treatments (procainamide, amiodarone, or cardioversion) is also appropriate for SVT with aberrant conduction and therefore for wide QRS tachycardias of uncertain origin. If an accessory atrioventricular pathway with rapid repetitive conduction during AF or flutter is suspected (Fig. 41.3C), administration of IV procainamide or cardioversion are first-line therapies.

POLYMORPHIC VENTRICULAR TACHYCARDIA

VT with a continually changing QRS morphology is referred to as PMVT and is most often due to cardiac ischemia, metabolic disarray, or drug toxicity, often associated with QT prolongation. PMVT is often self-terminating, but likely to recur with a significant risk of hemodynamic instability and degeneration to VF.

The combination of PMVT and QT interval prolongation (usually a corrected QT interval [QTc]) greater than 500 ms is called torsades de pointes. The name is derived from the electrocardiographic appearance of twisting around the baseline as displayed in Figure 41.10. QT prolongation can be

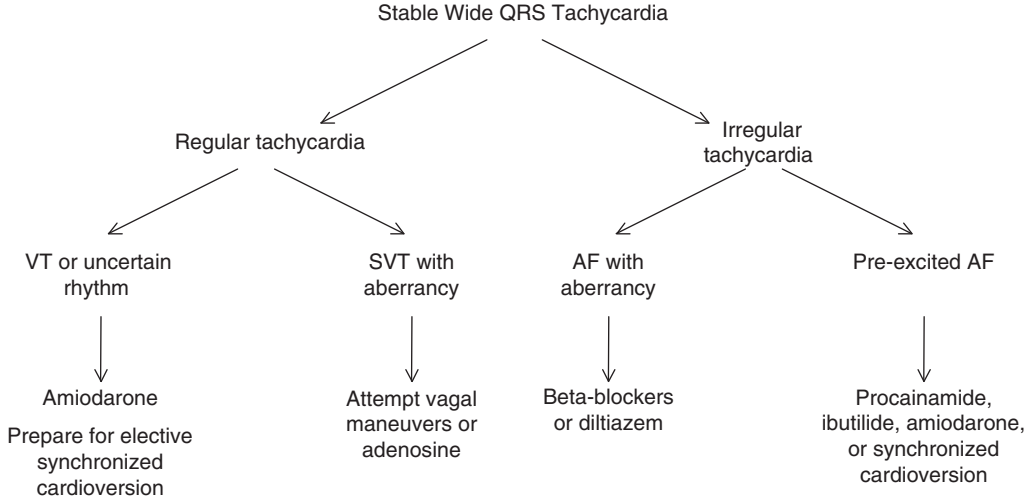

FIGURE 41.9. The algorithm for management of hemodynamically tolerated wide QRS tachycardia is shown. AF, atrial fibrillation; SVT, supraventricular tachycardia, VT, ventricular tachycardia.

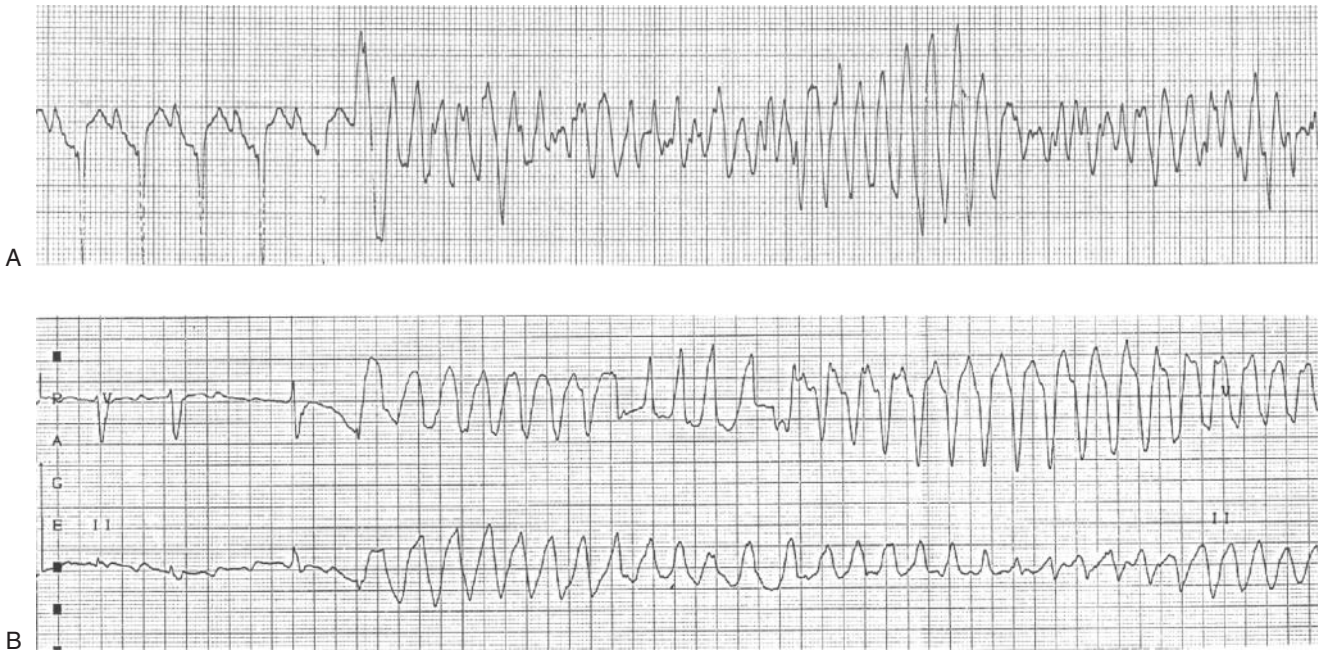

FIGURE 41.10. Two episodes of polymorphic ventricular tachycardia (VT) are shown. **A:** Polymorphic VT is due to acute myocardial infarction. The QT interval is normal prior to the onset of tachycardia. **B:** Torsades de pointes associated with QT prolongation prior to the onset of the tachycardia is present. A pause precedes onset of tachycardia.

acquired due to electrolyte abnormalities, QT-prolonging drugs, bradycardia, or a congenital ion channel disorder. A list of the acquired etiologies of TDP is provided in Table 41.2; a more extensive list is available at the QTdrugs.org Web site maintained and updated by the University of Georgetown, Department of Pharmacology. TDP often has a characteristic onset (Fig. 41.10B). A slowing of heart rate or pause produced by a premature ventricular contraction (PVC) further prolongs the QT interval. The T-wave of the longer QT interval is interrupted by the first beat of the PMVT. Thus, TDP is often referred to as "pause dependent."

TDP that leads to VF should immediately be defibrillated. Recurrent TDP is frequently suppressed by IV magnesium sulfate (1 to 2 g) that can be repeated in 5 to 15 minutes if no initial effect is seen [24]. Magnesium administration suppresses ventricular ectopy, but does not shorten the QT interval. It is often effective even if serum magnesium concentration is in the normal range. If ventricular ectopy recurs after initial administration, additional doses are warranted. Administration of large, repeated doses of magnesium should be avoided in the presence of severe renal insufficiency; hypermagnesemia with neuromuscular depression and respiratory arrest can occur. Neuromuscular depression is reversed by administration of IV calcium.

Correction of other electrolyte abnormalities and discontinuation of all medications that can prolong the QT interval is warranted. Because bradycardia prolongs the QT interval and increases the risk for further TDP, increasing heart rate with pacing, atropine, or isoproterenol administration can also suppress recurrent episodes of TDP. Temporary ventricular pacing is most reliable and should be implemented at a heart rate of 110 to 120 beats per minute and then titrated lower guided by suppression of ventricular ectopy. Because of its effect on increasing oxygen demand, isoproterenol is contraindicated if active cardiac ischemia is suspected.

PMVTs other than TDP are most commonly associated with acute myocardial ischemia and should be managed with anti-ischemic strategies including beta-blockers and revascularization. IV lidocaine and amiodarone can be considered for

recurrent episodes. If the cause of PMVT is unclear, such that both TDP and ischemia are possibilities, administration of IV magnesium and lidocaine are reasonable initial therapies, which are unlikely to aggravate arrhythmias from either cause.

SINUSOIDAL VENTRICULAR TACHYCARDIA

When the QRS has a similar duration to that of diastole, the tachycardia has a sinusoidal appearance (Fig. 41.1C). This is due to either very rapid monomorphic VT, also called ventricular flutter, which can occur due to any of the causes given previously in the chapter, or acute myocardial ischemia. Slow sinusoidal VT (Fig. 41.1C) occurs when the QRS is prolonged as a consequence of slowing of conduction through the myocardium. Such slow ventricular conduction is most commonly due to hyperkalemia or toxicity from a drug that blocks cardiac sodium channels, such as flecainide, propafenone, quinidine, procainamide, disopyramide, phenothiazines, or tricyclic antidepressants.

Hyperkalemia should be treated with administration of 1 g of IV calcium chloride or calcium gluconate, which promptly antagonizes the electrophysiologic effects of hyperkalemia. Administration of sodium bicarbonate intravenously also has almost-immediate effects. Calcium and $NaHCO_3$ should not be administered together in the same IV line, as they precipitate. Administration of hypertonic glucose and insulin has an effect in several minutes. The duration of action of these measures is transient, but does allow institution of measures to remove potassium with forced diuresis, potassium-binding resins (Kayexalate), or hemodialysis.

Slow sinusoidal VT due to toxicity from a sodium channel–blocking drug may respond to administration of hypertonic sodium in the form of sodium bicarbonate or sodium lactate [25,26]. Sodium bicarbonate administration is indicated for tricyclic antidepressant toxicity. Many of these drugs have a characteristic known as use-dependency, such that their electrophysiologic effect is greater at rapid heart rates. Slowing of the ventricular rate diminishes the toxicity. Thus, administration of β-adrenergic blockers can be helpful [27]. Supportive measures are required until the offending agent is excreted.

WIDE QRS TACHYCARDIAS DUE TO VENTRICULAR CONDUCTION OVER AN ACCESSORY PATHWAY

WCTs are also produced by conduction from atrium to ventricle over an accessory pathway in patients with the WPW syndrome (Fig. 41.3). These "pre-excited tachycardias" can be due to antidromic AV reentry (Fig. 41.3B) or AF or flutter conducting from atrium to ventricle over the accessory pathway (Fig. 41.3C). Clues that a wide QRS tachycardia may be a pre-excited tachycardia include: evidence of WPW on a prior ECG, with a short PR interval and a δ-wave (Fig. 41.3A); AF with a very fast ventricular response of 200 to 300 beats per minute (Fig. 41.3C); and irregularly irregular WCT with variation in beat-to-beat QRS morphology. Each QRS complex represents some degree of fusion between conduction over the accessory pathway and conduction through the AV node.

Pre-excited tachycardias should generally be managed as VT. Procainamide, which slows accessory pathway conduction, or electrical cardioversion are first-line therapies. IV lidocaine usually has little effect. Administration of medications that suppress AV nodal conduction without suppressing conduction over the accessory pathway can accelerate the ventricular response, precipitating VF or hemodynamic collapse. Thus, beta-blockers, diltiazem, verapamil, digoxin, and adenosine are contraindicated in this setting. IV amiodarone may also have this effect, because it suppresses AV conduction and should be administered with caution [28].

IMPLANTABLE CARDIOVERTER DEFIBRILLATORS

Implantable cardioverter defibrillators (ICDs) are a first-line therapy for many patients who have been resuscitated from a prior cardiac arrest or who are at high risk for arrhythmias and sudden cardiac death. An increasing number of patients with defibrillators are encountered in intensive care units (ICUs). Even when an ICD is present and programmed "on," its presence should not delay implementation of standard ACLS when VT or VF occurs. The ICD may deliver ineffective therapy or fail to detect the arrhythmia. External shocks, when required, should be delivered regardless of the presence of an ICD.

The ICD recognizes VT or VF largely by the presence of a heart rate that exceeds the programmed detection threshold. If an SVT exceeds the programmed rate threshold, the device will deliver an inappropriate therapy, either antitachycardia pacing or an electrical shock [29]. Recurrent episodes can lead to recurrent painful shocks. Occasionally antitachycardia pacing for an atrial arrhythmia initiates VT (Fig. 41.11). Recurrent inappropriate therapies can be managed by placing a magnet over the ICD pulse generator. This disables ICD arrhythmia detection. It is important to recognize that VT or VF will also not be detected with the magnet in place; external shocks will be required to treat these arrhythmias. Use of a magnet to suspend detection is a temporary maneuver until the inciting arrhythmia

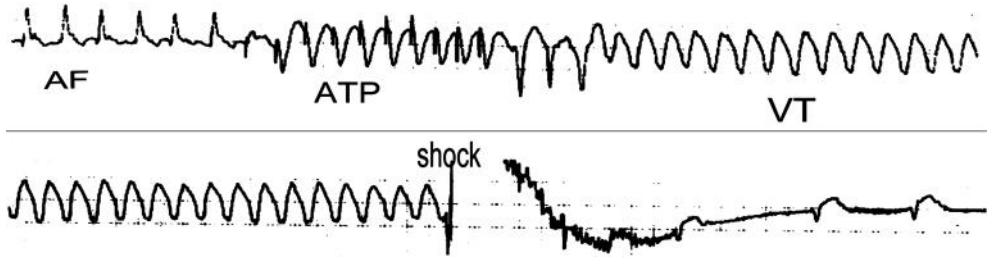

FIGURE 41.11. Tracings from a hospitalized patient who has an ICD are shown. From the *top left*, atrial fibrillation with a rapid ventricular response is present. The rapid ventricular response is incorrectly identified as ventricular tachycardia by the ICD and initiates a burst of antitachycardia pacing (ATP). ATP initiates sustained ventricular tachycardia (VT). The VT rate is faster than the previous rate, which falls into the programmed VF zone of the ICD, which then delivers a shock, restoring sinus rhythm. However, atrial fibrillation recurred (not shown) repeatedly. Recurrent ICD therapies were interrupted by placing a magnet over the ICD to suspend arrhythmia detection and treat the atrial fibrillation.

can be brought under control or the ICD can be reprogrammed to allow better arrhythmia discrimination.

Antiarrhythmic medications can have important interactions with ICDs [30]. These drugs can slow VT to a rate that it is lesser than the detect rate of the ICD. VT is then not detected or treated by the ICD. Antiarrhythmic drugs, particularly amiodarone, can increase the current required for defibrillation, such that the ICD no longer provides effective defibrillation; in this setting, external shocks are required.

NONSUSTAINED VT AND VENTRICULAR ECTOPY: "FIRST DO NO HARM"

PVCs and NSVT (more than three ventricular complexes) are common in the ICU particularly associated with myocardial ischemia, previous-healed myocardial infarction, and cardiomyopathies. Idiopathic PVCs also occur in some otherwise healthy patients, in whom they are of no consequence. The initial appearance of ventricular ectopy should prompt an evaluation for possible aggravating factors (Table 41.3). Increasingly frequent ectopy raises concern of increasing sympathetic tone possibly due to progression of the underlying illness. Treatment should be directed at the underlying condition. Therapy with β-adrenergic–blocking agents if not precluded due to hemodynamic or pulmonary impairment is reasonable. Other antiarrhythmic agents should, in general, be avoided.

NSVT is a marker for increased sudden death risk in patients who have had a prior myocardial infarction and in patients with left ventricular hypertrophy [31–33]. Patients with an ejection fraction 40% or lesser and NSVT should be considered for electrophysiologic study. Those with inducible VT have a 9% per year risk of sudden death; ICDs are protective, reducing total mortality from approximately 50% to 24% over 5 years [34,35].

Digitalis toxicity

Patients with PVCs or NSVT who have relatively preserved left ventricular function do not usually need specific antiarrhythmic therapy. Therapy with beta-blockers can be considered for symptomatic patients. Rarely, other drugs are required to control symptoms. Aggravating factors, such as electrolyte abnormalities, should be sought and corrected. Therapy with class I AADs or sotalol is generally not indicated and may increase mortality [36,37].

Accelerated idioventricular rhythm (AIVR) is a wide-complex ventricular rhythm at a rate faster than 40 beats per minute and slower than 100 beats per minute and is usually hemodynamically stable. The mechanism is probably related to enhanced automaticity. This rhythm often occurs in the first 12 hours following reperfusion of an acute myocardial infarction during periods of elevated sympathetic tone, and its onset is typically preceded by sinus slowing [38]. AIVR usually resolves without specific therapy; AAD treatment is rarely necessary.

Digitalis-induced arrhythmias include ventricular ectopic activity, an accelerated junctional rhythm, monomorphic VT, or VF. Rarely, digitalis causes *bidirectional tachycardia*, in which the QRS morphology alternates between two different morphologies; mortality is high if left untreated [39]. Patients with digitalis-induced VT should receive digoxin immune Fab fragments (Digibind) [40].

OVERVIEW OF DRUGS COMMONLY USED FOR MANAGEMENT OF VT/VF IN THE ICU

AADs (Table 41.4) are commonly grouped according to the Vaughan Williams classification scheme on the basis of whether their predominant action is to block sodium channels (class I), β-adrenergic receptors (class II), potassium channels (class III), or L-type calcium channels (class IV) [41]. Although this classification scheme is imperfect (many of the drugs affect multiple channels or receptors), it remains in common use. The narrow toxic–therapeutic window and potential for proarrhythmia necessitate use of AADs only when the potential risks are justified by the need to suppress an arrhythmia. For most drugs, the initial dosing guidelines provide a starting point for drug administration. Titration to achieve the desired effect is often required.

Class I AADs block sodium channels with either intermediate (IA), fast (IB), or slow (IC) onset and recovery of channel block during diastole. Class IC AADs such as *flecainide* and *moricizine* increase long-term mortality in patients with coronary artery disease and depressed ventricular function [42,43]. Such agents are rarely used for VT in the ICU.

Procainamide (IA) is a first-line agent for the treatment of hemodynamically stable WCT, and as an alternative agent for hemodynamically unstable WCT and VF. It is also a first-line agent for WCT due to the WPW syndrome. Procainamide is administered as an IV infusion at 20 to 30 mg per minute up to a total initial dose of 17 mg per kg. The loading dose may be followed by a maintenance infusion of 1 to 4 mg per minute. Procainamide has vasodilatory and negative inotropic effects. Arterial blood pressure should be monitored carefully during IV administration. It should be avoided in patients with depressed ventricular function (left ventricular ejection fraction <0.40). In addition, NAPA, an active metabolite of the drug, exerts class III effects that can lead to prolongation of repolarization (increased QTc) and TDP. Serum levels of both procainamide and NAPA should be monitored if the drug is

TABLE 41.4

DRUGS COMMONLY USED FOR VT/VF IN THE ICU (GROUPED BY VAUGHAN WILLIAMS CLASS AND "OTHER")

Class	Antiarrhythmic drug	Common indications	IV dose		Contraindications	Side effects	Comments
			Load	Maintenance			
IA	Procainamide	MVT, PMVT, WPW and AF, VF (second line)	20 mg/min until arrhythmia is suppressed or side effects occur up to 17 mg/kg total	1–4 mg/min	Hypotension, reduced EF, CHF (reduce dosage in renal failure), prolonged QT, previous TDP	Hypotension, negative inotropism, proarrhythmia, lupus-like syndrome	Active metabolite (NAPA) follow Proc and NAPA levels Discontinue if QRS widens by >50%
IB	Lidocaine	Monomorphic VT, polymorphic VT/VF	1.0–1.5 mg/kg (additional 0.75 mg/kg can be given as a second bolus)	1–4 mg/min	Seizure disorders, severe bradycardia or heart block, severe renal or hepatic dysfunction	Seizures, status asthmaticus, hypotension	Appears to be most effective during acute myocardial ischemia
II	β-adrenergic blockers	PMVT/MVT	Variable	Variable	Severe CHF; second- or third-degree heart block	Bradycardia, worsened CHF, AV delay, hypotension, bronchospasm	Proven mortality benefit in cardiac ischemia
III	Amiodarone	MVT, PMVT, VF	150 mg IV over 10 min (may be repeated multiple times up to ~2 g/24 h and 5–8 g total)	1 mg/min for 6 h and then 5 mg/min	Severe hepatic disease; second- or third-degree heart block	Hypotension, multiorgan toxicity (lung, liver, nervous system, eyes, skin, thyroid)	May be more effective than lidocaine for most ventricular arrhythmias
	Ibutilide	AF (cardioversion), WPW, and AF	1 mg IV (may repeat dose 10 min after initial dose)		Prolonged QT interval, electrolyte abnormalities (hypokalemia, hypomagnesemia), polymorphic VT	Torsades de pointes	
	Bretylium	VT/VF (second line)	5 mg/kg (may repeat)	1–2 mg/min	Severe renal failure	Frequent late hypotension	Removed from ACLS treatment algorithms due to limited supply
	Sotalol	*VT/VF	1.0–1.5 mg/kg at 10 mg/min*		Second- or third-degree heart block	Bradycardia, hypotension, TDP	*Not available intravenously in the United States
Other	Epinephrine	Cardiac arrest	1 mg IV (repeated as needed)	1–4 μg/min			
	Vasopressin	Pressor agent for cardiac arrest	40 U IV (not repeated)				Interchangeable with epinephrine
	Magnesium	Known low Mg^+, TDP	1–2 g (may be repeated)				

CHB, complete heart block; CHF, congestive heart failure; EF, ejection fraction; MVT, monomorphic VT; PMVT, polymorphic VT; TDP, torsades de pointes; VF, ventricular fibrillation; VT, ventricular tachycardia; AF, atrial fibrillation; WPW, Wolf–Parkinson–White.

continued for longer than 24 hours. In addition to the QTc interval, the width of the QRS complex should be monitored and the drug should be discontinued during initial loading or chronic therapy if the QRS widens by more than 50% of its baseline value.

Lidocaine (class IB) is indicated for the acute management of life-threatening ventricular arrhythmias, especially in patients suspected of having acute myocardial ischemia. It can be administered as 1.0 to 1.5 mg per kg IV bolus, which can be repeated to a maximum bolus of 3 mg per kg, followed by an infusion of 1 to 4 mg per minute. Unlike procainamide, lidocaine has few adverse hemodynamic side effects. Its toxicity is mainly due to neurologic side effects (seizures and tremors).

Beta-blockers (class II) antagonize the effects of β-adrenergic stimulation on the heart and have been shown to reduce mortality in patients with depressed ventricular function or ischemic heart disease during chronic therapy [44,45]. They can be considered for hemodynamically significant or symptomatic NSVT and PVCs, and for recurrent sustained ventricular tachyarrhythmias in which elevated sympathetic tone is felt to play a role. Negative inotropic effects, bradyarrhythmias, and aggravation of bronchospasm are major adverse effects. Metoprolol, propranolol, atenolol, and esmolol are all available for IV administration. *Metoprolol* can be given as a 5-mg slow IV push and can be repeated every 5 to 10 minutes up to a total of 20 mg IV or until the desired effect is obtained. Ongoing maintenance therapy can be administered as repeat IV boluses every 4 to 6 hours or through oral dosing. *Esmolol* has a short half-life (2 to 9 minutes), making it useful when there is concern that a beta-blocker may be poorly tolerated, such as in patients with hypotension or a history of bronchospasm. Termination of the infusion is followed by rapid dissipation of effect.

Class III AADs cause prolongation of repolarization primarily by potassium channel–blocking activity. This action is responsible for their antiarrhythmic and proarrhythmic (QTc prolongation and TDP) effects.

Amiodarone is usually classified as a class III agent, although it exhibits sodium, potassium, and calcium channel inhibition, as well as β-adrenergic–blocking effects. It has excellent efficacy in the management of ventricular arrhythmias and a low incidence of proarrhythmia [46]. Amiodarone is a first-line AAD option in the recently revised ACLS VF/pulseless VT algorithm [7]. Even though amiodarone causes QT prolongation, TDP is rare. IV amiodarone can be administered as 150 mg bolus over 10 minutes, followed by a continuous infusion at 1 mg per minute for 6 hours and then 0.5 mg per minute. Additional 150 mg boluses can be given for breakthrough arrhythmia up to a total load of approximately 2 g per 24 hours and 5 to 8 g total. Amiodarone has a large and variable volume of distribution (averaging 60 L per kg) and long half-life (averaging 53 days). Major complications during IV administration are hypotension and bradyarrhythmias. When administered through a peripheral IV line, amiodarone causes phlebitis; continuous infusions should be administered through a central venous catheter. During chronic long-term therapy, hepatic toxicity, hyper- or hypothyroidism, pneumonitis, pulmonary fibrosis, neuropathy, tremor, and skin toxicity are important concerns that require careful monitoring.

LONG-TERM MANAGEMENT AFTER RESUSCITATION FROM SUSTAINED VT/VF

Patients with ischemic heart disease and reduced ventricular function who are resuscitated from cardiac arrest or hemodynamically significant VT not attributable to acute myocardial infarction have a risk of recurrent cardiac arrest or VT that exceeds 30% to 40%. ICDs effectively terminate recurrent VT/VF and reduce mortality in these patients [47–49]. Thus, sudden cardiac arrest survivors warrant evaluation after resuscitation and management of any intercurrent illness to assess the need for placement of an ICD and other arrhythmia therapy. Catheter ablation of VT is a valuable treatment option for the control of recurrent arrhythmia. Therapeutic decisions are guided by the estimated risk of recurrence, underlying heart disease, functional status, and general prognosis.

Sustained Monomorphic VT

Sustained monomorphic VT is usually due to reentry through a region of myocardial scar, most commonly from an old myocardial infarction. Myocardial scars causing VT also occur in cardiomyopathies, cardiac sarcoidosis, arrhythmogenic right ventricular cardiomyopathy, and Chaga's disease. In all of these diseases, the substrate for the arrhythmia remains after resuscitation. The spontaneous recurrence rate exceeds 40% over the following 2 years. Patients who present with sustained monomorphic VT, but have elevated cardiac enzymes indicating infarction, should be presumed to remain at risk for VT from reentry from a prior infarct scar. An ICD or long-term therapy with amiodarone is generally considered after underlying myocardial ischemia and other aggravating factors are addressed. The underlying heart disease should be characterized; echocardiography and cardiac catheterization are often warranted.

Bundle Branch Reentry

Bundle branch reentry causes a unique form of monomorphic VT that results from a reentrant circuit utilizing the bundle branches as arms of the circuit. The reentry wave front typically circulates antegrade down the right bundle branch and up the left bundle branch, giving rise to a VT that has a left bundle branch block QRS configuration. In patients with left bundle branch block in sinus rhythm, the VT can have the same QRS morphology as sinus rhythm. This form of VT is most commonly seen in patients with nonischemic dilated cardiomyopathy [50]. Bundle branch reentry can be cured by radiofrequency ablation, but at least 25% of patients with this form of VT will have other VTs as well [51]. Therefore, an ICD is often recommended.

Rarely, sustained monomorphic VT occurs in a patient without structural heart disease. The most common of these idiopathic tachycardias originates from a focus in the right ventricular outflow tract, giving rise to VT that has a left bundle branch block, inferior axis QRS configuration. VT is often catecholamine sensitive and precipitated during exercise or physiologic stress, occasionally emerging during other illnesses. Idiopathic VT rarely causes cardiac arrest, although hypotension and syncope can occur [52]. Unlike other forms of VT, idiopathic VT is sometimes terminated with adenosine or vagal maneuvers [53]. Beta-blocker and verapamil (especially in IV form) can also be effective at terminating and suppressing idiopathic VT [54]. Long-term therapy focuses on suppression with beta-blockers or calcium channel blockers. Occasionally catheter ablation is required [55].

Polymorphic VTs

Patients who have had TDP should be viewed as having a susceptibility to the arrhythmia. All known precipitants of TDP or QT prolongation should be avoided (Table 41.3). Patient should be provided with a list of these medications. Following

removal of aggravating factors, evaluation for possible congenital long QT syndrome should be conducted. The diagnosis is suggested by persistent QT prolongation and QT prolongation on prior ECGs when potential offending drugs were absent and/or a family history of unexplained sudden death. Long-term therapy and follow-up are required.

If the patient has a family history of sudden death and has been resuscitated from PMVT, but the QT interval is normal, other familial sudden death syndromes should be considered. The *Brugada syndrome* is a unique familial cause of sudden cardiac death that accounts for some cases of idiopathic VF [56]. Patients with this syndrome have a baseline ECG with RBBB, ST-segment elevation in leads V_1 to V_3 and no evidence of structural heart disease [57]. *Catecholaminergic polymorphic ventricular tachycardia* (CPVT) is an inherited primary electrical disorder of the heart associated with a high rate of sudden death [58,59]. Autosomal-dominant mutations of the ryanodine receptor account for the majority of cases, but autosomal-recessive mutations of calsequestrin have also been reported [59]. These patients frequently present at an early age with stress-induced syncope or sudden cardiac arrest. The resting ECG is usually unremarkable, and both invasive and noninvasive testing fail to reveal signs of structural heart disease. Exercise testing often demonstrates runs of PMVT during exercise frequently with a beat-to-beat 180-degree rotation of the QRS axis (bidirectional tachycardia) [58]. Genetic testing can aid in the diagnosis. Beta-blockers titrated to maximal doses are the mainstay of therapy for CPVT [58]. An ICD may be warranted for treatment of patients with these syndromes.

PMVT due to acute myocardial infarction usually occurs in the first hour of the infarction and is unusual after initial resuscitation. Recurrent episodes should prompt assessment for ongoing ischemia. The risk of recurrent cardiac arrest is similar to that for patients with a similar-size infarction without cardiac arrest.

TABLE 41.5

ADVANCES IN THE MANAGEMENT OF VENTRICULAR TACHYCARDIA

- Acute management involves assessment of hemodynamic status, ECG evaluation and diagnosis of ventricular tachycardia versus supraventricular tachycardia with aberrancy.
- Immediate cardioversion should be provided for hemodynamically unstable VT.
- Reversible causes of VT (e.g., ischemia, electrolyte abnormalites) should be identified and treated.
- Antiarrhythmic drugs should be considered when initial attempts at cardioversion are unsuccessful or when VT recurs.
- Long-term management may include consideration for an implantable defibrillator in appropriately selected patients.

Cardiac Arrest of Unclear Cause

Often the cause of a cardiac arrest cannot be determined with certainty. The patient resuscitated from VF who has enzymatic evidence of non–Q-wave myocardial infarction, but depressed ventricular function and evidence of a prior myocardial infarction might have suffered VT from reentry in the old infarct scar or an ischemic arrhythmia. Treatment for ischemia and an ICD is often considered.

A summary of advances in the management of VT, based on randomized controlled trials or meta-analyses of such trials, is given in Table 41.5.

CHAPTER 42 ■ SUPRAVENTRICULAR TACHYCARDIAS: RECOGNITION AND MANAGEMENT IN THE INTENSIVE CARE SETTING

AMMAR HABIB, JOSEPH J. GARD, TRACI L. BUESCHER AND SAMUEL J. ASIRVATHAM

OVERVIEW AND CLASSIFICATION

Supraventricular tachycardias (SVTs) are frequently encountered in the intensive care unit (ICU) setting [1]. Although generally considered benign, in the context of the critically ill patient, SVTs can be particularly problematic, complicating care and at times, contributing to patient morbidity and mortality.

Atrial fibrillation (AF) and macroreentrant atrial tachycardias are the most common SVTs observed in ICU practice. However, regular reentrant tachycardias such as atrioventricular node reentry (AVNRT) may be initiated or exacerbated by the stress of critical illness or the use of adrenergic agents.

The intensive care provider should be familiar with the common varieties of SVTs and have an approach developed to quickly diagnose the exact arrhythmia (Fig. 42.1). Such diagnosis is essential in the formulation of a management plan for the treatment of acute events as well as prevention of recurrence.

Although several approaches for the diagnosis of SVT have been described, in the context of the critically ill patient, the use of easily recognized parameters aids quick diagnosis and thus prompt institution of a management plan. In most situations, three criteria—regularity of the tachycardia (regular or irregular), QRS width (narrow complex or wide complex), and, when relevant, measurement of the RP interval (interval between the preceding QRS complex and a recognized P wave during tachycardia) provide sufficient data for accurate diagnosis.

In this chapter, regular narrow complex tachycardia is addressed first, followed by the more common irregular tachycardias. Each category includes a description of the pathogenesis, electrocardiographic recognition, and general principles of management of the common varieties. Because of the frequency of occurrence of AF, this arrhythmia is discussed in relatively more depth. For each section, emphasis is placed on points of interest designed to specifically assist the caregiver for critically ill patients.

REGULAR NARROW COMPLEX TACHYCARDIA

When a regular narrow complex tachycardia (QRS duration <120 milliseconds) is observed, several important arrhythmias should be considered in the differential diagnosis. These include sinus tachycardia, AVNRT, atrioventricular reentrant tachycardia (AVRT) using an accessory pathway (AP), and automatic atrial tachycardia. Each of these arrhythmias is discussed in more detail in the text to follow. Atrial flutter may present as a regular tachycardia, but often because of variable atrioventricular (AV) conduction block, it manifests as an irregular tachycardia and may be confused with AF. Junctional tachycardia is also a rare regular narrow complex tachycardia that is typically self limited and very unusual in the adult intensive care patient population.

These tachycardias may be of sudden onset and abrupt termination (AVNRT, AVRT) or may occur and dissipate gradually (sinus tachycardia, automatic atrial tachycardia). A useful further distinguishing electrocardiographic feature within this subset of SVTs is the RP interval. First, a careful search for the P wave should take place. If the P wave is recognized, it should be determined whether it occurs closer to the preceding QRS or to the succeeding QRS complex. If the P wave occurs closer to the succeeding QRS (long R–P tachycardia), sinus tachycardia and atrial tachycardia should be considered (Fig. 42.2). When the P wave is closer to the preceding QRS (short R–P tachycardia), AVNRT or AVRT are likely although important exceptions exist [2–4].

The P wave morphology may also be useful in determining the mechanism of arrhythmia. The P wave in sinus rhythm (upright in leads II, III, and aVF and biphasic in lead V_1) is easily recognized. When an abrupt change in the P wave morphology occurs regardless of the heart rate, a nonsinus mechanism including atrial tachycardia should be suspected (Fig. 42.3).

Sinus Tachycardia

Metabolic stress commonly encountered in the critically ill patient often causes increased automaticity of the sinus node, producing a regular narrow complex tachycardia. Other causes of sinus tachycardia in the critical care setting include administration of adrenergic medications, hypovolemia, and inflammation. Sinus tachycardia is characterized on ECG by regular PR interval and a uniform P wave morphology that is upright in leads II, III, and aVF. Ventricular rate typically ranges from 100 to 140 beats per minute with gradual variation in response to the underlying clinical condition or therapeutic intervention.

Sinus tachycardia is often a normal physiologic response to underlying systemic illness. Treatment of the underlying cause usually helps slow down the heart rate. At times, however, the increased heart rate (albeit a physiologic response to some other stress) may itself be detrimental. For example, in patients with critical coronary disease, rapid sinus rates may give rise to an acute ischemic syndrome and possible ventricular arrhythmia. Similarly, in conditions such as critical mitral stenosis and severe diastolic dysfunction, rapid rates are detrimental as diastolic filling times need to be maximized. In these circumstances, temporary use of beta-blockers or calcium channel blockers

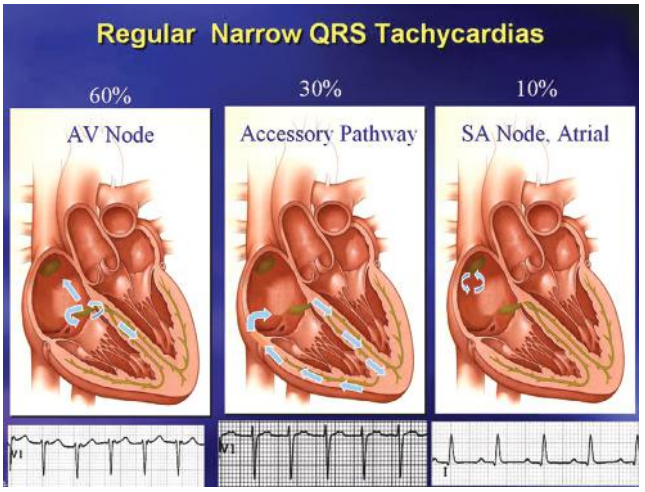

FIGURE 42.1. Narrow complex tachycardias in the intensive care unit. The most common regular narrow QRS tachycardias are atrioventricular node reentry, accessory-pathway related tachycardia, and automatic tachycardias such as sinus tachycardia and atrial tachycardia. These arrhythmias can be readily differentiated in most cases with careful analysis of the electrocardiogram. A long RP tachycardia (*right panel*) where each P wave is closer to the succeeding rather than the preceding QRS is characteristic of sinus tachycardia and atrial tachycardia. In tachycardias where an extranodal accessory pathway is used for retrograde conduction (orthodromic reciprocating tachycardia, ORT), a short RP interval is seen with an easily discernible retrograde P wave. With AV node reentry (*left panel*), because AV activation proceeds from a common turnaround point in or near the AV node, the R wave and P wave may be nearly simultaneous producing a very short RP interval and difficult to discern P wave (see text for details).

can decrease heart rates while the primary cause of the sinus tachycardia is being investigated.

Automatic *atrial tachycardias* are very similar in occurrence to sinus tachycardia in the intensive care setting. They are frequently seen in patients in shock, under stress, or on high doses of beta-adrenergic agents (epinephrine, high-dose dopamine). They can be readily distinguished from sinus tachycardia by close analysis of the P wave morphology. Unlike sinus tachycardia, however, these arrhythmias are not always a result of a persistent underlying abnormality (blood loss, hypoxia, etc.) and may be a primary cause of functional deterioration in a given patient [5,6]. Sodium channel blockers (class I antiarrhythmic agents) can be used for both acute termination and prevention of recurrences [7–9]. Typically, however, treatment of the underlying problem and decreasing the use of intravenous sympathomimetics is sufficient to prevent recurrence in patients who have developed atrial tachycardia in the setting of critical illness.

Specific Considerations in the Intensive Care Unit

In patients who are continuously monitored, sinus tachycardia can often be diagnosed by looking at the transition from normal heart rates to the present rate of tachycardia. For example, if the patient has a regular long R–P tachycardia at 170 beats per minute, all intervening rates from the baseline rate (100, 110, 130, 150 bpm, etc.) will be seen and demonstrate gradual onset of the tachycardia with progressively faster rates and a reverse pattern of resolution.

If an abrupt increase in heart rate is noted, a non-sinus mechanism should be suspected. However, some critically ill

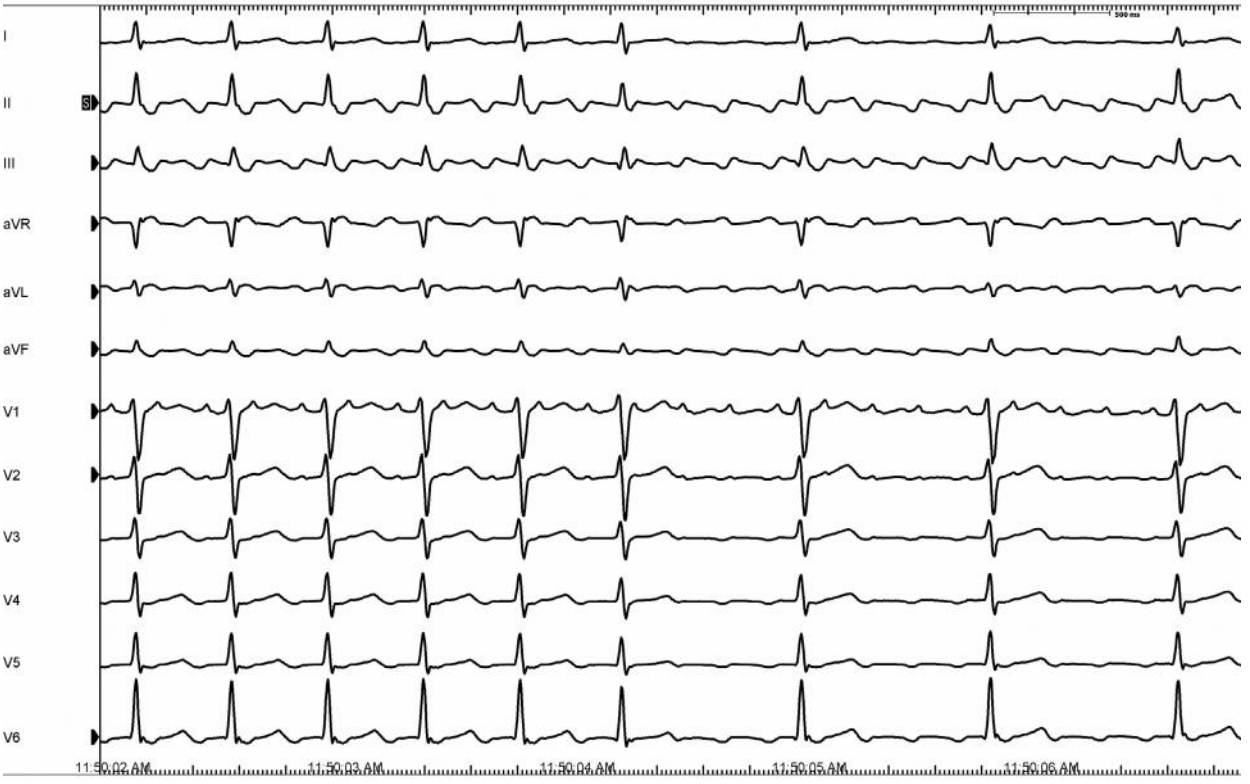

FIGURE 42.2. Patient with initially regular SVT than with a change in ventricular response rate. The underlying supraventricular arrhythmia is an atrial tachycardia (automatic or macroreentrant). Note the differences in P wave morphology to sinus rhythm with negative P waves in the inferior leads and all positive P wave (not biphasic) in lead V_1. The abrupt changes in ventricular responses may exacerbate symptoms especially in patients already compromised with critical illness.

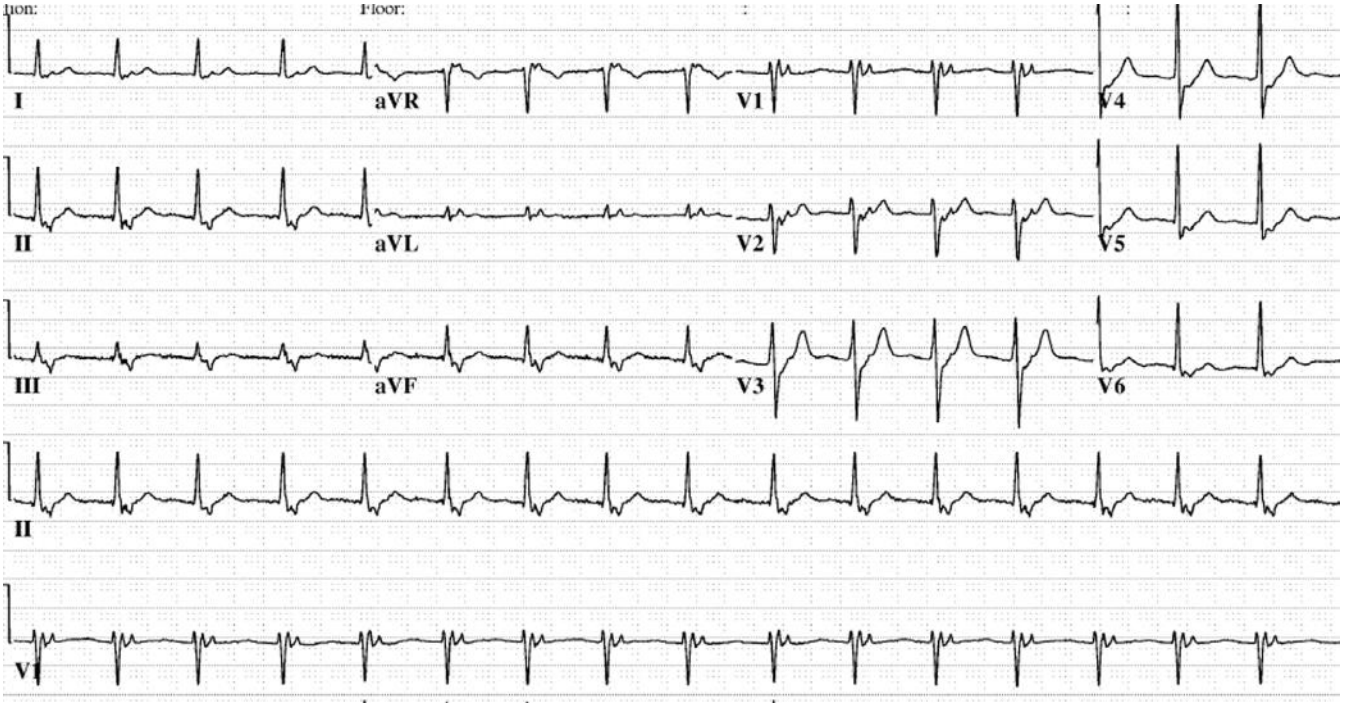

FIGURE 42.3. 12-Lead electrocardiogram of typical atrioventricular node reentry (AVNRT). The P waves are readily recognized just following the QRS complex. The regular tachycardia with short RP interval should raise suspicion for this arrhythmia. The P waves are typically very narrow in AVNRT as a result of the early septal activation during this tachycardia. AV nodal blockade will terminate the arrhythmia and likely prevent recurrence. This arrhythmia may be hemodynamically poorly tolerated even when relatively slow because of the near simultaneous atrioventricular activation. This results in atrial contraction against a closed atrioventricular valve producing increased back pressure in the venous beds (systemic and pulmonary).

patients develop inappropriate sinus tachycardia—a disorder of the autonomic control of the sinus node that results in P wave morphology identical to sinus rhythm but with abrupt and frequent increases in the heart rate for no apparent or definable reason [10–12]. Inappropriate sinus tachycardia may also be associated with other features of autonomic dysfunction and contribute to hypotension. Persistent tachycardia can be a feature of this condition, especially when patients recover from catastrophic illness.

Atrioventricular Nodal Reentry Tachycardia

AVNRT is a common arrhythmia in the ICU and the most common form of regular SVT, accounting for approximately 60% of cases [1,13]. It is more common in female patients between the ages of 20 and 40 years. Patients may complain of palpitations that occur with sudden onset and resolve spontaneously [14]. In addition, some patients may experience the urge to micturate either during or after termination of the rhythm. Older and debilitated patients may have severe symptoms in addition to the palpitations including angina and syncope.

AVNRT is a reentrant tachycardia that has a complex circuit. The atrial myocardial inputs to the AV node are discrete, involving an anterior input called the fast pathway and a posterior input in the region of the coronary sinus (CS) called the slow pathway. Because of these discrete inputs, in some patients, there is sufficient disparity in the conduction times and refractory periods of the two pathways, allowing initiation and maintenance of a reentrant tachycardia (AVNRT) [15–17].

In sinus rhythm, there is near simultaneous antegrade conduction through both the fast and slow pathway. Conduction proceeds more rapidly in the fast pathway and is responsible for the normal PR interval and conduction to the ventricle. Retrograde penetration of the slow pathway occurs and prevents the antegrade wave front through the slow pathway from reaching the AV node. Consequently, slow pathway activation remains electrically silent. When a premature atrial beat occurs, block in conduction down the fast pathway (relatively shorter refractory period) allows antegrade conduction with a long PR interval down the slow pathway. From this site, retrograde activation of the fast pathway may now occur and the reentrant arrhythmia ensues. Accordingly, the typical electrocardiographic feature of initiation of AVNRT is a premature atrial contraction with a long PR interval followed by the sudden onset of a regular narrow complex tachycardia with a very short RP interval.

AVNRT is characterized on ECG by a regular narrow complex tachycardia with P waves buried within or appearing either just before or after the QRS complex. The P wave is often closer to the preceding QRS complex, giving rise to a short RP tachycardia. The RP interval reflects the time from ventricular activation to atrial activation and is short in AVNRT because of the rapid conduction of the impulse retrograde to the atrium via the fast pathway. "Short RP" tachycardias signify fast retrograde activation that is characteristic of AVNRT. Ventricular rate is often noted to be between 150 and 250 beats per minute.

Acute management of symptomatic AVNRT often begins with attempts at Valsalva-like maneuvers which increase vagal tone and influence pathway refractoriness. If these are effective, no further therapy is usually required [18]. Medical therapy is indicated in patients with continued symptoms. Adenosine may be used as a first-line treatment and invariably terminates the

tachycardia. Other agents that may be used in the acute setting include intravenous (non-dihydropyridine) calcium channel blockers like verapamil or diltiazem. Beta-blockers and digoxin, like calcium channel blockers, may be used to slow conduction within the AV nodal system to interrupt reentry.

Specific Considerations in the Intensive Care Unit

Patients will typically have a history of AVNRT with symptomatic episodes in the setting of critical illness resulting from catecholamine stress and frequent premature atrial beats that initiate reentry. Repeated episodes may occur that result in hemodynamic instability. Once the diagnosis is established, it is important that cardioversion not be considered as primary management of this arrhythmia since recurrence is likely and simpler measures to terminate the arrhythmia exist. Any AV nodal blocking agent will terminate the arrhythmia (adenosine, esmolol, metoprolol, verapamil, etc.). A short-acting agent like adenosine may be tried first. If immediate reappearance is observed, intravenous infusion of an AV nodal blocking agent can be initiated and titrated both for blood pressure control as well as prevention of recurrence. Rarely, patients will have incessant AVNRT compromising their care. Anti-arrhythmic agents or urgent radiofrequency ablation can be considered in those situations.

Atrioventricular Reentry Tachycardia

AVRT is caused by a reentrant circuit that involves both the AV node and an extranodal AP. APs are typically muscular connections that traverse the AV annulus connecting atrial and ventricular myocardium directly, thus bypassing the AV node [19–21].

There are several manifestations with APs that may result in electrocardiographic changes and arrhythmia in the intensive care setting. In sinus rhythm, when the AP conducts in an antegrade direction, a typical constellation of electrocardiogram (ECG) findings result. The early part of the QRS is abnormal (δ wave) because of preexcitation of the ventricular myocardium rather than depolarization via the usual infrahisian conduction system. The combination of a short PR interval in addition to the δ wave enables ECG diagnosis of preexcitation. Wolff–Parkinson–White (WPW) syndrome results when reentrant tachycardia occurs in the presence of this pattern of preexcitation.

Reentrant tachycardias include those with antegrade conduction down the AV node and up the AP (orthodromic-reciprocating tachycardia) and the inverse circuit with antegrade conduction down the AP and retrograde conduction up the AV node (antidromic tachycardia). Finally, preexcited atrial fibrillation is a potentially life-threatening arrhythmia, the recognition and management of which is discussed in the text to follow (Figs. 42.4–42.6).

AVRT is a reentrant narrow complex tachycardia like AVNRT. Patients with AVRT have an AP that allows conduction to bypass the AV node. An impulse, either a premature atrial contraction or a premature ventricular contraction, travels to the AV node through the bundle of His, activating the ventricular system. Subsequently, the propagation travels up the AP causing retrograde conduction back to the atrium. This circuit is known as *orthodromic* AVRT because the antegrade pathway conducts the impulse to the ventricles via the normal AV node and His–Purkinje system. Orthodromic AVRT generally has a narrow QRS complex but may have a wide QRS complex when there is an underlying bundle-branch block. The ventricular rate continues to be controlled by the AV node during orthodromic AVRT. Because it is a regular narrow complex

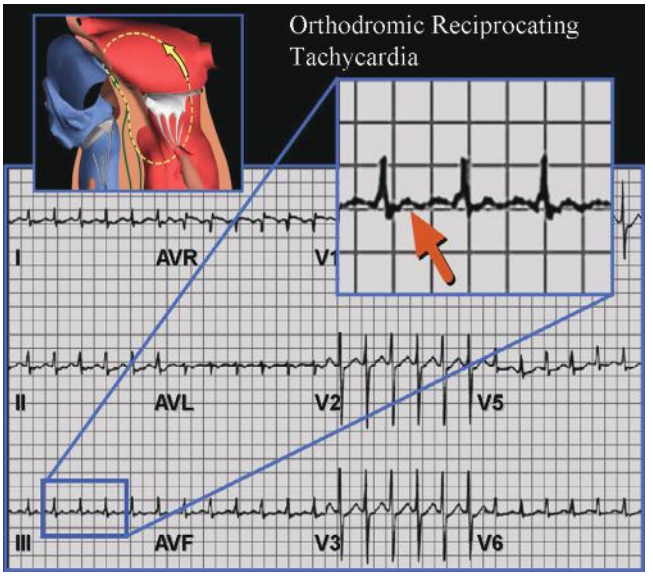

FIGURE 42.4. When an extranodal accessory pathway is present, the most common arrhythmia is ORT (orthodromic reciprocating tachycardia). Conduction occurs down the normal AV conduction system and up the accessory pathway producing a short RP tachycardia with an RP interval typically more than 100 ms.

tachycardia, it may be difficult to distinguish this rhythm from AVNRT or atrial tachycardia (discussed later). Termination of this rhythm usually transpires secondary to AV nodal conduction fatigue, increased vagal tone, or a premature extrasystolic beat.

Antidromic tachycardia manifests as a regular *wide* complex tachycardia and can occur in patients with antegrade conducting APs [22,23] (Fig. 42.7). This variant is less common but important to recognize since it may be confused with ventricular tachycardia. Initiation typically occurs with a premature atrial contraction that blocks in the AV node. Antegrade conduction proceeds via the AP to the ventricle with the return

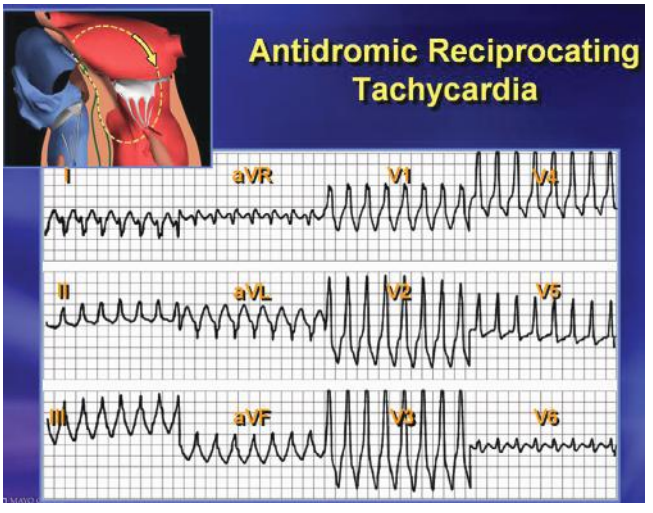

FIGURE 42.5. When an extranodal accessory pathway is present, a regular wide complex tachycardia may also result. Here, the tachycardia circuit proceeds antegrade down the accessory pathway and up through the AV nodal conduction system producing a regular wide QRS tachycardia with the QRS morphology dependent on the site of the accessory pathway. ART, antidromic-reciprocating tachycardia.

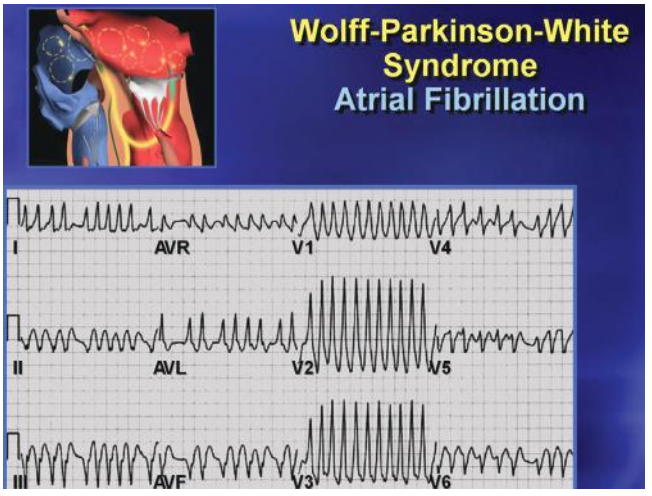

FIGURE 42.6. Potential life-threatening arrhythmia seen in patients when extranodal accessory pathway is preexcited atrial fibrillation. The AV node normally protects the ventricle from rapid ventricular rates during atrial fibrillation. However, when an accessory pathway is present, conduction may proceed down the accessory pathway as well as the AV node producing extremely rapid ventricular rates. The characteristics of a preexcited AF electrocardiogram include irregularly irregular R-R intervals along with rapid rates and importantly, irregular QRS duration and morphology as well (see text for details).

limb of the circuit through retrograde AV nodal conduction. Both orthodromic and antidromic AVRT are dependent on AV nodal conduction, and thus, AV nodal blockade (adenosine, beta-blockers, etc.) will terminate the arrhythmia and prevent recurrence. In contrast, a *preexcited* tachycardia occurs when another SVT (independent of the pathway) such as sinus tachycardia, AF, atrial flutter, etc., arises, but because of the presence of the antegrade conducting AP, rapid conduction to the ventricle takes place, bypassing the AV node. For these arrhythmias, AV nodal blockade would be contraindicated as there would be promotion of rapid aberrant conduction via the AP predisposing to ventricular arrhythmias. This is particularly problematic during AF when direct conduction through the antegrade AP may lead to ventricular fibrillation. The 2003 American College of Cardiology/American Heart Association (ACC/AHA) SVT management guidelines indicated that the incidence of sudden death with WPW is increased in patients with a minimum R-R interval <250 milliseconds during AF (regardless of whether AF is spontaneous or induced), a history of symptomatic tachycardia, multiple APs, and Ebstein's anomaly [24].

The acute management of regular tachycardia in patients with APs (orthodromic or antidromic AVRT) is similar and consists of AV nodal blockade to terminate the arrhythmia and the use of longer-term beta-blockers or calcium channel blockers to prevent recurrence. AV nodal blocking therapy is often sufficient as a temporizing maneuver until the patient's critical illness subsides and definitive ablation therapy can be offered [25,26].

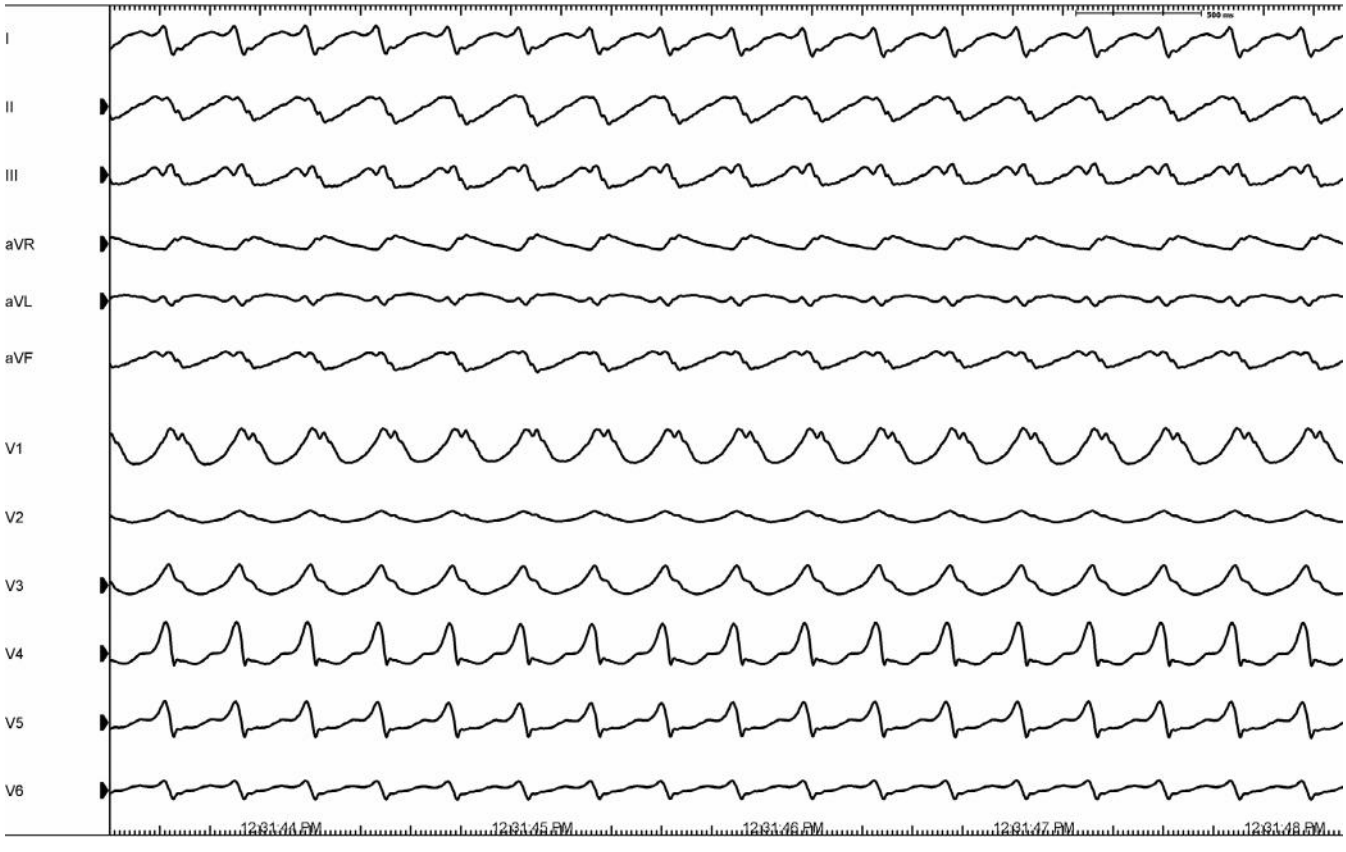

FIGURE 42.7. Regular wide complex tachycardia. When a regular wide complex tachycardia is seen in the critical care setting, ventricular tachycardia should always be considered. However, if the baseline electrocardiogram shows preexcitation, an *antidromic* tachycardia can be diagnosed and easily terminated with any AV nodal blocking agent. If the baseline electrocardiogram is not available, wide QRS tachycardia with consistent 1:1 R–P association in the absence of structural heart disease should raise suspicion for an accessory pathway-mediated mechanism.

Acute Management of Hemodynamically Significant AVRT

Valsalva-like maneuvers that increase vagal tone may be attempted initially. As with acute treatment of AVNRT, adenosine may be used as a first-line agent for medical management. Because of its very short half-life, a trial of adenosine may be attempted in patients with tenuous hemodynamics prior to emergent cardioversion. However, adenosine may potentially cause increased atrial vulnerability, a serious proarrhythmic side affect [27,28]. An alternative category of drugs often administered in the acute setting for treatment of orthodromic AVRT includes intravenous calcium channel blockers. Intravenous verapamil may be used and repeated every 2 to 3 minutes for acute termination of orthodromic AVRT but may be relatively contraindicated in patients with significant hypotension or depressed ventricular function or heart failure. Additional agents that may be used and often considered second-line treatment include intravenous beta-blockers (like metoprolol and propranolol) and procainamide. Rather than having a direct effect on AV nodal conduction, procainamide acts on the atrial and ventricular myocardium, causing decreased conduction and increase refractoriness of APs and the His–Purkinje system.

In contrast, when an irregular wide complex tachycardia is noted in a patient with known WPW, urgent intervention is required [29–31]. Preexcited AF once recognized, should be immediately terminated (Fig. 42.8). If the patient is hemodynamically unstable, urgent cardioversion is required. If not, an antiarrhythmic agent such as procainamide can be used. Procainamide may chemically convert the patient from AF to sinus rhythm and in addition, suppress conduction via the AP.

Patients with AVRT should be referred to a cardiac electrophysiologist for possible radiofrequency catheter ablation. Catheter ablation is highly successful, is associated with low risk, and eliminates the need for long-term drug therapy [32]. Ablation is often considered first-line therapy in young patients who prefer a curative approach.

Specific Considerations for the Intensive Care Setting

Preexcited AF should be immediately recognized and treated when observed but is an unusual presentation in critically ill patients. More commonly, repeated episodes of reentrant AVRT (usually orthodromic) arise in patients with known APs. Frequent and sometimes incessant episodes can result from the stress of critical illness combined with possible discontinuation of previously used AV nodal blocking agents for medical management. Judicious use of short-acting intravenous beta-blockers will help prevent recurrences of arrhythmia without major untoward hemodynamic consequences.

Caregivers of the critically ill patient must also be aware that the presence of a WPW pattern on the EKG by itself is not a contraindication to use beta-blockers or other AV nodal blocking agents if clinically required for comorbid illnesses such as coronary disease. If, however, a patient with WPW has AF, AV nodal blocking agents should be avoided or used in conjunction with antiarrhythmic agents like procainamide to suppress AP conduction (Fig. 42.9).

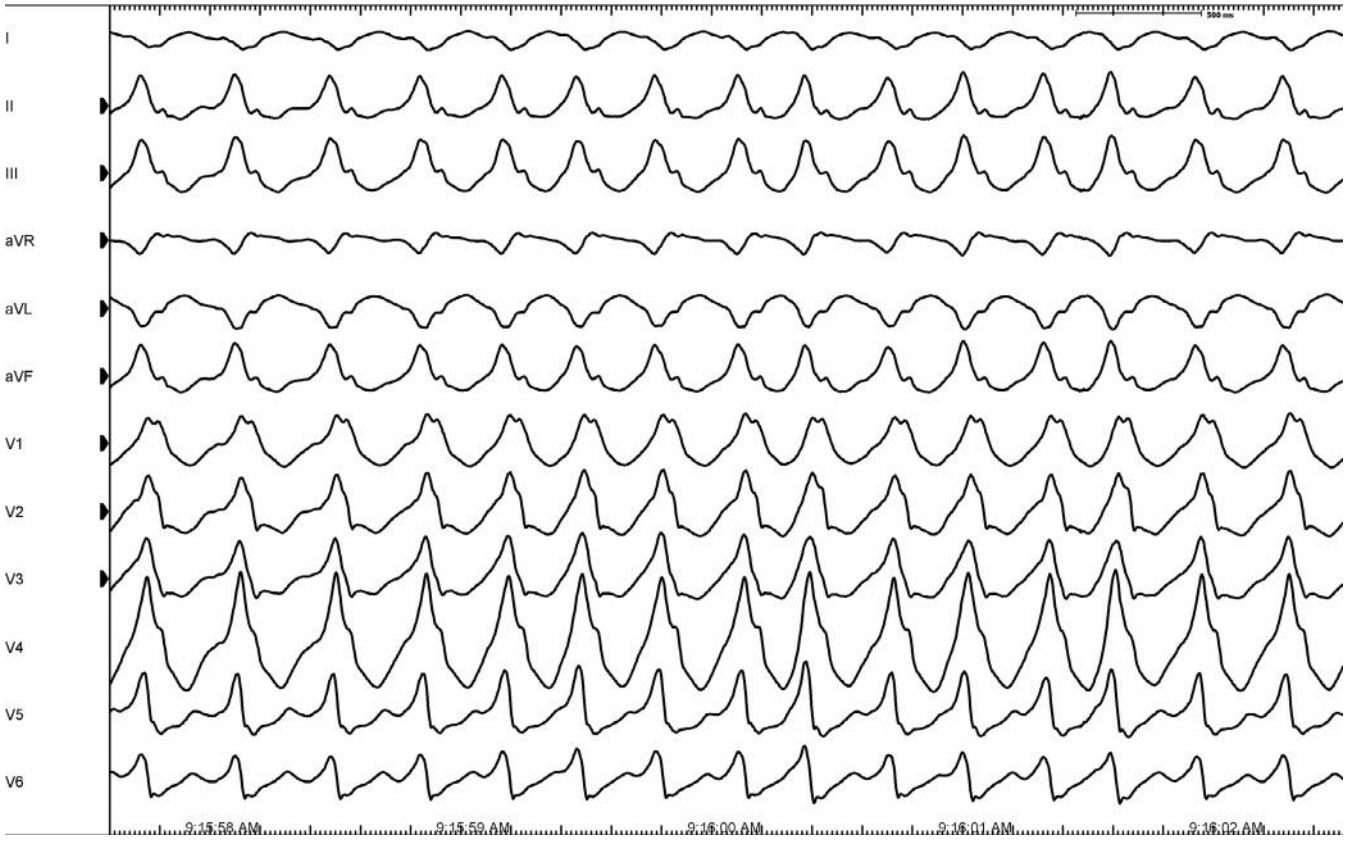

FIGURE 42.8. Preexcited atrial fibrillation. All caregivers for critically ill patients should be familiar with this pattern. An irregular wide complex tachycardia is noted. Importantly, the ventricular rates are fast, and each QRS morphology is slightly different. Especially if the baseline electrocardiogram had shown preexcitation (WPW) pattern, this urgent condition of preexcited atrial fibrillation should be immediately recognized. Regardless of present symptoms, cardioversion should be considered if the patient is relatively unstable; chemical cardioversion with an agent such as procainamide that may convert the atrial fibrillation to sinus rhythm and simultaneously slow conduction to the accessory pathway can be tried.

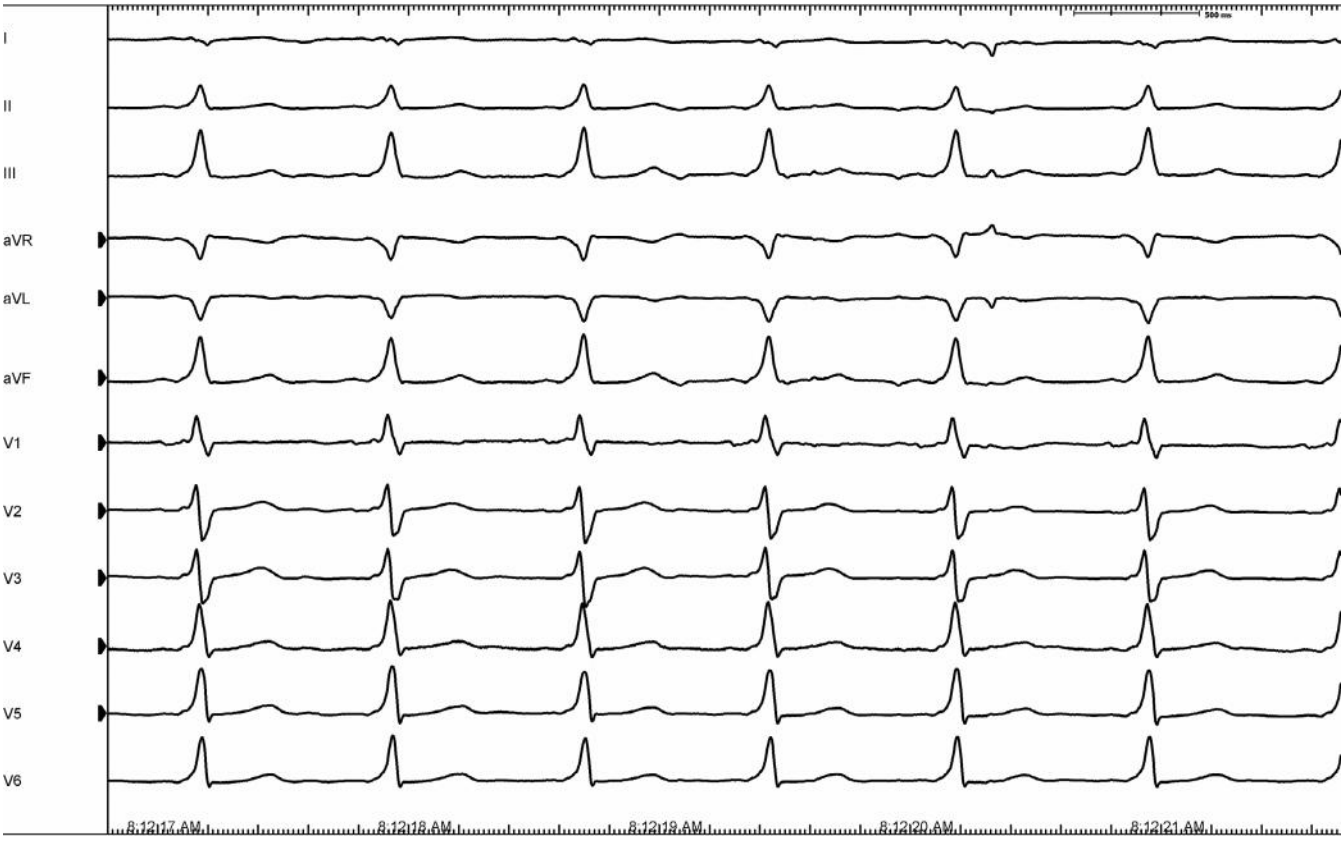

FIGURE 42.9. Characteristic electrocardiogram in patient with antegrade preexcitation. Note the short PR interval and the δ wave clearly seen in the lateral precordial leads and lead II. The R wave seen in lead V_1 and negative δ wave in lead I is consistent with the left-sided accessory pathway. If a patient with this baseline electrocardiogram develops atrial fibrillation, this should be treated as a medical emergency because of risk of ventricular fibrillation from the atrial fibrillatory waves conducting to the ventricle via this pathway without the intervening protective effects of the AV node.

IRREGULAR NARROW COMPLEX TACHYCARDIA

Several of the regular narrow complex tachycardias already discussed may occasionally present with irregular R-R intervals. However, by far, the most common irregular narrow complex tachycardia occurring in an ICU setting is AF. In this section, we discuss this common arrhythmia in detail, presenting information on pathogenesis, recognition of variants, and acute management in the critically ill patient. Although less common, atrial flutter with variable conduction block and multifocal atrial tachycardia should be distinguished from AF since management differs significantly.

Atrial Fibrillation

AF is the most common type of arrhythmia, and the most common SVT seen in the ICU. Incidence increases with age; it is found in less than 0.1% of adults younger than 55 years but in more than 9% of the population age 80 years or older [33,34]. AF is characterized by the presence of chaotic appearing multiple shifting reentrant atrial wavelets that may appear flat or irregular. Classification of AF usually depends on the duration and frequency of occurrence. Paroxysmal AF makes up about 40% of cases and may last up to 7 days, terminating spontaneously. Nonparoxysmal AF lasts more than 7 days and requires cardioversion for termination. Identification of AF is important clinically because of the increased risk of hemodynamic instability and mortality associated with this arrhythmia in the intensive care setting. AF is characterized by irregular atrial contractions, as demonstrated on ECG by irregularly irregular f waves that may manifest as continuous irregular variation in the baseline (Fig. 42.10).

AF may become problematic to patients in the intensive care setting due to hemodynamic instability. Hemodynamic compromise is likely in cases of AF associated with rapid ventricular response, especially when associated with diastolic dysfunction. In addition, hemodynamic instability is common in AF with rapid ventricular response in patients in whom a more prolonged diastolic filling period would be desirable, such as mitral stenosis, hypertrophic obstructive cardiomyopathy, restrictive cardiomyopathy, or constrictive pericardial disease. Patients with underlying WPW syndrome who develop AF can have hemodynamic instability due to a rapidly conducting antegrade AP as previously mentioned. If antegrade AP conduction is present during AF, ECG findings show an irregular wide complex tachycardia with varying degrees of ventricular preexcitation. As mentioned previously in the discussion of AVRT management, AV nodal blocking agents are contraindicated in this instance as they may enhance antegrade AP conduction and increase risk of ventricular fibrillation.

Another important complication of AF is thrombus formation in the left atrium that may embolize to the cerebral circulation and ultimately result in ischemic stroke. Therefore, early recognition of AF, its risk factors, and proper treatment is prudent in the management of the critically ill patient.

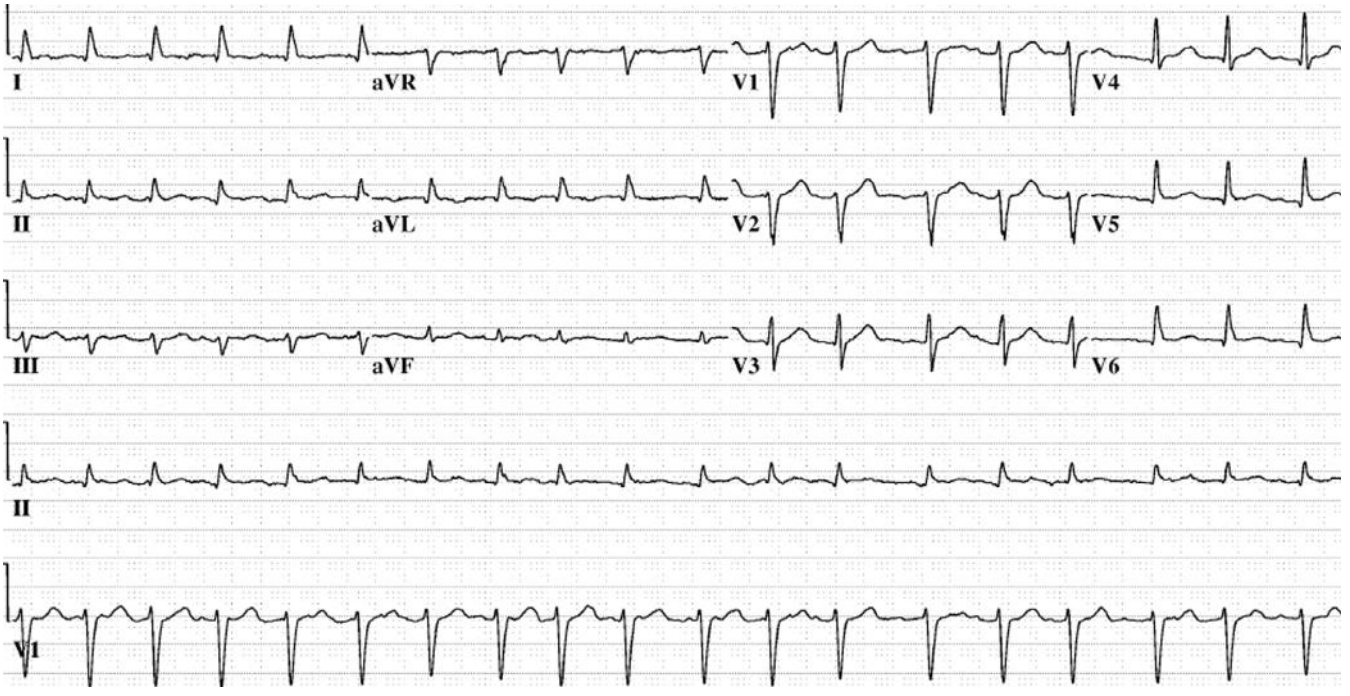

FIGURE 42.10. Atrial fibrillation with rapid ventricular rates. In some leads, there is an appearance of organization of the arrhythmia (flutter-like). However, this is inconsistent in other leads and is often seen in atrial fibrillation, particularly in patients with left atrial hypertrophy. The ventricular rates are irregular and management will depend on the associated hemodynamic changes (see text for details).

Causes of Atrial Fibrillation

Initiation and maintenance of AF varies and often is multifactorial. The three main initiating causes include rapidly discharging triggers or foci, the autonomic nervous system that triggers activity, and substrate abnormalities that permit and promote wavelet reentry [35–37]. The pulmonary veins are lined with myocardium that has a shorter effective refractory period and is capable of more rapid discharge than the endocardium. The muscular lining of the pulmonary veins is the most common site of rapid discharge leading to the initiation and maintenance of AF. The autonomic nervous system is also an important source in initiating AF. Sympathetic stimulation may facilitate altered automaticity and result in focal discharge. In addition, enhanced vagal tone may shorten the refractory period and increase heterogeneity. Patients with conditions like myocarditis, congestive heart failure, valvular heart disease, coronary artery disease, hypertension, and other diseases leading to atrial stretch and interstitial fibrosis may develop AF due to these substrate abnormalities. Substrate abnormalities cause heterogeneity in electrophysiologic cellular properties leading to breakdown in waveform propagation and multiple wavelet reentry. Because of electrical remodeling, the more frequent AF occurs, the greater the likelihood of further AF episodes [38,39].

In addition, several reversible risk factors have been identified to be associated with AF, and these should be recognized by the practitioner to aid in proper management. The most common underlying disease that may lead to AF is hypertension [40]. Studies have shown that treatment of hypertension with ACE inhibitors or ARBs may reduce the incidence of AF, especially in patients with altered left ventricular function [41]. The utilization of beta-blockers is also effective in controlling ventricular response. AF has been associated with up to 10% of patients suffering from an acute myocardial infarction. The underlying mechanism is thought to be secondary to atrial stretch or remodeling due to cardiomyopathy [42]. Other cardiac risk factors include pericarditis, myocarditis, congenital heart disease, and valvular heart disease. Obesity and metabolic syndrome have also been linked to AF [43]. Pulmonary embolism is also a risk factor for AF and should never be overlooked in the intensive care or postoperative setting. Consumption of excessive amounts of alcohol is a well-known risk factor for AF. Binge drinkers have a significantly increased risk of developing AF, a phenomenon referred to as *holiday heart syndrome* [44]. Moderate use of alcohol, in contrast, has not been consistently shown to be associated with AF [45]. Surgery, both cardiac and noncardiac is also associated with the development of AF. Cardiac surgeries, especially coronary artery bypass grafting and valvular repair or replacement, have a greater association with the development of AF than noncardiac surgeries. Perioperative administration of beta-blockers for prophylactic treatment has been shown to significantly reduce the incidence of AF in this setting [46,47]. Additional noncardiac risks factors associated with AF include obstructive sleep apnea, thyrotoxicosis, and inflammatory states.

AF is common in the surgical perioperative period (predominantly in the first 4 postoperative days), and as previously mentioned, most often observed in patients undergoing cardiac surgery. Studies have reported that AF may occur in up to 40% of patients undergoing coronary artery bypass grafting and up to 60% in those undergoing combined coronary grafting and valve surgery [48–50]. Postoperative AF may be reduced by administration of prophylactic doses of beta-blockers, calcium channel blockers, amiodarone, corticosteroids, or even lipid-lowering agents [51–54]. The increased incidence of AF in the perioperative setting is unknown but thought to be secondary to atrial ischemia, atrial incisions, pericarditis, inflammation, changes in autonomic tone, and large fluid shifts. Important risk factors for the development of AF postoperatively include cessation of beta-blocker therapy, chronic obstructive pulmonary disease, left atrial enlargement, advanced age, heart

failure, and a previous history of AF. Atrial fibrillation in this setting is self-limited and usually resolves completely within 8 weeks.

Management of Atrial Fibrillation

The goal of AF treatment is to minimize symptoms (palpitations, shortness of breath, lightheadedness, dizziness, and fatigue), prevent or reduce tachycardia-induced cardiomyopathy, and prevent thromboembolic complications like stroke. Whether treatment of AF results in favorable outcomes is unknown. Although the Framingham study showed increased incidence of mortality in patients with AF after adjustment for common confounders, other, more recent studies have not shown that treatment contributes to improved survival rates [55]. However, as with all other arrhythmias, it is prudent to evaluate and assess the hemodynamic stability of a patient with AF. As mentioned previously, critically ill patients may develop hemodynamic instability in association with AF, especially those for whom a shortened diastolic filling period would be detrimental (e.g. mitral stenosis, hypertrophic obstructive cardiomyopathy, restrictive cardiomyopathy, constrictive pericarditis) or WPW. In these instances, synchronized direct current (DC) cardioversion is indicated. Premedication with an anxiolytic, opiates, or generalized anesthesia is appropriate. DC cardioversion usually results in successful conversion to normal sinus rhythm in a majority of cases. Treatment with intravenous procainamide or ibutilide may also be used in patients with AF and a wide-complex tachycardia associated with hemodynamic instability as these patients may have underlying WPW. Eventually, patients with AF in the setting of underlying WPW should undergo radiofrequency ablation of the AP once deemed clinically suitable.

In hemodynamically stable patients, a more conservative management approach is taken. Once the patient is considered to be hemodynamically stable, a history and physical examination focusing on delineating a possible reversible cause of AF should be undertaken. Common, reversible causes of AF in the critically ill patient include myocardial infarction, pericarditis, infection or inflammation, pulmonary embolism, hyperthyroidism, recent cardiac surgery, and stroke. In addition, a review of possible iatrogenic causes including administration of proarrhythmic medications like common sympathomimetics should be made. Special attention to electrolyte abnormalities and correction should also be done. The ultimate goal of therapy for otherwise hemodynamically stable patients who develop acute onset AF is improvement of quality of life by controlling rate, rhythm, or both, and providing anticoagulation when indicated.

Strategies that focus on either rate control or rhythm control in hemodynamically stable patients may be used. Rate control refers to an approach that uses AV nodal blocking agents to decrease ventricular rate and improve hemodynamics. Calcium channel blockers, beta-blockers, or even AV nodal ablation may be used to control the ventricular rate. Conversely, rhythm control is an attempt to keep the patient in sinus rhythm. Strategies include cardioversion, antiarrhythmic drug treatment, percutaneous ablation, and various surgical procedures. As discussed previously, the ultimate goal of treatment of AF is to improve the quality of life. Therefore, management with both rate control and rhythm control provides the greatest improvement in symptoms. However, the AFFIRM (Atrial Fibrillation Follow-up Investigation of Rhythm Management) trial, a study of 4,060 patients older than 65 years with a history of AF and additional risk factors for stroke and death who were randomly assigned to receive either rate control or rhythm control therapy showed no significant difference in improvement of quality of life between rate control strategies and rhythm control strategies [56]. As a result, individualizing treatment strategies to the patient's needs is important in management of AF. Although treatment strategies may vary, elderly patients who have minimal symptoms are often managed with rate control, whereas younger patients with significant symptoms and structural heart disease are often managed with rhythm control.

Specific Considerations for the Intensive Care Setting. In all patients with AF, systematic consideration to whether rate or rhythm control strategies should be adopted, and a decision as to which anticoagulation strategy is most appropriate should be made. In the critically ill patient, timely judgment regarding treatment with either urgent control of rate or rhythm becomes more crucial. In addition, a careful analysis of the potential risks associated with slowing of the heart rate or the development of proarrhythmic complications from antiarrhythmic therapy is needed.

Atrial fibrillation with obvious hemodynamic collapse requires urgent cardioversion regardless of anticoagulation status, attempts at rate control, etc. This situation is quite rare. Whenever significant hemodynamic compromise is noted in a patient with AF (particularly with reasonably controlled rates), another cause for hypotension or shock should be investigated. However, in patients with significant valvular disease (critical aortic stenosis) or with severe diastolic ventricular dysfunction (longstanding hypertension, hypertrophic cardiomyopathy), the onset of AF can be very symptomatic and occasionally lead to hypotension, pulmonary edema, and findings consistent with cardiogenic shock.

Nevertheless, in most situations, the clinician should assess systematically for optimal methods to control rate, and if symptoms continue despite rate control, methods to restore sinus rhythm and assess for anticoagulation are needed.

Rate Control

Rate control for patients with AF is often pursued not only to help alleviate symptomatic palpitations, but also to prevent hemodynamic compromise and prevent tachycardia-induced cardiomyopathy that may occur with prolonged rapid ventricular rates. Rate control provides adequate ventricular filling and reduces rate-related ischemia, thus, improving symptoms. On the basis of parameters used in the AFFIRM trial, rate control can be defined as having a resting heart rate of less than 80 beats per minute and a maximal heart rate less than 110 beats per minute during a 6-minute walk [57]. AV nodal blocking agents like beta-blockers and calcium channel blockers are the most commonly used agents in this setting. These agents have predominantly safe profiles. Conversely, awareness of calcium channel blockers' association with heart failure exacerbation must be recognized in patients with low left ventricular ejection fractions. Amiodarone may also be used to achieve rate control. In patients with labile blood pressures, digoxin is often used to provide rate control but may prove insufficient as a single agent.

Alternatively, in chronic settings beyond the scope of the ICU, AV node ablation combined with permanent pacemaker implantation may be considered when pharmacologic rate control therapy is either unsuccessful or not tolerated [58,59]. It is important to note that although AV node ablation decreases symptoms and improves quality of life, studies have shown no impact on overall survival [60,61].

Rate Control Issues in the Intensive Care Setting. Rate control can be particularly difficult when patients are hypotensive in AF as a result of coexisting critical illness. Digitalization is sometimes effective; however, in states of high circulating catecholamines, digoxin is not useful. Administering intravenous calcium just prior to initiating an intravenous calcium channel blocker (diltiazem, verapamil) may sometimes minimize

hypotension while achieving reasonable rate control. Careful scrutiny of the utilization of intravenous sympathomimetic agents and titration of dose to decrease AV nodal conduction should be considered. For example, changing from high-dose dopamine or epinephrine to phenylephrine in a patient with septic shock may be sufficient to support the blood pressure without necessarily increasing AV nodal conduction and thus rapid ventricular rates.

Rhythm Control

Management of AF in stable patients may be geared toward restoration of sinus rhythm. DC or chemical cardioversion strategies can be employed. This may be a good option for young patients, but older patients with cardiomegaly and left atrial enlargement are less likely to have successful results. Hemodynamically stable patients who have documented development of acute AF for duration of 48 hours or less may proceed with early cardioversion. Alternatively, hemodynamically stable patients with AF that has lasted for more than 48 hours or have an unknown duration of AF may still undergo cardioversion. It is important to rule out intracardiac thrombus that may be associated with AF and can subsequently embolize with cardioversion and return to normal sinus rhythm. Therefore, two different strategies may be undertaken. First, transesophageal echocardiogram (TEE) can be utilized to rule out intracardiac thrombus formation. Once thrombus is excluded by TEE, cardioversion may proceed using the aforementioned strategies. Subsequent anticoagulation with warfarin is prudent, with an INR goal of 2 to 3 for at least 4 weeks [62]. Another strategy that may be used in patients with AF that has lasted for more than 48 hours or unknown duration is to anticoagulate with a goal INR of 2 to 3 for 3 weeks prior to cardioversion. Patients are subsequently instructed to continue anticoagulation therapy for an additional 4 weeks after cardioversion to prevent thromboembolic events that may result from delayed atrial mechanical recovery in this setting.

Concomitant use of antiarrhythmic medications with DC cardioversion increases the probability not only of successful cardioversion, but also maintenance of sinus rhythm for longer periods of time. Because antiarrhythmic drugs have many proarrhythmic side effects, the particular regimen chosen depends on the clinical setting and the underlying cardiovascular disease. Flecainide, propafenone, or sotalol are often used for patients without underlying structural heart disease. Amiodarone and dofetilide are often recommended in patients with underlying heart failure, while sotalol or dofetilide may be used in patients with coronary artery disease. Consultation with a cardiologist is recommended.

Drugs often used for chemical cardioversion in the acute setting include procainamide, flecainide, propafenone, dofetilide, and ibutilide. Although this is often an appropriate strategy, studies have shown pharmacologic cardioversion to be less effective than DC cardioversion in combination with antiarrhythmic drugs [63]. Studies have demonstrated a better outcome and safety profile with ibutilide compared with propafenone [64,65]. AV nodal blocking agents like beta-blockers or calcium channel blockers should be used with class Ia and Ic antiarrhythmics to prevent conversion of AF to a slow atrial flutter with 1:1 AV conduction.

Rhythm Control Issues in the Intensive Care Setting. A frequent clinical scenario in which AF is encountered in the ICU is the postcardiac surgical patient. The incidence of AF in these patients is high (8% to 34%) [33,49,66]. Because of this, unless a contraindication is present, many ICUs use amiodarone prophylactically in the postoperative period. When AF occurs in other situations and rate control is suboptimal, the choice of antiarrhythmic agent depends primarily on whether structural heart disease is present or not. In patients with structural heart disease, intravenous amiodarone is preferred with attempt at cardioversion either for hemodynamic instability or following initial amiodarone loading. In the absence of structural heart disease, when oral medication can be administered, rate control with a beta-blocker and initiation of a class Ic agent is a common management strategy. In addition, the temporary use of IV amiodarone can be considered until the medical illness subsides and long-term rhythm control with less toxic antiarrhythmic agents or with nonpharmacologic treatment options can be considered [33,51,53,67,68].

Prevention of Thromboembolic Complications

An important aspect in the management of AF is implementation of risk-appropriate anticoagulation. Studies have consistently shown an increase in cardioembolic stroke rates in patients with AF [69–71]. In addition to causing a hypercoagulable state, AF impairs proper atrial contraction leading to blood stasis in the left atrium and ultimately a physiologic state promoting thrombus formation [72,73]. Therefore, an understanding of risk factors for stroke in patients with AF is essential. Risk factors may be easily remembered by using the mnemonic *CHADS2*, which stands for *c*ardiac failure (recent heart failure), history of *h*ypertension, *a*ge greater or equal to 75 years, history of *d*iabetes, and a history of *s*troke or a transient ischemic attack [74]. The number 2 stands for the fact that a history of stroke counts as 2 risk factors points. The CHADS2 mnemonic is also used as a risk stratifying score to help predict patients at significantly increased risk of developing an ischemic stroke from a cardioembolic event in the setting of AF [74]. Based on these scores, the annual predicted stroke risk can be calculated. The adjusted annual stroke rate increases from 1.9% in patients with a CHADS2 score of 0% to 18.2% in patients with a CHADS2 score of 6.

Once the CHADS2 score and the risk for stroke are estimated for patients with AF, the decision on the type of prophylactic antithrombotic therapy, if any, needs to be determined. On the basis of the 2006 ACC/AHA/ESC guidelines for the management of AF, aspirin 81 mg to 325 mg daily is recommended for patients with no risk factors for thromboembolism (CHADS2 score of 0) [75]. Patients with a single risk factor or a CHADS2 score of 1 may be managed with either aspirin 81 to 325 mg daily or an adjusted-dose warfarin regimen with an INR goal of 2.0 to 3.0 [75]. For patients with risks that confer a high-risk score (a previous stroke or TIA, rheumatic mitral stenosis, or a CHADS2 score of 2 or higher), warfarin is recommended with an INR goal of 2.0 to 3.0 [75]. Anticoagulation with other agents like unfractionated or low-molecular-weight heparin may be used as alternative bridging therapy in patients requiring certain procedures or surgeries.

Anticoagulation Issues Relevant in the Intensive Care Unit. Appropriate anticoagulation in the critically ill patient is particularly problematic even when following present guidelines and using the CHADS2 scoring system [76,77]. Postsurgical patients, patients at risk for intracranial bleeding, patients with closed head or closed chest trauma, etc., frequently have a contraindication for systemic anticoagulation. If the patient has chronic AF and the CHADS2 score is ≤ 2, in general, anticoagulation can be safely discontinued for the period of the acute illness. In patients with CHADS2 >2, anticoagulation free intervals should be minimized and aspirin provided if not also contraindicated.

For patients who are hemodynamically compromised with new onset AF, urgent cardioversion can be performed regardless of anticoagulation status. When less urgent, TEE may first be performed to exclude evidence of an intra-atrial thrombus prior to cardioversion and reinitiation of anticoagulation when

the risk of bleeding is minimal [78,79]. Atrial appendage occlusion devices, exclusion devices, or minimally invasive surgical techniques may be particularly useful in these situations and are being investigated for clinical efficacy and safety [80,81].

Atrial Flutter

Atrial flutter, like AF, is one of the most common arrhythmias encountered in the critically ill patient. It is identified by a characteristic sawtooth pattern of atrial activity at an atrial rate of 240 to 320 beats per minute. Although variable ventricular conduction may occur, a 2:1 transmission commonly transpires, resulting in a ventricular response rate of about 150 beats per minute. The mechanism of common atrial flutter is a macroreentry loop around the tricuspid annulus. The loop often runs in a counterclockwise direction, causing negative flutter waves in the inferior leads (II, III, aVF). Other reentry patterns may also be encountered but are beyond the scope of this chapter. Occasionally the ventricular rate may be greater than 150 beats per minute, making identification of the flutter waves difficult. Vagal maneuvers like carotid sinus massage or adenosine, a medication that briefly blocks AV nodal conduction, may be used in these instances to slow down the rate and allow for more accurate identification of the arrhythmia.

Patients with an acute onset of atrial flutter often present with symptoms of palpitations, dyspnea, chest discomfort, and worsening symptoms of heart failure. As with AF, prompt assessment of hemodynamic status is critical in this setting. Management of atrial flutter is similar to AF, and the same guidelines for rate control, rhythm control, and anticoagulation apply [82]. Rate control in atrial flutter often proves more difficult than in AF. Unlike AF, which has multiple reentrant wavelets, typical atrial flutter is composed of a single, fixed reentrant pathway that provides a target amenable to cure by radiofrequency catheter ablation. Ablation is usually performed within the right atrium between the tricuspid annulus and the inferior vena cava to interrupt the atrial flutter circuit [83]. Atrial flutter not associated with a typical reentrant circuit has less successful ablation outcomes [84]. Ablation of the AV node with subsequent permanent pacemaker implantation, a method used in management of AF, may be an option in certain circumstances.

Managing Atrial Flutter in the Intensive Care Unit

Atrial flutter is frequently an unstable arrhythmia in terms of ventricular rate response. Specific caution is necessary when instituting β-adrenergic agents in patients with otherwise well-controlled response rates. Rapid change from 2:1, 3:1 AV conduction to 1:1 conduction and ventricular rates of 300 beats per minute or more can occur. Such abrupt changes in ventricular rate are uncommon with AF but should be expected with atrial flutter. Cardioversion to sinus rhythm prior to initiating pharmacological agents that enhance AV nodal conduction should be considered. Unlike with AF, immediate recurrence of atrial flutter is uncommon, and therefore, routine administration of an antiarrhythmic agent to prevent return may not be required.

Urgent radiofrequency ablation for atrial arrhythmia is rare in the critically ill patient. However, if atrial flutter with rapid rates and recurrence following cardioversion is seen, the procedure can be considered. Procedural success for atrial flutter ablation is highest for cavotricuspid isthmus dependent flutter. This specific arrhythmia can be recognized by the flutter wave morphology wherein the terminal segment of the flutter wave in lead V_1 is positive [85,86]. The use of antiarrhythmic agents like procainamide or flecainide may further organize an atrial flutter and decrease the *atrial* rate of the flutter. This may, however, paradoxically result in more rapid ventricular conduction which can be consequential in critically ill patients. Low dose AV nodal blocking agents should be instituted simultaneously when membrane active drugs, such as type Ic agents, are started for atrial flutter in the ICU setting.

Patients with persistent atrial flutter, especially of more than a year's duration may have significant underlying sinus node dysfunction. When cardioversion or pace termination of the flutter is planned, prolonged sinus node pauses may occur, and standby external or endocardial temporary pacing should be considered [87] (Fig. 42.11).

Multifocal Atrial Tachycardia

Another commonly encountered irregular narrow complex tachycardia in the ICU is multifocal atrial tachycardia (MAT). This SVT is caused by several abnormal atrial foci. Thus, MAT is characterized by at least three different P wave morphologies in a single lead with variable PR intervals. The atrial rate often varies between 100 and 180 beats per minute with no single, dominant pacemaker. MAT is highly associated with underlying pathologic processes that increase atrial pressures. Common etiologies for the development of MAT include chronic obstructive pulmonary disease, pneumonia, pulmonary embolism, mitral stenosis, and congestive heart failure. Other common causes include various electrolyte and acid–base disturbances. Management of MAT involves aggressive treatment of the underlying disease. Acute measures aimed at ventricular rate control include calcium channel blockers or beta-blockers with varying degrees of success [88–90]. It is important to note that because this particular population is more prone to bronchospastic disease, calcium channel blockers may be preferred. Digoxin should not be used in this setting, as it shortens atrial refractoriness which may worsen the rhythm.

Multifocal Atrial Tachycardia in the Intensive Care Setting

Rate control can be extremely difficult with this arrhythmia. Unless underlying theophylline toxicity or hypoxia is corrected, managing rapid ventricular rates and symptoms resulting from deleterious hemodynamic effects are often futile. Consideration for AV node ablation in refractory patients even in the setting of critical illness can be considered, especially if rapid rates compromise attempts to manage the patient's hypotension and other complicating medical illnesses. Intravenous magnesium as hypoxia is being addressed may also help temporize patient compromise until hypoxia is corrected or a definitive procedure is performed [91].

SUMMARY

Management of SVT in critically ill patients can be challenging. To maximize results, quick and accurate diagnosis of the exact arrhythmia mechanism is required. The caregiver should have an approach to analyzing the electrocardiogram during SVT. If a *regular* narrow complex tachycardia is noted, then a careful search for the P wave should be made. An abrupt onset arrhythmia with a short RP interval is likely a reentrant SVT either AVNRT or AVRT. In both arrhythmias, adenosine for immediate conversion of the arrhythmia and intravenous AV nodal blocking therapy for prevention of recurrence is highly effective. Cardioversion is of little value in this situation because of the likelihood of recurrence and the almost certain conversion of the arrhythmia with pharmacological agents. When the P wave is difficult to identify, examine the terminal portion of the QRS complex to look for pseudo R′ waves (lead V_1) or pseudo S waves (leads II, III, and aVF) (Fig. 42.12).

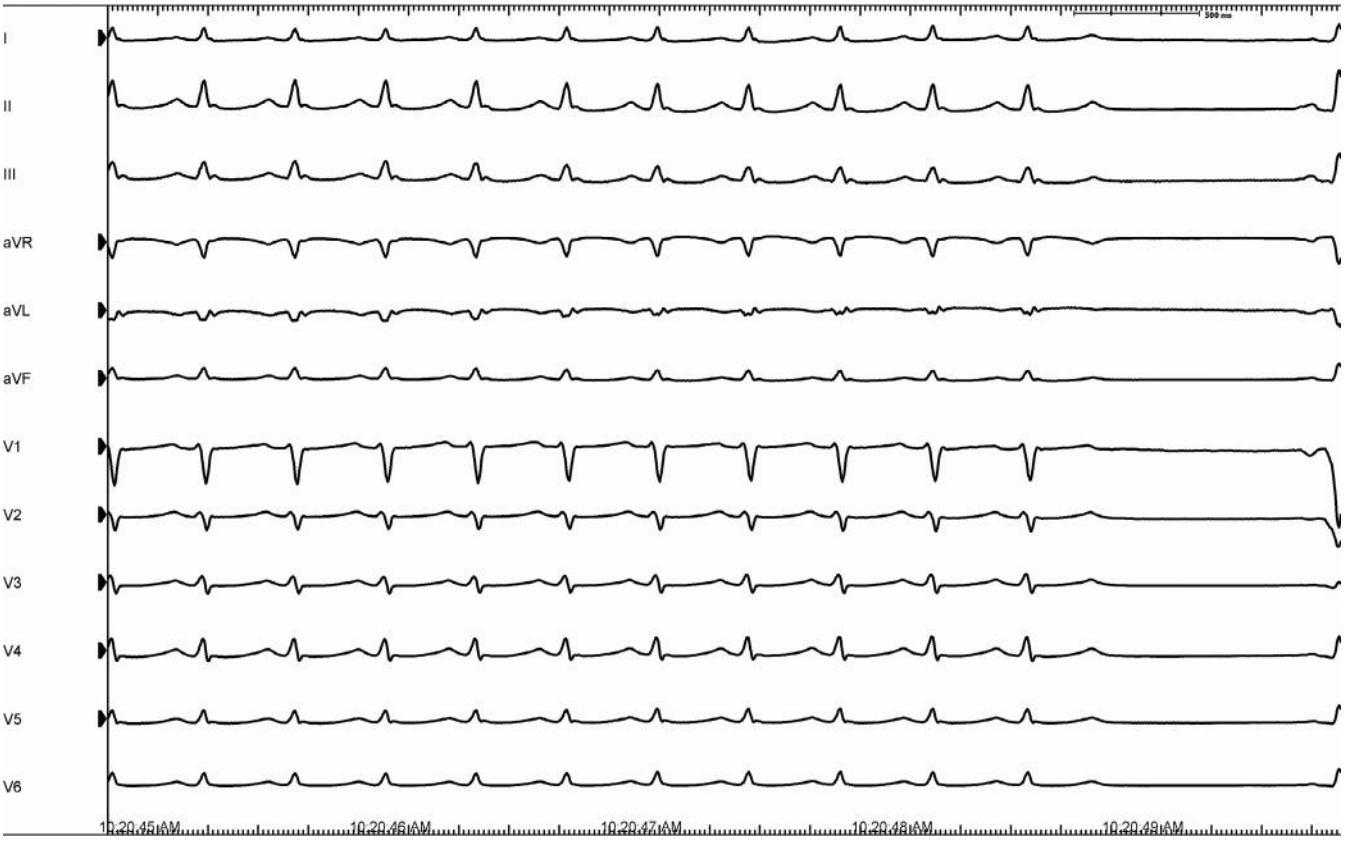

FIGURE 42.11. Slow supraventricular tachyarrhythmia. In a critically ill patient, the initial arrhythmia may be mistaken for sinus tachycardia. However, closer scrutiny of the P wave morphology defines a non-sinus mechanism (absence of terminal negative portion in the P wave in lead V_1). Note the abrupt termination that would essentially exclude a sinus mechanism. If recurrences are seen and associated with hemodynamic changes, intravenous antiarrhythmic agents can be considered. Automatic atrial tachycardias are often catecholamine sensitive, and when possible, the use of these agents for therapy should be minimized when the arrhythmia is seen. Note also the significant pause on termination of the arrhythmia suggesting underlying sinus node dysfunction.

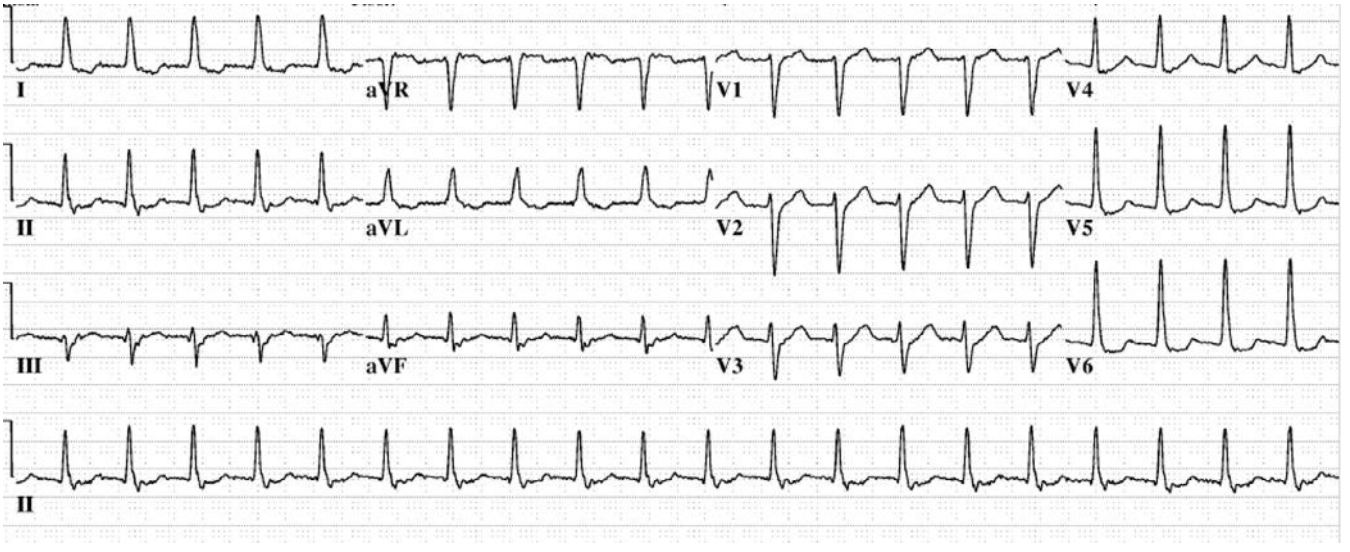

FIGURE 42.12. 12-Lead electrocardiogram in a patient with symptomatic atrioventricular node reentry during hospitalization. Note the P waves are difficult to define; however, the late "S" waves easily recognized in leads II, III, and aVF (pseudo S wave) are characteristic of this arrhythmia.

TABLE 42.1

SUMMARY OF EVIDENCE-BASED RECOMMENDATIONS FOR TREATMENT OF VARIOUS SUPRAVENTRICULAR TACHYCARDIAS

Disease	Treatment
Atrioventricular nodal reentrant tachycardia (AVNRT)	Adenosine Calcium channel blockers Beta-blockers
Atrioventricular reentry tachycardia (AVRT)—*hemodynamically stable*	Adenosine Calcium channel blockers Beta-blockers Procainamide Refer for possible ablation therapy
AVRT with underlying atrial fibrillation/atrial flutter	AV node blocking agents contraindicated
AVRT with wide complex (WPW)—*hemodynamically unstable*	Urgent cardioversion
AVRT with wide complex (WPW)—*hemodynamically stable*	Procainamide
Atrial fibrillation Hemodynamically stable	*See text regarding anticoagulation* *Rate control*: Beta-blockers, calcium channel blockers, amiodarone, digoxin, AV junction ablation *Rhythm control*: Cardioversion, antiarrhythmic drug treatment, ablation, various surgical procedures
Hemodynamically unstable	DC cardioversion Procainamide or ibutilide may be used in cases of wide-complex tachycardia (underlying WPW)
Atrial flutter	Management approach similar to atrial fibrillation
Multifocal atrial tachycardia	Calcium channel blockers Beta-blockers

Note: **Identifying an underlying cause of arrhythmia should always be attempted.**

For a gradual onset tachycardia with a long RP interval, either sinus tachycardia, inappropriate sinus tachycardia, or atrial tachycardia is likely. If the P wave morphology is not consistent with sinus rhythm, then an atrial tachycardia is present, and antiarrhythmic therapy with rate control is likely effective. If the P wave morphology is consistent with sinus rhythm, sinus tachycardia is most likely, and treatment directed to the underlying mechanism (blood loss, fever, hypotension, etc.) will likely result in eventual decrease in the sinus rates. No specific rhythm-based therapy is required. Inappropriate sinus tachycardia should be considered when no underlying cause for rapid sinus rates is noted and is often seen in the critically ill patient following the period of stress.

If an irregular SVT is noted, AF is most likely, but a search for regular flutter waves or multiple P wave morphologies (multifocal atrial tachycardia) is needed since these latter arrhythmias require a different management approach as detailed in the text.

Atrial fibrillation is by far the most common SVT arrhythmia encountered in the critical care setting. For each patient, rate control should be optimized, anticoagulation issues addressed, and when symptoms continue despite these measures, restoration of sinus rhythm strongly considered.

A summary of evidence-based management of supraventricular tachycardia is given in Table 42.1.

CHAPTER 43 ■ BRADYARRHYTHMIAS AND TEMPORARY PACING

GAURAV A. UPADHYAY AND JAGMEET P. SINGH

INTRODUCTION

Implicated in over 40% of sudden cardiac deaths in the hospital, bradyarrhythmias are an important and heterogeneous group of cardiac rhythm disturbances [1]. Broadly classified, bradyarrhythmias are the manifestations of either a failure of cardiac impulse generation or impulse conduction leading to heart rates slower than normal sinus rhythm. By historical convention, normal sinus rhythm is defined between 60 and 100 beats per minute. Normal sinus rhythm is spontaneously generated by depolarizing pacemaker cells in the high right atrium within the sinoatrial (SA) node, and conducted through the atrium across internodal pathways to the atrioventricular (AV) node and subsequently to the bundle of His and to the left and right bundle branches of the Purkinje system [2,3]. Bradyarrhythmias may either be physiologic and benign, as in sinus bradycardia in athletes, or pathologic and warranting intervention, as in symptomatic bradycardia from either sinus node dysfunction or ventricular asystole from high-grade AV block.

Bradyarrhythmias may arise through several distinct mechanisms. Reduced automaticity in the SA node may be driven by hypoxia, hypothermia, or increased parasympathetic influence from gastrointestinal distress or genitourinary dysfunction. Periatrioventricular inflammation may reduce impulse propagation, as in Lyme's disease, myocarditis, or systemic lupus erythematosus. Significant AV and even infranodal block can occur in the setting of myocardial ischemia, drug toxicity or overdose, and severe electrolyte disturbance. Management begins by identifying the etiology of bradyarrhythmia and then attempting to restore normal sinus rhythm by correction or elimination of the identified precipitant. In situations where the bradyarrhythmia causes acute hemodynamic instability, the need for either pharmacologic intervention or electrical support through temporary cardiac pacing must be evaluated.

The purpose of this chapter is to review the pathophysiology of various bradyarrhythmias and to review treatment options available. Particular attention is placed on transcutaneous and transvenous pacing, as these advanced modalities are commonly employed in the medical and cardiac intensive care settings.

PATHOPHYSIOLOGY

Disorders of Impulse Generation

The most commonly encountered bradyarrhythmias of the normal conduction system include sinus bradycardia and sinus arrhythmia, both of which can be manifestations of normal physiologic states. Arbitrarily defined as a sinus node impulse rate of less than 60 beats per minute, sinus bradycardia may be a manifestation of an enhanced vagal tone seen commonly

in athletes. Increased parasympathetic and decreased sympathetic tone during sleep also leads to bradycardic resting heart rates in nonathletes. Sinus arrhythmia is characterized as phasic changes observed in heart rate, secondary to autonomic influences on the sinus node triggered by normal respiration.

Sinus Arrhythmia

Thought to be due to reflex inhibition of vagal nerve tone during inspiration, sinus arrhythmia is the reduction in time from one P wave to another (P-P interval) between sinus discharges, leading to an increase in heart rate during inspiration and slowing during expiration, which is thought to help improve and synchronize alveolar gas exchange [4]. As such, respiratory sinus arrhythmia is considered the sign of a healthy conduction system. Marked sinus arrhythmia may even manifest with sinus pauses for 2 seconds or longer, but is rarely pathologic by itself. Small changes in P-wave morphology and PR interval can be attributed to variation in the pacemaking site within the SA node due to differential vagal stimulation. This periodicity in the heart rate is most pronounced in the young and decreases with age. The direct impact of the autonomic nervous system on the sinus node and sinus arrhythmia is confirmed by the fact vagal tone can be abolished through parasympathetic blockade by atropine or through anatomic denervation of hearts after cardiac transplant. Autonomic system dysregulation due to microvascular disease (as in diabetes) or degeneration (as in Shy–Drager syndrome) also reduces sinus arrhythmia. Indeed, depression of respiratory sinus arrhythmia after myocardial infarction is associated with an increased risk of sudden cardiac death [5]. In contrast to respiratory sinus arrhythmia, nonrespiratory sinus arrhythmia is the change of P-P intervals varying at random and may reflect drug toxicity from digitalis, intracranial hemorrhage, or ischemic heart disease [6].

Sinus Bradycardia

Symptomatic sinus bradycardia or sinus pauses causing reduced cardiac output or hemodynamic instability may be due to extracardiac disorders which profoundly increase vagal tone such as bowel obstruction, urinary retention, nausea and vomiting, or intracranial mass. Pharmacologic agents such as parasympathomimetic drugs, digitalis, beta-adrenergic-blocking drugs, and calcium antagonists can also exacerbate sinus bradycardia. Other disorders, such as carotid sinus hypersensitivity may also increase vagal tone and lead to transient ventricular asystole due to sinus arrest lasting up to 3 seconds or longer. Although some patients may require permanent pacemaker implantation due to recurrent, activity-related symptomatic pauses, they rarely require temporary pacemaker support as the negative chronotropic effect is relieved once pressure is removed from the carotid.

Sinus Node Dysfunction

Inappropriate SA node automaticity and disordered impulse generation is called sinus node dysfunction (also described as *sick sinus syndrome* by Ferrer [7]). It is commonly a disorder of senescence, although can occur at any age due to destruction of sinus node cells through infiltration, collagen vascular disease, trauma, ischemia, infection, or idiopathic degeneration [8]. Sinus node dysfunction affects men and women equally, commonly in the age range of 65 to 75 years, and is the primary indication for over 50% of permanent pacemaker implants in the United States [9,10]. Indeed, sinus node dysfunction comprises of a constellation of abnormalities of the sinus node characterized by inappropriate sinus bradycardia (in the absence of drugs), sinus arrest and chronotropic incompetence. Subsidiary and latent pacemakers further downstream become active in states of such dysfunction, and can give rise to bradyarrhythmias and tachyarrhythmias. These may originate in the atrium (e.g., atrial tachycardias, multifocal atrial rhythms, paroxysmal atrial fibrillation) or ventricles (e.g., idioventricular rhythms, ventricular tachycardias [VTs]). Coexisting AV nodal disturbance and block are also common, and intermittent periods of bradycardia punctuated by tachycardia have given rise to the term "tachy–brady syndrome." Many of these patients go on to need permanent pacemakers for effective rate control. The presentation in the intensive care setting is often due to an exacerbation of the underlying sinus node dysfunction through the use of cardioactive medications (see Table 43.1), which may result in a reduced cardiac output from diminished heart rate or unstable tachyarrhythmias. Given the diversity of potential etiologies and manifestations of sinus node dysfunction, it is often more useful to distinguish temporary or reversible causes of the syndrome (e.g., drug toxicity) from permanent etiologies (e.g., idiopathic fibrosis, degenerative changes of the conductive system) to identify the appropriate management strategy.

TABLE 43.1

CARDIOACTIVE DRUGS THAT MAY INDUCE OR WORSEN SINUS NODE DYSFUNCTION

- Beta-blockers
- Calcium channel blockers (e.g., verapamil, diltiazem)
- Sympatholytic antihypertensives (e.g., α-methyldopa, clonidine, guanabenz, reserpine)
- Cimetidine
- Lithium
- Phenothiazines (rarely)
- Antihistamines
- Antidepressants
- Antiarrhythmic agents
  - May cause sinus node dysfunction (SND) in normal subjects: amiodarone
  - Frequently worsens *mild* SND: flecainide, propafenone, sotalol
  - Infrequently worsens *mild* SND: digitalis, quinidine, procainamide, disopyramide, moricizine
  - Rarely worsens *mild* SND: lidocaine, phenytoin, mexiletine, tocainide
- Opioid blockers

Adapted from Podrid, Kowey: *Cardiac Arrhythmia.* Philadelphia, PA, Lippincott Williams and Wilkins, 2001 (Permission needed).

Disorders of Impulse Conduction

Conduction block may occur at any point in the conduction system and represents a failure of impulse propagation. This can occur at the level of the SA node, as in SA exit block, or further downstream, as in AV block or interventricular block. Importantly, conduction block is distinct from the normal physiologic phenomenon of interference, in which a preceding impulse causes a period of refractoriness due to inactivation of ion channels. Common terminology also differentiates between first-degree block, in which an impulse is delayed; second-degree block, in which impulses are intermittently transmitted; and third-degree block, in which impulses are not transmitted and dissociation may ensue. Bradyarrhythmias usually result from a combination of conduction block and disordered automaticity, for example, as in sinus rhythm with third-degree heart block and bradycardic junctional escape rhythm. Common types of conduction block are briefly reviewed here.

Sinoatrial Block

SA block, also called SA exit block, manifests as sinus arrest of variable length on the surface ECG. On the basis of a study of U.S. Air Force personnel, the prevalence is approximately 1% in otherwise normal subjects [11]. Considered by some to be a manifestation of sinus node dysfunction, the pathophysiology of SA block is a defect of impulse generation or propagation within the SA node. First-degree SA block cannot be detected on surface ECG as sinus node depolarization is not inscribed separately from atrial depolarization (the P wave). Type I second-degree SA block is the progressive prolongation of conduction block within the sinus node until complete exit block occurs. This manifests on surface ECG as progressive shortening of P-P intervals till a pause occurs. Type II second-degree SA block is the spontaneous block of a sinus impulse which leads to a sinus pause whose duration is an exact multiple of the preceding P-P interval. Third-degree SA block simply manifests as sinus arrest, usually with the eventual appearance of a subsidiary pacemaker rhythm such as a junctional escape. Sinus node dysfunction can be studied in the electrophysiology laboratory and quantified by techniques to specifically examine the sinus node electrograms, sinus node recovery time, and SA conduction studies. In the intensive care setting, diagnosis can be challenging, and it is usually sufficient to simply be able to recognize third-degree SA block which may necessitate temporary pacing if subsidiary pacemakers are not active or do not provide sufficient cardiac output.

Atrioventricular Block

AV block is frequently observed on surface electrocardiography, and may anatomically occur anywhere in the conduction system outside of the SA node. It is clinically important to attempt to distinguish AV block at the level of the AV node with block within or below the level of the His bundle, as infranodal block may be associated with instability and a worse clinical outcome. First-degree AV block is defined as a prolongation of the PR interval greater than 0.20 seconds, and is generally felt to be due to a block of impulse conduction at the level of the AV node, although when associated with bundle-branch block, may occur further down in the His–Purkinje system. In a study of over one hundred thousand airmen, the prevalence of first-degree AV block was found to be 0.65% [12]. In a 30-year longitudinal study, the association of first-degree AV block with a narrow QRS complex was thought to be largely benign [13]. More recent data from the Framingham cohort, however, suggest that significant PR prolongation may be associated with increased risks of atrial fibrillation, pacemaker implantation, and all-cause mortality over time [14]. Marked first-degree AV block may lead to hemodynamic derangement when atrial systole occurs in close proximity to the preceding ventricular systole, manifesting with symptoms similar to the pacemaker syndrome, although this is rare [15]. In the intensive care setting, second- and third-degree AV block are of greater significance.

Second-degree AV block was classified into two types by Mobitz in 1924 [16]. Mobtiz type-I second-degree AV block, or Wenckebach-type block, is characterized by progressive prolongation of the PR interval before nonconduction. Analogous to type I SA block which demonstrates shortening of P-P intervals, there is progressive shortening of the R-R intervals prior to a dropped beat in Mobitz type-I block. Irrespective of QRS width, Mobitz type-I block, or Wenckebach phenomenon, usually represents an appropriate physiologic response to increasing heart rate through decremental conduction in the AV node, and rarely requires intervention. Mobitz type-II block, on the other hand, usually represents infranodal disease, particularly when associated with a wide complex QRS. On the surface ECG, Mobitz type-II block manifests as a sudden nonconduction of an atrial impulse without change in preceding PR interval. Attention should be taken to distinguish Mobitz type-II block from block of a premature atrial complex, which is due to physiologic interference and not due to pathological involvement of the AV node. Mobitz type-II block is of significance in the clinical setting, as it may herald impending complete heart block, particularly when multiple consecutive impulses are nonconducted (often referred to as "advanced" or "high-grade" heart block). Third-degree AV block, or complete heart block, occurs with the absence of atrial impulse propagation to the ventricles and will manifest with ventricular standstill in the absence of an escape rhythm. When reversible etiologies are present, temporary pacing is critical toward providing electrical support, especially in the setting of ventricular asystole due to complete heart block. Temporary pacing is indicated when the subsidiary escape rhythm is unstable and cannot maintain hemodynamic stability, leading to cerebral hypoperfusion or further cardiac instability

Similar to sinus node dysfunction, there are myriad etiologies which may lead to AV block. In the intensive care setting, common etiologies include electrolyte disturbance, notably hyperkalemia or hypermagnesemia; drug toxicity, particularly from cardioactive drugs such as beta-adrenergic-blocking agents, nondihydropyridine calcium-channel blockers, digitalis derivatives, and antiarrhythmics; myocardial ischemia from inferior or anteroseptal infarction; infection from myocarditis or endocarditis, particularly involving the aortic valve; and trauma from cardiac surgery, catheter trauma, or radiation. Clinical history obtained from the patient is critical in determining the potential duration of the block and also prioritizing appropriate treatment modalities.

Intraventricular Block

Failure in ventricular activation due to block in the His–Purkinje system may also be the cause of complete heart block. The left and right bundle branches are commonly divided into a trifascicular system, consisting of the right bundle branch and the left anterior and posterior fascicles [17]. Although a septal fascicle has also been identified in anatomic studies, ECG manifestations of septal conduction block are debated and remain to be defined [18]. Bifascicular block is present when either left anterior or left posterior fascicular block is associated with right bundle branch block. Clinically, complete heart block is most often preceded by chronic bifascicular block, although the progression is often slow [19]. However, when first-degree AV block is associated with chronic bifascicular block and symptomatic bradycardia, there is an increased risk of sudden cardiac death (this combination is sometimes erroneously referred to as "trifascicular block"). Alternating bundle branch block seen on successive ECG tracings, either manifesting with sequential right and left bundle branch block, or right bundle branch block with left anterior and left posterior fascicular block, is also associated with increased mortality and can be correctly identified as representing intermittent trifascicular block.

Similar to other forms of conduction block, there are numerous potential etiologies which may lead to intraventricular block, although ischemia in the setting of a myocardial infarction (MI) is the most common in the intensive care setting. The SA nodal artery receives its blood supply from the proximal right coronary artery in 55% of the population, from the circumflex in 35%, and from both in approximately 10%. The AV nodal artery, on the other hand, arises from the posterior descending artery in 80% of cases, 10% from the circumflex, and approximately 10% from both arteries. Although, an inferior MI may lead to varying degrees of AV block from AV nodal artery ischemia or enhanced vagal tone from exaggeration of the Bezold–Jarisch reflex, intraventricular block is

uncommon. An anterior MI, on the other hand, may cause ischemia of the fascicles directly and is associated with greater extent of left ventricular dysfunction. In the prethrombolytic era, new fascicular or bundle branch blocks were common after an MI and were associated with a significantly increased risk of mortality [20]. A simple scoring model characterizing the risk of progression to complete heart block after MI was developed by Lamas based on ECG criteria [21]. Patients with evidence of conduction block on ECG, including first or second-degree block (both type I and type II), left anterior and posterior fascicular block, right bundle branch block, or left bundle branch block had a linear relationship between their score (number of characteristics on presenting ECG) and the development of complete heart block. Patients without ECG evidence of any conduction block on presentation had a less than 4% risk of subsequent complete heart block, in contrast to those with scores of two, in whom the risk of developing complete heart block was 45%. Because of the relatively common incidence of bradycardia after MI, the American College of Cardiology (ACC) and the American Heart Association (AHA) have clear guidelines on intervention, including the use of temporary pacing, for AV and intraventricular disturbance (Table 43.2), which will also be further discussed later.

TABLE 43.2

ACC/AHA GUIDELINES FOR TREATMENT OF ATRIOVENTRICULAR AND INTRAVENTRICULAR CONDUCTION DISTURBANCES DURING STEMI[a]

Application of transcutaneous patches and standby transcutaneous pacing

Class I
- Normal AV conduction *or* first-degree AV block *or* Mobitz type-I second-degree AV block with new bundle branch block
- Normal AV conduction *or* first-degree AV block *or* Mobitz type-I second-degree AV block with fascicular block + RBBB
- First-degree AV block with old or new fascicular block (LAFB or LPFB) *in anterior MI only*
- First-degree AV block *or* Mobitz type-I *or* type-II second-degree AV block with old bundle branch black
- Mobitz type-I *or* type-II second-degree AV block with normal intraventricular conduction
- Mobitz type-I *or* type-II second-degree AV block with old or new fascicular block (LAFB or LPFB)

Class IIa
- First-degree AV block with old or new fascicular block (LAFB or LPFB) *in nonanterior MI only*

Class IIb
- Alternating left and right bundle branch block
- Normal AV conduction with old bundle branch block
- Normal AV conduction with new fascicular block (LAFB or LPFB)
- First-degree AV block with normal intraventricular conduction
- Mobitz type-II second-degree AV block with new bundle branch block
- Mobitz type-II second-degree AV block with fascicular block + RBBB

Class III
- Normal AV conduction with normal intraventricular conduction

Temporary transvenous pacing

Class I
- Alternating left and right bundle branch block
- Mobitz type-II second-degree AV block with new bundle branch block
- Mobitz type-II second-degree AV block with fascicular block + RBBB

Class IIa
- First-degree AV block *or* Mobitz type-I second-degree AV block with new bundle branch block
- First-degree AV block *or* Mobitz type-I second-degree AV block with fascicular block + RBBB
- Mobitz type-II second-degree AV block with old bundle branch block
- Mobitz type-II second-degree AV block with normal intraventricular conduction
- Mobitz type-II second-degree AV block with old or new fascicular block (LAFB or LPFB) *in anterior MI only*

Class IIb
- Normal AV conduction with new bundle branch block
- Normal AV conduction with fascicular block + RBBB
- Mobitz type-I *or* type-II second-degree AV block with old bundle branch block
- Mobitz type II second-degree AV block with old or new fascicular block (LAFB or LPFB) *in nonanterior MI only*

Class III
- Normal AV conduction *or* first-degree AV block *or* Mobitz type-I second-degree AV block with normal intraventricular conduction
- Normal AV conduction *or* first-degree AV block *or* Mobitz type-I second-degree AV block with old or new fascicular block (LAFB or LPFB)
- Normal AV conduction with old bundle branch block

[a]Except where specified, all indications include anterior *and* nonanterior MI.
AV, atrioventricular; BBB, bundle branch block; BP, blood pressure; LAFB, left anterior fascicular block; LBBB, left bundle branch block; LPFB, left posterior fascicular block; MI, myocardial infarction; RBBB, right bundle branch block.

TREATMENT

Appropriate management of bradyarrhythmia is predicated upon identification of potential etiologies, selection of appropriate medical therapy, and assessment requirement for temporary cardiac pacing to maintain hemodynamic stability. Given the heterogeneous causes for bradyarrhythmias, in the acute setting it is critical to (1) identify and correct potential precipitants, (2) define a period for which medical or device therapy will be tried in the short term, and (3) identify the need for permanent pacing if it exists.

Medical Therapy

Upon initial presentation to the hospital emergency department, compromising bradycardia (or bradyarrhythmia leading to hemodynamic insufficiency) may be successfully resolved by conservative measures such as making the patient lie flat and bed rest in up to 40% of patients. Approximately 60%, however, require some form of pharmacologic therapy and 20% of these will go on to require advanced intervention with temporary pacing [22]. Conservative medical therapy is an effective measure for treating symptomatic bradycardia when applied with attention to potential etiology. Atropine (0.6 to 1.0 mg IV repeated every 5 minutes until desired effect or maximum dose of 0.04 mg per kg), is an anticholinergic whose well-documented vagolytic properties lead to increase in heart rate as well as blood pressure in settings of enhanced parasympathetic tone [23]. It has also been studied extensively in the setting of MI, and although may be associated with a small risk of worsening ischemia, is the drug of choice for treatment of AV block after inferior MI [24,25]. However, care should be taken to begin with doses of 0.6 mg or greater, as lower doses may cause a paradoxical increase in bradycardia. Aminophylline infusion (50 to 250 mg administered over 60 seconds, repeating as necessary) has also been studied in atropine-resistant AV block after inferior myocardial infarction [26]. Aminophylline has been shown to be effective in humans, and its mechanism of action is via the antagonism of locally accumulating adenosine during ischemia [27,28]. According to the 2005 AHA Guidelines regarding cardiopulmonary resuscitation, epinephrine (1 to 2 mg IV bolus along with 2 to 10 μg per min infusion) may also be considered for symptomatic bradycardias that are nonresponsive to atropine [29].

Isoproterenol infusions (5 to 20 μg per minute) or dopamine (5 to 20 μg per kg per minute) may also be used in an attempt to stimulate chronotropy during nonischemic bradyarrhythmias. These infusions should particularly be used cautiously in the setting of cardiogenic shock since they reduce coronary perfusion pressure and substantially increase the risk of worsening myocardial ischemia. Pharmacologic overdose is a common etiology of bradyarrhythmia. Glucagon (initial dose of 0.05 mg per kg or 3 to 5 mg followed by continuous infusion of 1 to 5 mg per hour) may also be of significant benefit in bradycardias due to beta-adrenergic or calcium antagonist toxicity [30]. By activating adenyl cyclase, glucagon increases cyclic AMP and increases intracellular calcium ion flux independently from the adrenergic receptor [31].

Other common causes of bradyarrhythmia include electrolyte disturbance and acidosis. When bradycardia is thought to be driven by acidosis, temporizing measures may include administration of sodium bicarbonate (1 mEq per kg) prior to initiation of hemodialysis or continuous venovenous hemofiltration. Similarly, the treatment of hyperkalemia often involves immediate steps to shift potassium to the intracellular compartment (e.g., calcium, glucose, insulin), along with initiation of longer-acting agents to stimulate potassium excretion (e.g., loop diuretic, sodium polystyrene sulfonate). These types of medical interventions must be tailored with attention to the underlying etiology of the bradyarrhythmia, along with concurrent assessment of whether advanced support through temporary cardiac pacing is indicated.

Device Therapy

Temporary cardiac pacing involves the application of electrical stimulation to the heart in order to override intrinsic rhythm and provide an exogenous source of pacemaking function. Whereas guidelines for permanent pacing have been clearly summarized by the ACC, the AHA, and the Heart Rhythm Society (see Table 43.3), indications for temporary cardiac pacing outside of acute MI remain undefined and up to individual clinical assessment [32]. The most frequent use of temporary cardiac pacing is to improve circulatory hemodynamics by improving cardiac output through increased heart rate in the setting of symptomatic bradycardia (i.e., bradycardia resulting in hypotension, cerebral hypoperfusion, or resulting systemic effects). Overdrive pacing of the heart may also be used to terminate some types of tachyarrhythmias, including sinus node reentry, AV node reentry, and AV reciprocating tachycardia with accessory bypass tract, although is rarely used for this purpose in clinical practice given the efficacy of medications and cardioversion [33]. There is still a role, however, for suppression of pause-dependent polymorphic VT (*torsades de pointes*) in limited situations while concurrent treatment of the underlying metabolic disturbance or proarrhythmic trigger is underway [34].

The decision to employ temporary cardiac pacing is made with attention to the temporality of the inciting arrhythmia. If the bradyarrhythmia is thought to be due to a transient precipitant which can be managed pharmacologically (as described earlier), medications are generally preferred due to their lower infectious and mechanical complication rates. Nearly 50% of patients in whom temporary pacing is used, however, ultimately require permanent pacemakers before discharge (see also Table 43.3) [35]. In these patients, delay in use of temporary pacing may expose patients to adverse outcomes.

Modalities which are available to deliver electrical stimulation include transcutaneous patches, transvenous endocardial leads, epicardial leads (usually placed at the time of surgery), transthoracic pacing through percutaneous needle insertion through the chest wall, or pacing through esophageal electrodes (which is primarily used for atrial pacing). Cardiac stimulation has also been demonstrated in humans through transcutaneous ultrasound energy delivery, although this approach remains largely investigational [36]. Although epicardial lead placement is common after cardiac surgery, the most commonly used modalities in medical and intensive care units are transcutaneous and transvenous pacing.

Transcutaneous Pacing

Temporary pacing has been used for the management of bradyarrhythmias since 1952, when the technique of transcutaneous pacing was initially described by Paul Zoll, who delivered a pulsating current through two electrodes attached via hypodermic needles to the chest walls of two patients with ventricular standstill [37]. Since that time, transcutaneous pacing has emerged as the first-line nonpharmacologic therapy for symptomatic bradycardia. Transcutaneous pacing systems consist of a pulse generator attached to high impedance external patch electrode pads (see Fig. 43.1). Most newer systems also incorporate defibrillator function in a stand-alone unit that provides combined antibradycardia, antitachycardia, and defibrillation capacity [38]. Pacing parameters have not changed over the past three decades, and include output, sensitivity, and

TABLE 43.3

ACC/AHA/HRS CLASS I RECOMMENDATIONS FOR PERMANENT PACING

Recommendations for permanent pacing in sinus node dysfunction
SND with documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms
Symptomatic chronotropic incompetence
Symptomatic sinus bradycardia that results from required drug therapy for medical conditions
Recommendations for permanent pacing in acquired atrioventricular block in adults
Third-degree and advanced second-degree AV block at any anatomic level associated with bradycardia and symptoms (including heart failure) or ventricular arrhythmias presumed to be due to AV block
Third-degree and advanced second-degree AV block at any anatomic level associated with arrhythmias and other medical conditions that require drug therapy that results in symptomatic bradycardia
Third-degree and advanced second-degree AV block at any anatomic level in awake, symptom-free patients in sinus rhythm, with documented periods of asystole ≥3.0 sec or any escape rate less than 40 bpm, or with an escape rhythm that is below the AV node
Third-degree and advanced second-degree AV block at any anatomic level in awake, symptom-free patients with AF and bradycardia with 1 or more pauses of at least 5 sec or longer
Third-degree and advanced second-degree AV block at any anatomic level after catheter ablation of the AV junction
Third-degree and advanced second-degree AV block at any anatomic level with postoperative AV block that is not expected to resolve after cardiac surgery
Third-degree and advanced second-degree AV block at any anatomic level associated with neuromuscular diseases with AV block, such as myotonic muscular dystrophy, Kearns–Sayre syndrome, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy, with or without symptoms
Second-degree AV block with associated symptomatic bradycardia regardless of type or site of block
Asymptomatic persistent third-degree AV block at any anatomic site with average awake ventricular rates of 40 bpm or faster if cardiomegaly or LV dysfunction is present or if the site of block is below the AV node
Second- or third-degree AV block during exercise in the absence of myocardial ischemia
Recommendations for permanent pacing in chronic bifascicular block
Advanced second-degree AV block or intermittent third-degree AV block
Type II second-degree AV block
Alternating bundle-branch block
Recommendations for permanent pacing after the acute phase of myocardial infarction
Persistent second-degree AV block in the His–Purkinje system with alternating bundle-branch block or third-degree AV block within or below the His–Purkinje system after ST-segment elevation MI
Transient advanced second- or third-degree infranodal AV block and associated bundle-branch block. If the site of block is uncertain, an electrophysiological study may be necessary
Persistent and symptomatic second- or third-degree AV block
Recommendations for permanent pacing in hypersensitive carotid sinus syndrome and neurocardiogenic syncope
Recurrent syncope caused by spontaneously occurring carotid sinus stimulation and carotid sinus pressure that induces ventricular asystole of more than 3 sec
Recommendations for permanent pacing after cardiac transplantation
Persistent inappropriate or symptomatic bradycardia not expected to resolve and for other Class I indications for permanent pacing
Recommendations for permanent pacemakers that automatically detect and pace to terminate tachycardias
Reasonable for symptomatic recurrent SVT that is reproducibly terminated by pacing when catheter ablation and/or drugs fail to control the arrhythmia or produce intolerable side effects
Recommendations for permanent pacing to prevent tachycardia
Sustained pause-dependent VT, with or without QT prolongation

SND, sinus node dysfunction; AV, atrioventricular; SVT, supraventricular tachycardia; VT, ventricular tachycardia; MI, myocardial infarction.
Adapted from the 2008 ACC/AHA/HRS guidelines for device-based therapy of cardiac rhythm abnormalities. *Circulation* 117:2820–2840, 2008 (Permission needed).

rate, all of which can be manipulated in order to optimize capture and patient comfort [39].

Initiation of transcutaneous pacing begins with placement of electrode pads. Modern systems usually employ self-adhesive large-area (>80 cm^2) electrode pads which are impregnated with a conducting gel. Polymer-based electrode pads of low impedance are generally now preferred. Although the anteroposterior position is sometimes employed in hospital settings, most commercial machines suggest anterolateral positioning of pads to improve speed of application (see Fig. 43.2) and allow for continuous cardiopulmonary resuscitation with chest compressions if necessary. When possible, removal of chest hair with shaving reduces impedance [40]. Pulling away of hair follicles with extra pads is also effective and can be performed quickly in emergency situations. To synchronize pacing, most systems also require the placement of one to three additional electrodes to sense native QRS discharge.

A square-wave impulse is delivered over 20 to 40 milliseconds by the generator and is seen as a "spike" on its display. The relatively long pulse width attempts to reduce skeletal muscle and cutaneous nerve stimulation while still maximizing threshold of cardiac myocyte capture. Capture is achieved when each pacing discharge is immediately followed by a wide QRS complex of uniform morphology. Although most impulse generators can produce output of up to 200 mA, most healthy subjects will capture between 40 and 80 mA [41]. The patient threshold is defined as the lowest output that yields consistent electrical ventricular capture. In hospital settings, higher thresholds (up

FIGURE 43.1. External pacemaker/defibrillator (pulse generator). (Courtesy of ZOLL Medical Corporation.)

to 140 mA output or more) are commonplace and may due to multiple etiologies. Suboptimal lead positioning—particularly over bone—as in the scapula, sternum, or spine, is an avoidable cause of increased pacing threshold. Other factors which may elevate thresholds that are beyond operator control include patient body habitus or obesity, transient myocardial ischemia, trapped pericardial fluid, mediastinal air, significant emphysema, use of positive pressure ventilation, or anoxia from prolonged resuscitation efforts [41,42].

By default, pacing mode in most machines is set at ventricular sensing, pacing, and inhibition in response to native ventricular conduction. Asynchronous pacing is usually only used during brady asystolic arrest, when cardiopulmonary resuscitation may cause artifact, particularly during chest compressions. Pacing rates of up to 180 bpm can also be achieved by most machines, allowing for overdrive pacing in the treatment of tachycardia or shortening of QT interval as needed. Hemodynamic response, as measured by cardiac output and blood pressure augmentation, is comparable with or better than right ventricular endocardial transvenous pacing [43].

Widespread use over the past three decades has established the overall efficacy of transcutaneous pacing in the treatment of bradyarrhythmia. In the largest single retrospective review of clinical trials in 1985, Zoll reported an overall success rate that approached 80% [41]. The use of newer electrode pads with improved capture yield a performance rate of nearly 100% when used in the very early and prophylactic treatment of bradyarrhythmias [44]. Timing is, of course, critical, and transcutaneous pacing for out of hospital asystolic arrest has been shown to be of no benefit [45].

Complications

The safety profile of transcutaneous devices has been well established over the past five decades, and suggests that its use is remarkably well tolerated. The primary limitation in its use is patient discomfort, and skin injury at contact site is the most commonly reported complication [41]. Prolonged animal pacing models have variably shown very small areas of focal myocardial injury, although no such injury has been shown in humans postmortem [41,42]. In normal individuals, transcutaneous pacing produces no measurable release of myoglobin, myocardial creatine kinase, or lactate dehydrogenase [42]. Also importantly, transcutaneous pacing has never been shown to induce arrhythmia, even in patients in whom MI or transvenous pacing precipitated ventricular tachycardia or ventricular fibrillation previously [41]. Taken together, transcutaneous pacing has supplanted transvenous pacing as the initial modality for bradyarrhythmic treatment in the emergency setting, particularly when pacing is only needed for short durations and patient comfort is not a primary consideration.

Transvenous Pacing

Furman and Robinson first described placement of an electrode catheter into the right ventricle for the management of high-grade conduction block in 1958 [46]. Transvenous electrodes circumvent patient discomfort and offer a reliable means of temporary pacemaker support in acute settings. Commonly used catheters are either bipolar electrodes, usually steel or platinum-tipped, embodied in plastic which may be flexible and associated with an inflatable balloon, or semirigid catheters which are deployed alone or with stylets. Most catheters have relied upon passive-fixation, although active-fixation, screw-in catheters with externalized pacemakers have also been recently employed for more prolonged temporary pacing requirements [47,48]. Preformed "J"-shaped catheters are also used for placement into the atrial appendage, but are not usually used in temporary pacemaking applications (see Fig. 43.3). Leads are attached to temporary pacemaker generators, which are generally constant-current output devices (see Fig. 43.4),

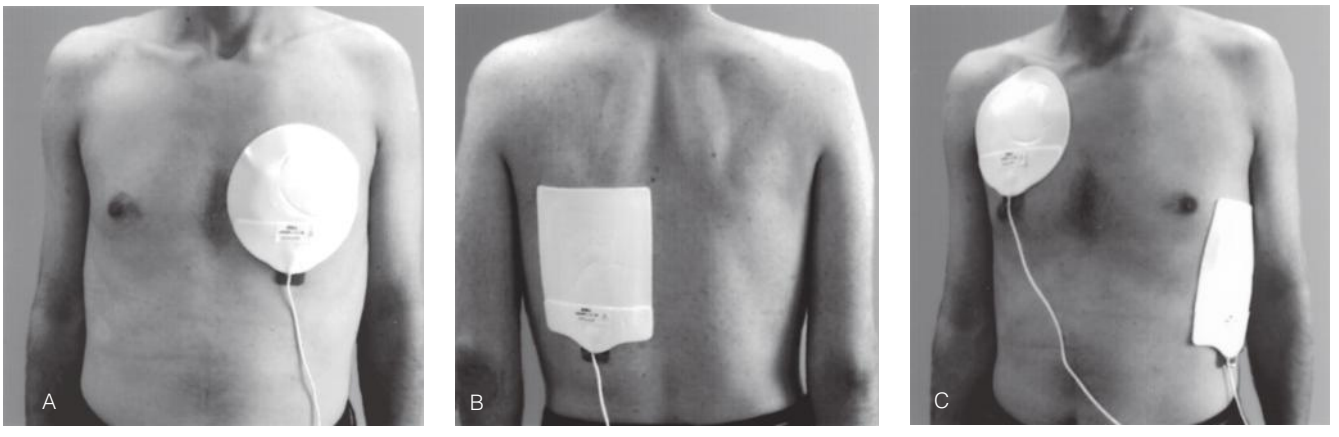

FIGURE 43.2. A, B: Positioning of transcutaneous electrode pads anteroposterior. **C:** Anterolateral positioning.

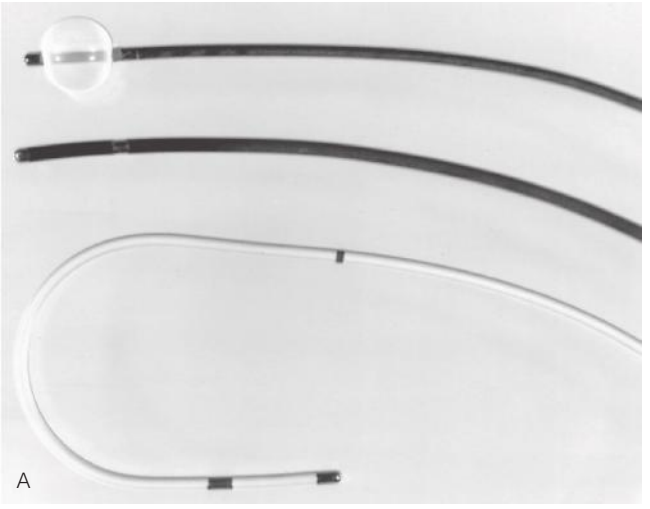

FIGURE 43.3. A: Cardiac pacing catheters. *Top*: Balloon tipped, flow-directed wire. *Middle*: Standard 5-Fr pacing wire. *Bottom*: Atrial J-shaped wire. **B:** Example of a balloon-tipped lumened pacing catheter with distal and proximal electrodes. FIGURE 43.4. Temporary atrioventricular demand pulse generators, older (*left*) and recent (*right*) models. Adjustable parameters on the older model include pacing mode (synchronous or asynchronous), ventricular rate, ventricular current output (in milliamperes), atrial output (in milliamperes), and atrioventricular interval (in milliseconds). The newer model also allows atrial sensing.

although externalized pacemakers have been used for longer periods of electrical support in the setting of systemic infection [47,48]. Standard pulse generators deliver output ranging from 0 to 20 mA at a pulse width of 1 to 2 milliseconds. Optimal pacing thresholds are considered less than 1 mA, as thresholds usually escalate with patient movement or catheter dislodgement. In addition, thresholds may be affected by medications, electrolyte disturbances and ischemia; therefore, devices are usually set to discharge at an output of three to five times threshold.

Multiple approaches for placement have been described, including internal jugular, subclavian, femoral, and antecubital fossa vein routes [35,49–54]. Of these, the right internal jugular vein is preferred for ease as well as the lowest rate of complication [55]. A stereotypic transition of ECG recordings has been observed when advancing the catheter from the internal jugular or subclavian vein to the superior vena cava (see Fig. 43.5) [56]. Atrial- (or P wave) dominated ECG recordings are seen in the high and low right atrium. The QRS is readily seen

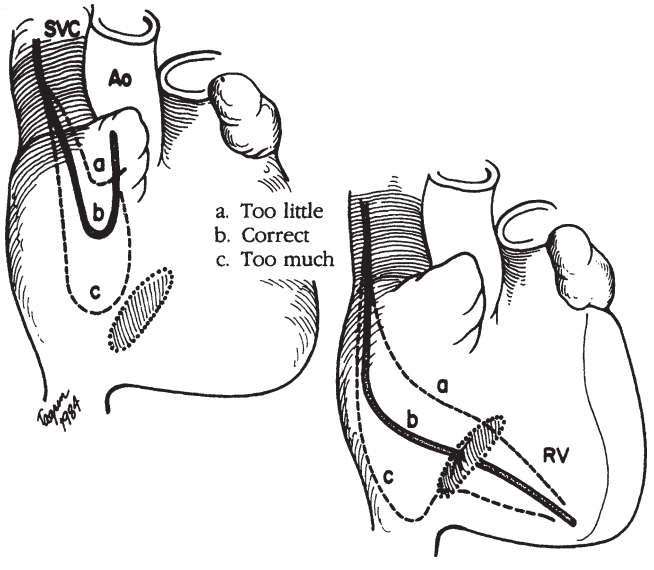

FIGURE 43.7. Sketch of fluoroscopic projection of catheter position. Ao, aorta; RV, right ventricle; SVC, superior vena cava [From Harthorne JW, Eisenhauer AC, Steinhaus DM: Cardiac pacing, in Eagle KA, Haber E, De Sanctis RW (eds): *The Practice of Cardiology: The Medical and Surgical Cardiac Units at the Massachusetts General Hospital*. Boston, Little, Brown and Company, 1989, p 315, with permission.]

from within the right ventricle. The catheter is then advanced to the right ventricular apex. After contacting the myocardium, a characteristic pseudo-"injury current" appearance is seen (see Fig. 43.6), representing catheter pressure against the ventricular wall and not actual injury to muscle. Figure 43.7 shows a sketch of a right anterior oblique fluoroscopic projection of proper positioning of both ventricular and atrial catheters. Table 43.4 provides a summary outline for bedside positioning of an electrode catheter in the right ventricle.

Complications

Transvenous pacing offers a reliable and stable means of cardiac pacing, which is generally easier for patients to tolerate, but associated with a greater risk of complications because of its invasive procedural placement. Multiple studies have reported on complications associated with transvenous pacing, although there has been marked variability in defining and measuring what constitutes a complication [35,49–54]. In a representative group of three studies, the overall complication rate ranged from 13% to 18% (see Table 43.5) [49,50,54]. Of these, induction of ventricular arrhythmia is the most immediately

TABLE 43.4

BEDSIDE POSITIONING OF A TEMPORARY ELECTRODE CATHETER

- Setup
  - Sterile preparation (gowns, gloves, masks, drape, hat)
  - Equipment (pacing electrode catheter, pulse generator, surface electrodes, sheath)
- Connections
  - V1 surface electrode connects to distal electrode
  - Proximal electrode catheter connects to positive pole of pulse generator
- Testing components
  - Inflate balloon to test integrity
  - Document V1 recordings when inserting electrode catheter into the sheath
- Procedure
  - Carefully advance electrode catheter 15 cm and inflate balloon
  - Observe V1 transition with advancement of catheter (see Fig. 43.5)
  - Atrial (P wave) dominant
  - Ventricular (QRS) dominant
  - Injury current
  - Stop advancing once injury current is detected
- Pacing preparation
  - Confirm proximal electrode is connected to positive pole of pulse generator
  - Disconnect distal electrode from V1 surface lead and connect to the negative pole of the pulse generator
- Pacing
  - Attempt pacing at 10 mA with the highest sensitivity
  - Observe capture
  - Determine thresholds and set output two to three times threshold (generally 5 mA)
- Postprocedure
  - Document distance electrode is within the sheath
  - Confirm position with a chest radiograph
- Routine care of pacemaker and site, including:
  - Pacing parameters (threshold, rate, sensitivity, output)
  - Skin site (observing for infection)

TABLE 43.5

COMPLICATIONS OF TEMPORARY TRANSVENOUS PACING[a]

Complication	Donovan [50]	Lumia [49]	Austin [54]
Ventricular tachycardia/ fibrillation	4.8	8.5	6.0
Other arrhythmias	NR	2.8	NR
Phlebitis	NR	4.2	5.0
Pulmonary embolism	NR	1.4	3.0
Hematoma/bleeding or arterial puncture	4.8	1.4	4.0
Perforation	1.9	2.1	4.0
Abscess at site	NR	0.7	3.0
Pneumothorax	1.0	NR	NR
Pacing failure with ventricular asystole	1.0	NR	NR
Diaphragm pacing	2.9	NR	NR

[a] All numbers are percentages.
NR, not reported.

life threatening, with myocardial puncture, pneumothorax, arterial bleeding and induction of infection leading to sepsis also being potentially deadly. Lead dislodgment can occur in a substantial number of patients within the first 48 hours of use, requiring replacement or re-positioning of the temporary pacemaker wire.

In a recent exhaustive narrative review, average rates of complications were compiled for 3,747 patients across 15 studies of cardiac pacing (see Table 43.6) [55]. Rates of infection were complications in as high as half of all procedures reported in some studies. In addition, older patients were at higher risk for suffering a complication, but that risks were lower when temporary pacemaker placement was performed by a specialist rather than a general practitioner. Given these findings, fluoroscopic placement of transvenous catheters by experienced personnel is preferred. In addition, prophylactic antibiotics should be considered for all temporary cardiac pacemakers, as these measures have already been shown to reduce the risk of infections after permanent pacemaker insertion [57].

With these concerns in mind, temporary transvenous pacing may still be required to definitively treat bradyarrhythmia and support patients through hemodynamic collapse. Attention to potential complications and meticulous technique can lower risks for what may be a lifesaving procedure.

TABLE 43.6

MOST COMMON COMPLICATIONS OF TEMPORARY PACING WIRE INSERTION ACROSS 15 STUDIES AND 3,747 PATIENTS [55]

Complication	Average rate (%)	Range (%)
Failure of access	15	6–40
Failure to place lead	10	5–25
Sepsis	9	2–18
Arterial puncture	4	0–6
Lung/myocardium puncture	2	0–4
Arrhythmias	1	0–2

SUMMARY

Cardiac bradyarrhythmias represent a heterogeneous group of rhythm disturbances of impulse generation or conduction. These may include potentially reversible etiologies such medication overdose and electrolyte disturbance, to progressive conduction system defect and irreversible ischemia. Appropriate treatment hinges upon the identification of the etiology of bradyarrhythmia in order to identify and eliminate precipitants if possible while initiating appropriate medical therapy. In situations of hemodynamic embarrassment, a concurrent assessment is made of whether temporary cardiac pacing may be required to bridge patients through acute instability and recovery or to permanent pacemaker placement. In the intensive care unit, commonly used modalities include transcutaneous pacing and transvenous pacing, which should be selected based on balance of patient comfort, potential for complication, and duration of use.

CHAPTER 44 ■ HOW TO MANAGE CARDIAC PACEMAKERS AND IMPLANTABLE DEFIBRILLATORS IN THE INTENSIVE CARE UNIT

MELANIE MAYTIN AND USHA B. TEDROW

INTRODUCTION

Cardiac device technology has made great advancements since the introduction of the first implantable pacemaker in 1958. Since then, the number of cardiac device implants continues to increase annually as a result of the aging of the general population, expanding indications for device therapy, and ongoing innovation in the technology of cardiac pacing and defibrillation. As a result, many patients presenting to the intensive care unit (ICU) with noncardiac illness may have implanted cardiac devices. This chapter aims to briefly review basic cardiac device function and programming with emphasis on device malfunction and troubleshooting. A discussion of the indications for permanent pacing, defibrillator or resynchronization therapy is outside the scope of this text; for additional information regarding these topics, the reader is referred to the American College of Cardiology/American Heart Association/Heart Rhythm Society 2008 Guidelines for Device-Based Therapy of Cardiac Rhythm Abnormalities [1].

GENERAL DEVICE MANAGEMENT

Normal Device Function and Special Considerations

Identification of the type of device is critical in interpretation of its function. Although the patients would ideally be able to provide information regarding the type of device that has been implanted (pacemaker, implantable cardioverter defibrillator (ICD), cardiac resynchronization device, etc.) or carry a device identification card with them at all times, this is frequently not the case in hospitalized patients. Substantial device information can be gleaned from a chest radiograph, including the lead configuration, the type of device, abnormalities in lead position or integrity, and even the device manufacturer (Fig. 44.1A–C). Identification of the device manufacturer is essential if formal device interrogation or reprogramming is planned as each device company uses different software and programmers to communicate with their respective devices (Fig. 44.2). The overwhelming majority of devices implanted are manufactured by one of three companies, and patient device information and technical support are available 24 hours a day (Table 44.1).

The device system consists of a pulse generator or battery, logic circuits, and pacing or defibrillator lead(s). All implantable cardiac devices have programmable pacemaker functions. These devices can both sense intrinsic electrical depolarization and excite myocardial tissue through an artificial electrical stimulus delivered near the lead tip. Electrical stimuli can be delivered in many ways depending on how the device is programmed. Pacing nomenclature is standardized to easily communicate information regarding the device and the pacing mode (Table 44.2). Pacing algorithms are best understood as a function of timing cycles. A pacemaker operates like a timer with programmable intervals to coordinate all sensed and paced events. Nontracking modes of pacing (AAI, VVI, DDI) deliver electrical impulses at set intervals (*lower rate limit*) unless a sensed electrophysiologic cardiac event occurs in the appropriate chamber before the end of the programmed interval (in which case the timer resets, Fig. 44.3). Dual-chamber devices programmed to a tracking mode can provide pacing at the programmed lower rate or track-sensed intrinsic conduction up to a programmed *upper rate limit*. There is no sensing in asynchronous pacing modes (AOO, VOO, DOO) and electrical stimuli are produced at programmed intervals unaffected by intrinsic conduction.

Magnets

The placement of a magnet over a device affects pacemakers and defibrillators differently. Application of a magnet to a pacemaker will cause the reed switch to close and result in asynchronous pacing. The pacing rate is company-specific with a different rate once battery depletion has occurred. Thus, placement of a magnet over the device can assist with the determination of battery status and device identification. If exposure to electromagnetic interference (EMI) is anticipated, positioning a magnet over the device can prevent inappropriate pacing inhibition. On removal of the magnet, the pacing mode will revert to the originally programmed settings, and, in general, formal device interrogation is not required. In contrast, application of a magnet to a defibrillator will disable all antitachycardia therapies but will *not* affect the pacing mode. Therefore, magnets can be used to prevent inappropriate therapies due to supraventricular tachycardia (SVT), lead fracture, or EMI. On removal of the magnet, defibrillator therapies will be restored, and, in general, formal device interrogation is not required.

Electromagnetic Interference

In hospitals, many potential sources of EMI exist. Sources of electromagnetic energy that could possibly interfere with device function include magnetic resonance imaging (MRI), electrocautery, defibrillation, radiation therapy, neurostimulators, TENS units, radiofrequency ablation, electroconvulsive therapy, video capsule endoscopy, extracorporeal shock wave lithotripsy and therapeutic diathermy [2,3]. EMI exposure most commonly results in inappropriate inhibition or triggering of pacing stimuli, inappropriate ICD tachyarrhythmia

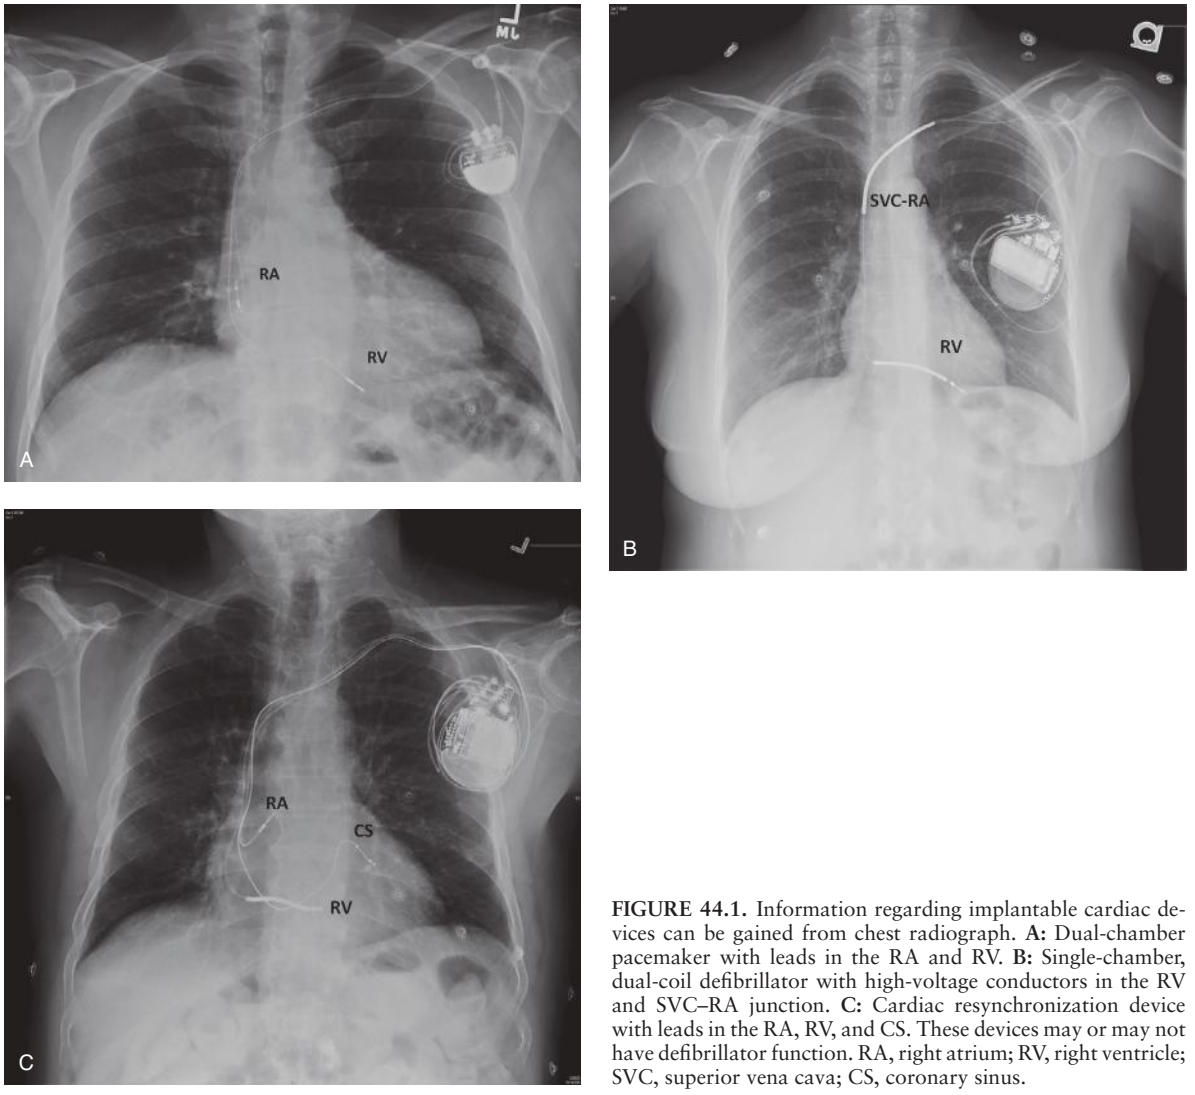

FIGURE 44.1. Information regarding implantable cardiac devices can be gained from chest radiograph. **A:** Dual-chamber pacemaker with leads in the RA and RV. **B:** Single-chamber, dual-coil defibrillator with high-voltage conductors in the RV and SVC–RA junction. **C:** Cardiac resynchronization device with leads in the RA, RV, and CS. These devices may or may not have defibrillator function. RA, right atrium; RV, right ventricle; SVC, superior vena cava; CS, coronary sinus.

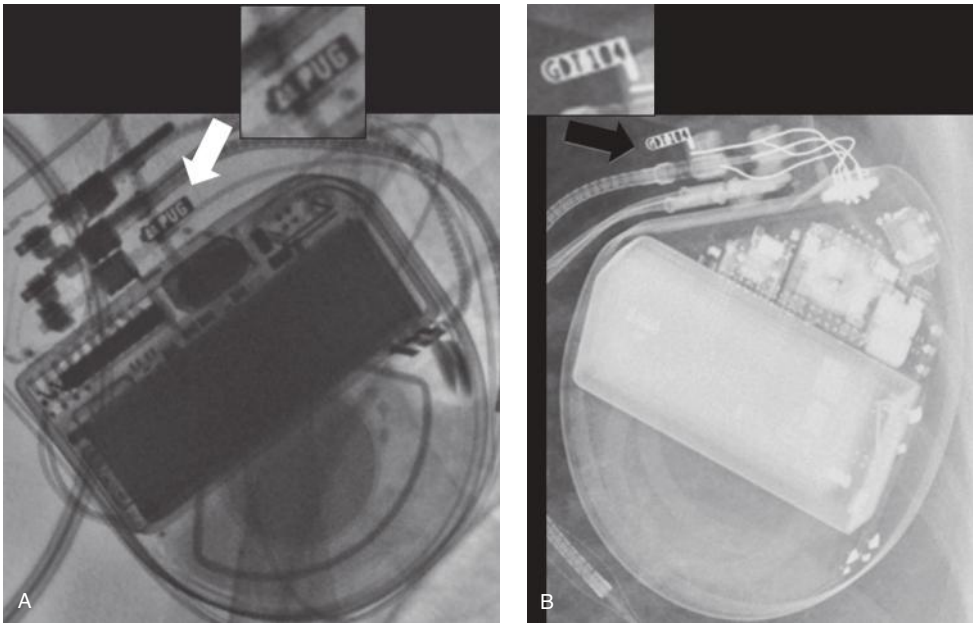

FIGURE 44.2. Many cardiac devices are marked with a radiopaque code that specifically identifies the manufacturer and model of the device. **A:** Medtronic ICD with magnified view of radiopaque code (inset). The manufacturer is identified by the Medtronic logo at the extreme left of the code and the model by the three letter code that represents the engineering series number. **B:** Boston Scientific ICD with magnified view of radiopaque code (inset). The manufacturer and model are identified by the radiopaque codes "GDT" and "104", respectively.

detection and therapy and reversion to an asynchronous pacing mode (*noise-reversion mode*).

Inappropriate inhibition of ventricular pacing can be catastrophic in the pacemaker-dependent patient; similarly atrial oversensing with inappropriate ventricular tracking could result in a myriad of symptoms including heart failure exacerbation, hypotension, or angina. Improper ICD tachyarrhythmia detection due to EMI could potentially be arrhythmia-inducing as a result of unsynchronized inappropriate shock delivery during the vulnerable period of repolarization. Noise-reversion mode is an algorithm that reverts transiently to asynchronous pacing in response to rapid frequency signals. The algorithm is designed to protect against inappropriate inhibition of pacing when high-frequency signals are sensed. Although this algorithm is present in all pacemakers regardless of manufacturer, this is not the case for ICDs. Less frequently, EMI can result in reprogramming of the device parameters or permanent circuitry or lead damage. When EMI exposure is unavoidable, certain measures can be taken to minimize the potential risk. For example, pacemaker or defibrillator patients requiring surgery with electrocautery should have a magnet placed over the device during the operation. Other forms of EMI (e.g. MRI, radiation therapy) carry substantial risk and may prompt the revision or removal of the entire cardiac device system prior to planned exposure. Care should be taken to avoid sources of EMI in device patients or, if exposure to EMI cannot be avoided, at a minimum, measures should be taken to minimize potential harm with consideration of device interrogation following exposure.

Mode Switch

Mode switch is a programmable pacing algorithm that automatically changes the pacing mode to a nontracking mode in response to a sensed atrial arrhythmia. The purpose of this algorithm is to prevent inappropriately fast ventricular tracking at the upper rate limit in response to a rapid atrial tachyarrhythmia. Once the device has mode switched, it will remain in a nontracking mode until the atrial rate has fallen below the mode switch threshold for a specific number of intervals. This algorithm is very useful for patients with paroxysmal atrial arrhythmias (e.g. SVT, atrial fibrillation or atrial flutter). The atrial rate at which mode switch occurs is programmable in most devices and the feature can even be programmed "off."

Line Management

The placement of central venous catheters in cardiac device patients warrants special consideration. Depending on the location and age of the device and the planned location of central venous access, a number of potential complications can occur. Reported complications associated with central venous catheters in cardiac device patients include lead damage from needle puncture [4], lead dislodgement, and inappropriate ICD therapies [5]. In addition, central venous stenosis as a consequence of prior cardiac device implantation may present a challenge to central venous catheter placement ipsilateral to the device [6]. Cardiac device infections and device-related endocarditis represent a particularly serious hazard of indwelling central venous catheters necessitating removal of the entire device system [7]. Central venous access should be performed contralateral to the device whenever possible.

Magnetic Resonance Imaging

The likelihood that patients with cardiac devices will require an MRI is high [8] but this imaging modality is not without risks in these patients. The potential hazards of magnetic resonance imaging in cardiac device patients include movement of the device, programming changes, asynchronous pacing, activation of tachyarrhythmia therapies, inhibition of pacing output, and induced lead currents that could lead to heating and cardiac stimulation [9], resulting in altered pacing and defibrillation thresholds, device damage, asystole, arrhythmias, or even death [10]. Although an implantable cardiac device remains a strong relative contraindication to MRI, certain centers have developed protocols for performing MRIs in cardiac device patients [11] and MRI-safe pacemakers are being developed. If an MRI is the only diagnostic imaging option in a cardiac device patient, imaging at 1.5 Tesla with appropriate programming and monitoring can likely be undertaken safely with careful assessment of the risk–benefit ratio on a case-by-case basis [11–14].

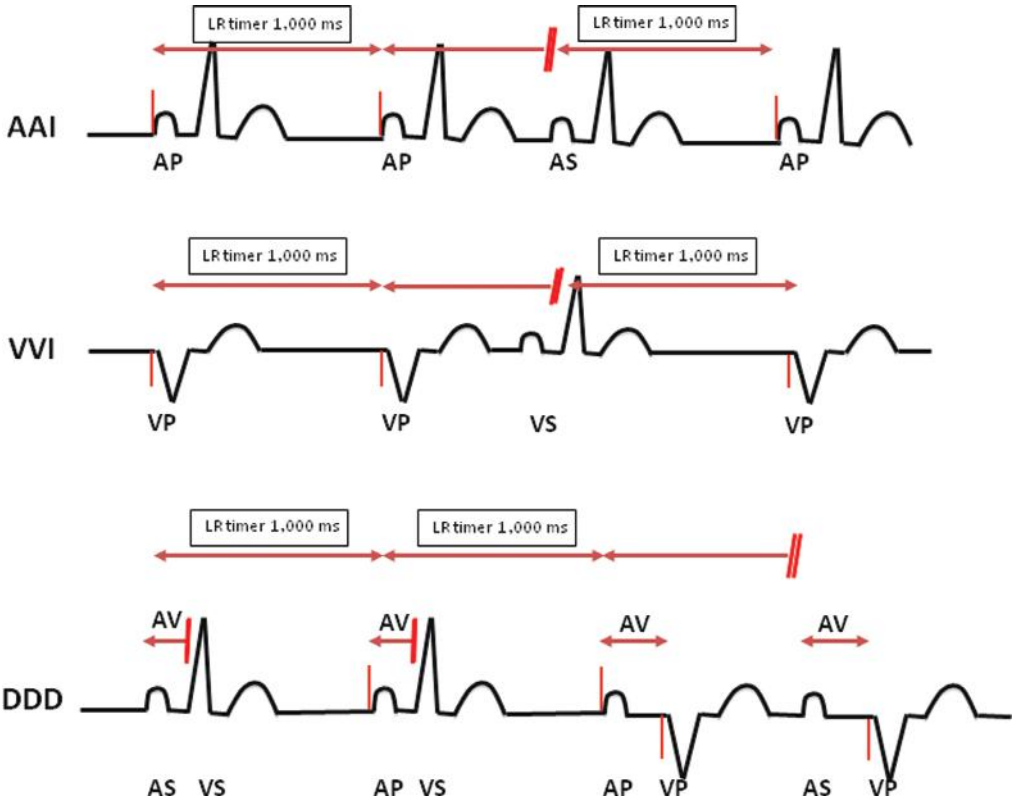

FIGURE 44.3. Timing of events in various pacing modes. AAI is an atrial nontracking mode of pacing that provides backup atrial pacing at the programmed lower rate limit. Similarly, VVI is a ventricular nontracking mode of pacing that provides backup ventricular pacing at the programmed lower rate limit. DDD is a dual-chamber mode of pacing that can both inhibit and trigger events in both the atrium and the ventricle. AS, atrial-sensed event; AP, atrial-paced event; VS, ventricular-sensed event; VP, ventricular-paced event; LR, lower rate limit.

External Defibrillation

In the event of a cardiac arrest or hemodynamically unstable arrhythmia in a patient with an implantable cardiac device, resuscitative efforts should proceed as per guidelines without deviation. Defibrillation or cardioversion can result in permanent damage to the cardiac device; to minimize these risks, the defibrillation pads should be placed at least 10 cm from the pulse generator [15]. Other potential risks of external defibrillation include device reprogramming [16] and myocardial damage at the interface with the lead resulting in an acute rise in threshold [17]. Following defibrillation or cardioversion, cardiac devices should be interrogated formally to insure proper function and programming. Again, the low potential risk of damage to the device should *not* impede usual and necessary resuscitative efforts for the patient.

Infection

Cardiac device-related infection encompasses a disease spectrum from pocket infection to device-related endocarditis. The clinical manifestations of cardiac device-related infection are protean and can range from pain at the implant site without cutaneous manifestations to minor erythema or swelling of the device pocket (Fig. 44.4A) to overt erosion of the system (Fig. 44.4B) to device-related endocarditis (Fig. 44.4C) [18,19]. In the absence of bacteremia, systemic manifestations and leukocytosis are rare. Cultures of the device leads yield the highest results and, *Staphylococci* are the primary pathogen identified [20]. A high index of suspicion is warranted in a patient with implanted pacemaker or ICD and signs and symptoms of infection. Cardiac device-related infection requires prompt removal of the entire device system for complete treatment unless significant comorbidities preclude extraction [7,18]. Although no specific vegetation size has been established as a contraindication to transvenous extraction, most experts agree that vegetations greater than 3 cm in size are better treated surgically [7]. Patients with device-related endocarditis require a minimum of six weeks of intravenous antibiotics and pose a particular problem with respect to the timing of re-implant in pacemaker-dependent patients.

Pacemaker Malfunction

Oversensing

Sensing problems are one of the most common causes of pacemaker malfunction (Table 44.3). Oversensing is defined as the sensing of physiologic or nonphysiologic events that should not be sensed. Consequently, oversensing can lead to inappropriate inhibition of pacemaker output (Fig. 44.5). Physiologic events that can be the cause of oversensing include far-field P waves, wide QRS complexes, T waves, and myopotentials, either pectoral or diaphragmatic. Typically, oversensing due to physiologic events can be overcome by decreasing the programmed sensitivity. Nonphysiologic oversensing may be the result of EMI or hardware problems such as loose setscrew or lead dislodgement or fracture and will likely require device revision to correct. Oversensing and failure to pace in a pacemaker-dependent patient can be catastrophic. Application of a magnet over the device will change the device to an asynchronous

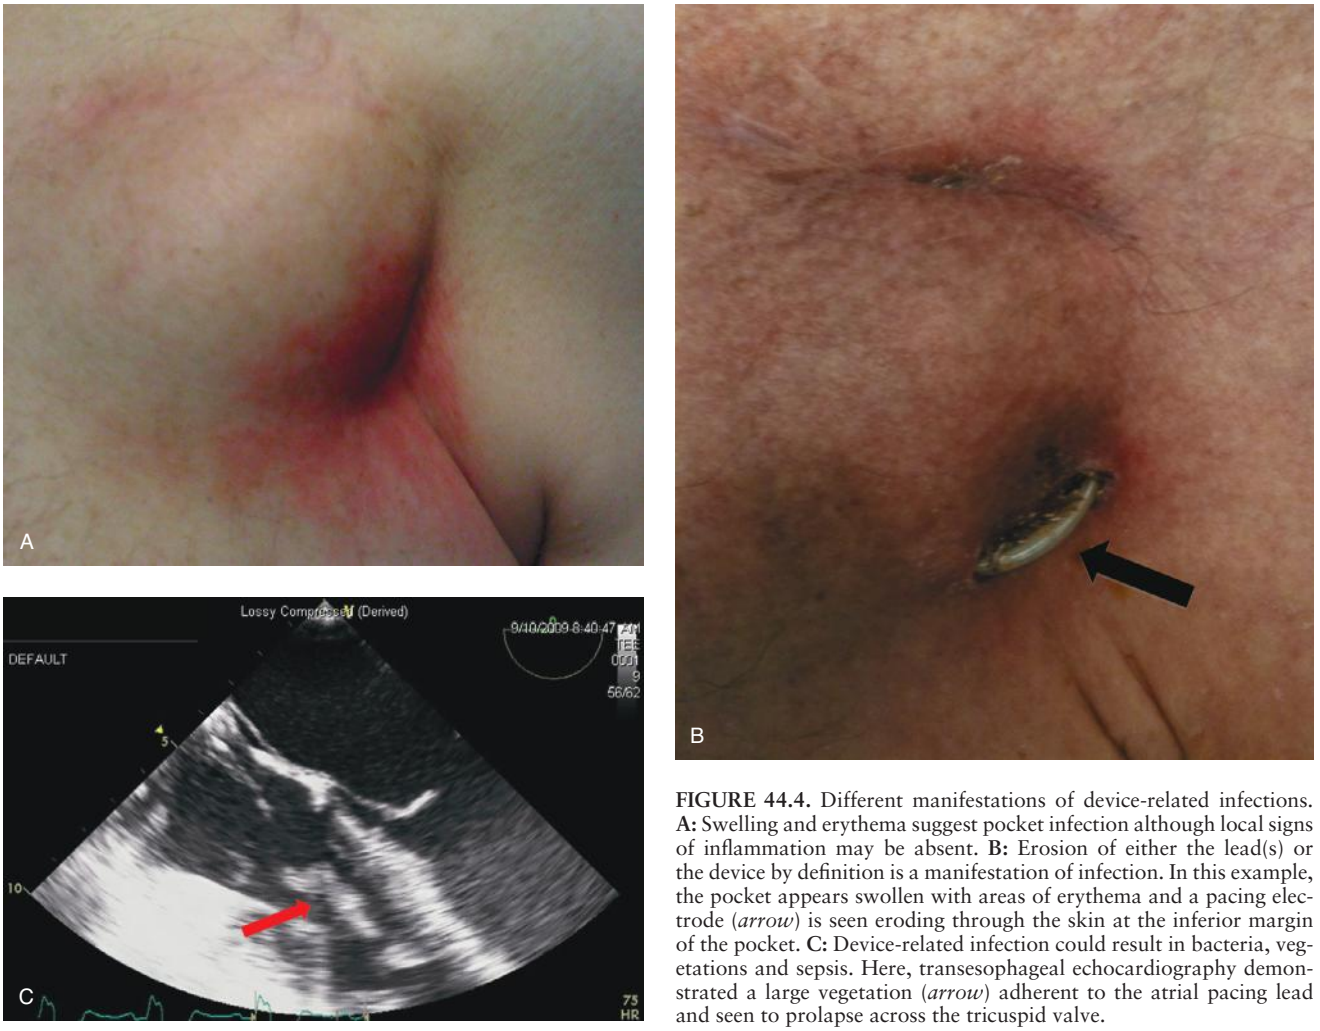

FIGURE 44.4. Different manifestations of device-related infections. **A:** Swelling and erythema suggest pocket infection although local signs of inflammation may be absent. **B:** Erosion of either the lead(s) or the device by definition is a manifestation of infection. In this example, the pocket appears swollen with areas of erythema and a pacing electrode (*arrow*) is seen eroding through the skin at the inferior margin of the pocket. **C:** Device-related infection could result in bacteria, vegetations and sepsis. Here, transesophageal echocardiography demonstrated a large vegetation (*arrow*) adherent to the atrial pacing lead and seen to prolapse across the tricuspid valve.

pacing mode and insure more reliable delivery of pacing until a formal evaluation can be performed.

Undersensing

In contrast, undersensing occurs when the device fails to sense intrinsic events. This results in the generation of unnecessary pacemaker impulses and "overpacing." Undersensing may be a result of alterations in electrogram amplitude of physiologic events or may represent hardware failure. Antiarrhythmic drug therapy, myocardial infarction, and metabolic derangements can alter electrogram amplitude transiently or permanently. Undersensing may be potentially corrected by changing the programmed sensitivity. Other etiologies of undersensing are similar to those of noncapture (lead dislodgement, perforation, or fracture). Asynchronous pacing modes, due to EMI or battery depletion, can mimic undersensing on surface electrocardiogram.

Noncapture

Noncapture occurs when electrical impulses emitted from the device fail to capture myocardium. The surface electrocardiogram will demonstrate pacing stimuli without evidence of capture (Fig. 44.6). Loss of capture can be intermittent or permanent, but often necessitates device revision. Causes of noncapture can be divided into changes in capture threshold and hardware malfunction. The capture threshold can rise in the first 4 to 6 weeks following lead implant due to inflammatory changes at the lead-myocardial border although this has become less relevant clinically with the advent and widespread use of steroid-eluting leads. A rise in capture threshold can be overcome by increasing the pacemaker output. Other causes of elevated capture thresholds include myocardial fibrosis or infarction near the exit of the pacing stimulus, metabolic derangements (specifically, hyperkalemia, acidemia and hyperglycemia), and certain medications. Class Ia, Ic, and III antiarrhythmic drugs [21–27] can increase capture thresholds as can mineralocorticoids and hypertonic saline [28]. If the capture threshold exceeds the maximal programmable output, this is termed *exit block*. Primary hardware problems such as lead dislodgement, perforation or fracture, and battery depletion can all result in noncapture. A chest radiograph can help diagnose specific lead issues (Fig. 44.7A–C). Formal pacemaker interrogation or magnet application can identify battery depletion.

No Output

The complete absence of pacemaker stimuli despite magnet application suggests complete battery depletion or generator damage. Damage to the generator can occur rarely as a result of direct trauma [29] or external defibrillation [15].

Pacemaker-Mediated Tachycardia

Pacemaker-mediated tachycardia (PMT) refers to any sustained tachyarrhythmia that is dependent on continued pacemaker participation in the circuit. Classically, the term PMT is used to

TABLE 44.3

TROUBLESHOOTING PACEMAKER MALFUNCTION

describe an endless loop tachycardia in dual-chamber devices consisting of ventricular pacing, retrograde atrial activation, appropriate sensing and triggered ventricular pacing perpetuating the tachycardia (Fig. 44.8). PMT should be suspected when ventricular pacing occurs at the programmed maximum tracking rate of the device. The PMT circuit can be interrupted with magnet application and the arrhythmia terminated.

DEVICE-SPECIFIC CONSIDERATIONS

Implantable Cardioverter Defibrillator

Electrical Storm

Electrical or ventricular tachycardia (VT) storm is defined as three or more episodes of VT or ventricular fibrillation within a 24-hour period. When a patient presents with electrical storm, suppression of the arrhythmias are of paramount importance. Identifying the trigger can be difficult [30] but attempts should be made to identify and correct potentially treatable causes (Table 44.4). Repeated defibrillator therapy is painful and highly stressful, can cause heightened sympathetic tone and result in early battery depletion, myocardial ischemia/stunning, and recurrent ventricular arrhythmias [31,32]. Thus, initial treatment should consist primarily of sympathetic blockade with beta-blockers and anxiolysis with benzodiazepines. Amiodarone is often the antiarrhythmic agent of choice [33,34]. Refractory cases may require intubation and deep anesthesia [35]; stellate ganglion blockade can be considered in extreme cases [36]. Catheter ablation is effective in the treatment of electrical storm and can be considered for electrical storm despite chronic antiarrhythmic therapy and for refractory cases [37].

Ineffective Defibrillation

Successful defibrillation occurs when a critical mass of myocardium is successfully depolarized and depends on shock vector, lead position, and the electrical milieu. The optimal three-dimensional orientation of the ICD shock vector should deliver energy uniformly throughout the left ventricle. The vector is dependent on the position of the high-voltage coils in the right ventricle (RV) and superior vena cava (SVC)-right atrial (RA) junction and the active can in relation to the left ventricle. Typically, the RV coil is the cathode and the SVC–RA coil and ICD can form the anode with current traveling from cathode to anode.

Implantable defibrillators can fail to deliver effective defibrillation therapy in certain situations. Elevated defibrillation thresholds (DFT) can occur as a result of metabolic derangements, myocardial ischemia, pneumothorax, hypoxia, multiple defibrillations, drug therapy, delays in arrhythmia detection, and device hardware malfunction (Table 44.5). Immediate management should consist of external defibrillation and treatment of potential reversible causes. Long-term management may require device revision or cessation/addition of specific antiarrhythmic medications.

Inappropriate Therapies

Inappropriate therapies are common in patients with implantable defibrillators regardless of indication [38] and are

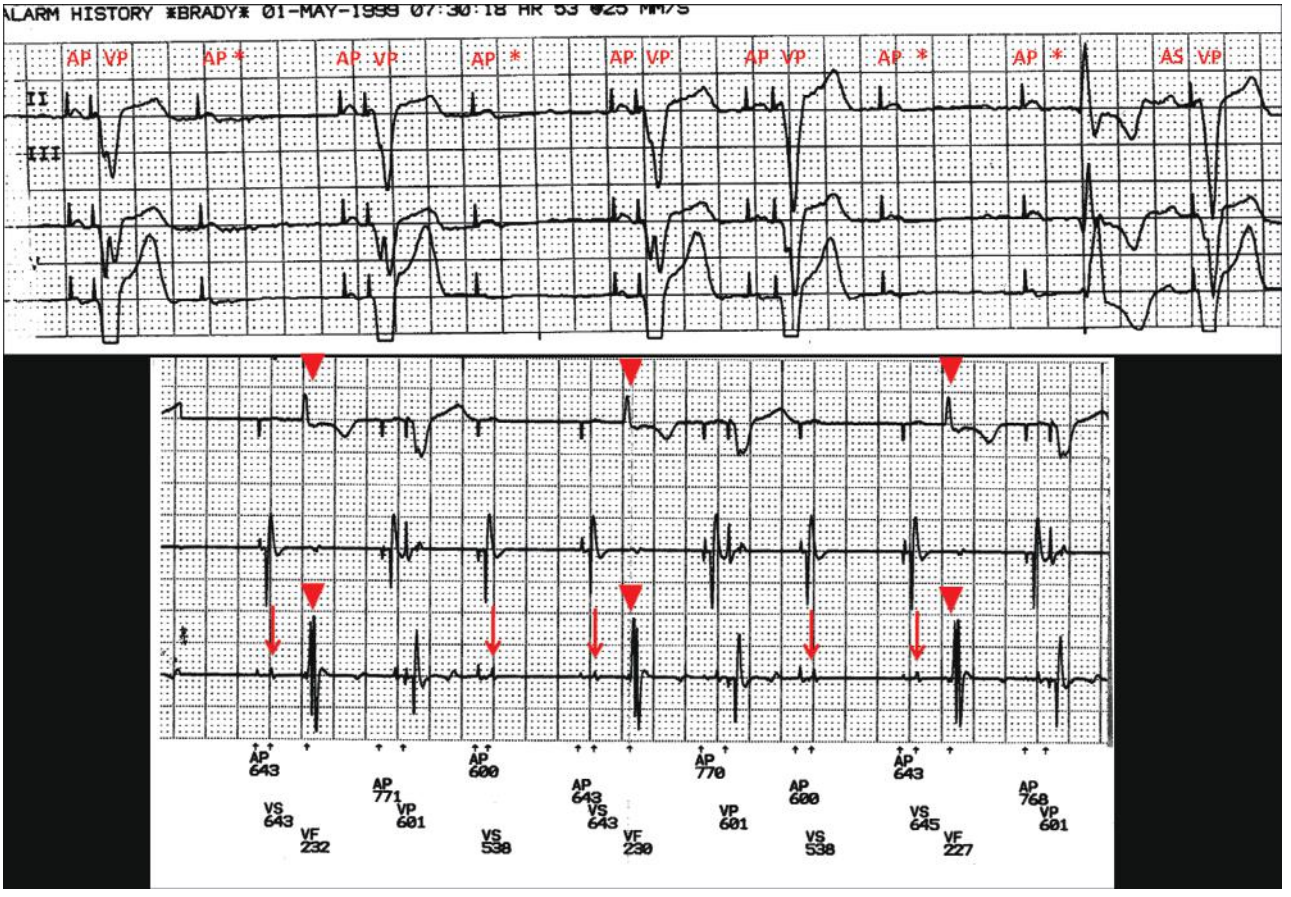

FIGURE 44.5. Dual-chamber defibrillator with evidence of ventricular oversensing. The top panel demonstrates atrial (AP) and ventricular (VP) sequential pacing with the intermittent absence of ventricular pacing stimuli (*asterisks*) following atrial paced events. The bottom panel represents the intracardiac electrograms from the same device with ventricular oversensing of atrial events (*arrows*). When intrinsic ventricular conduction does occur (*arrowheads*), the device incorrectly labels the event as "VF" (*arrowheads*) or a ventricular event that because of timing falls into the programmed ventricular fibrillation detection zone.

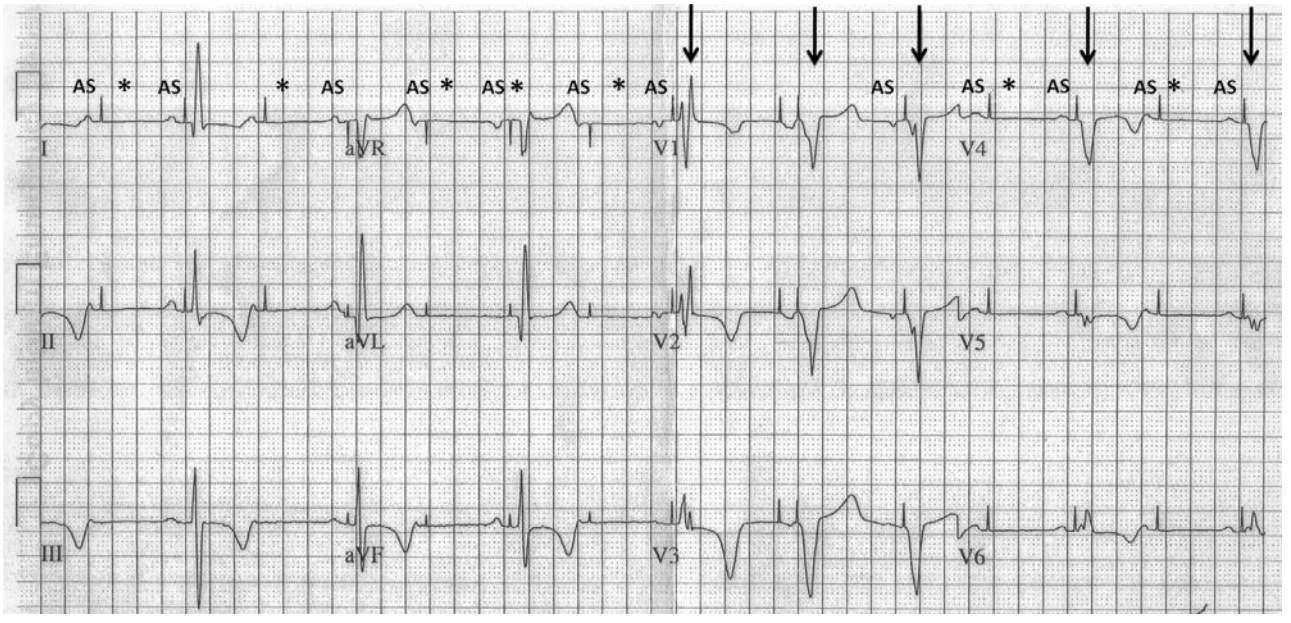

FIGURE 44.6. Surface electrocardiogram with intermittent loss of ventricular capture. There is appropriate atrial sensing (AS) and tracking as evidence by pacing stimuli at a fixed interval following the P wave but intermittent failure of ventricular output to capture the myocardium (*asterisks*). Evidence of varying degrees of fusion between intrinsic conduction and ventricular pacing is also observed (*arrows*).

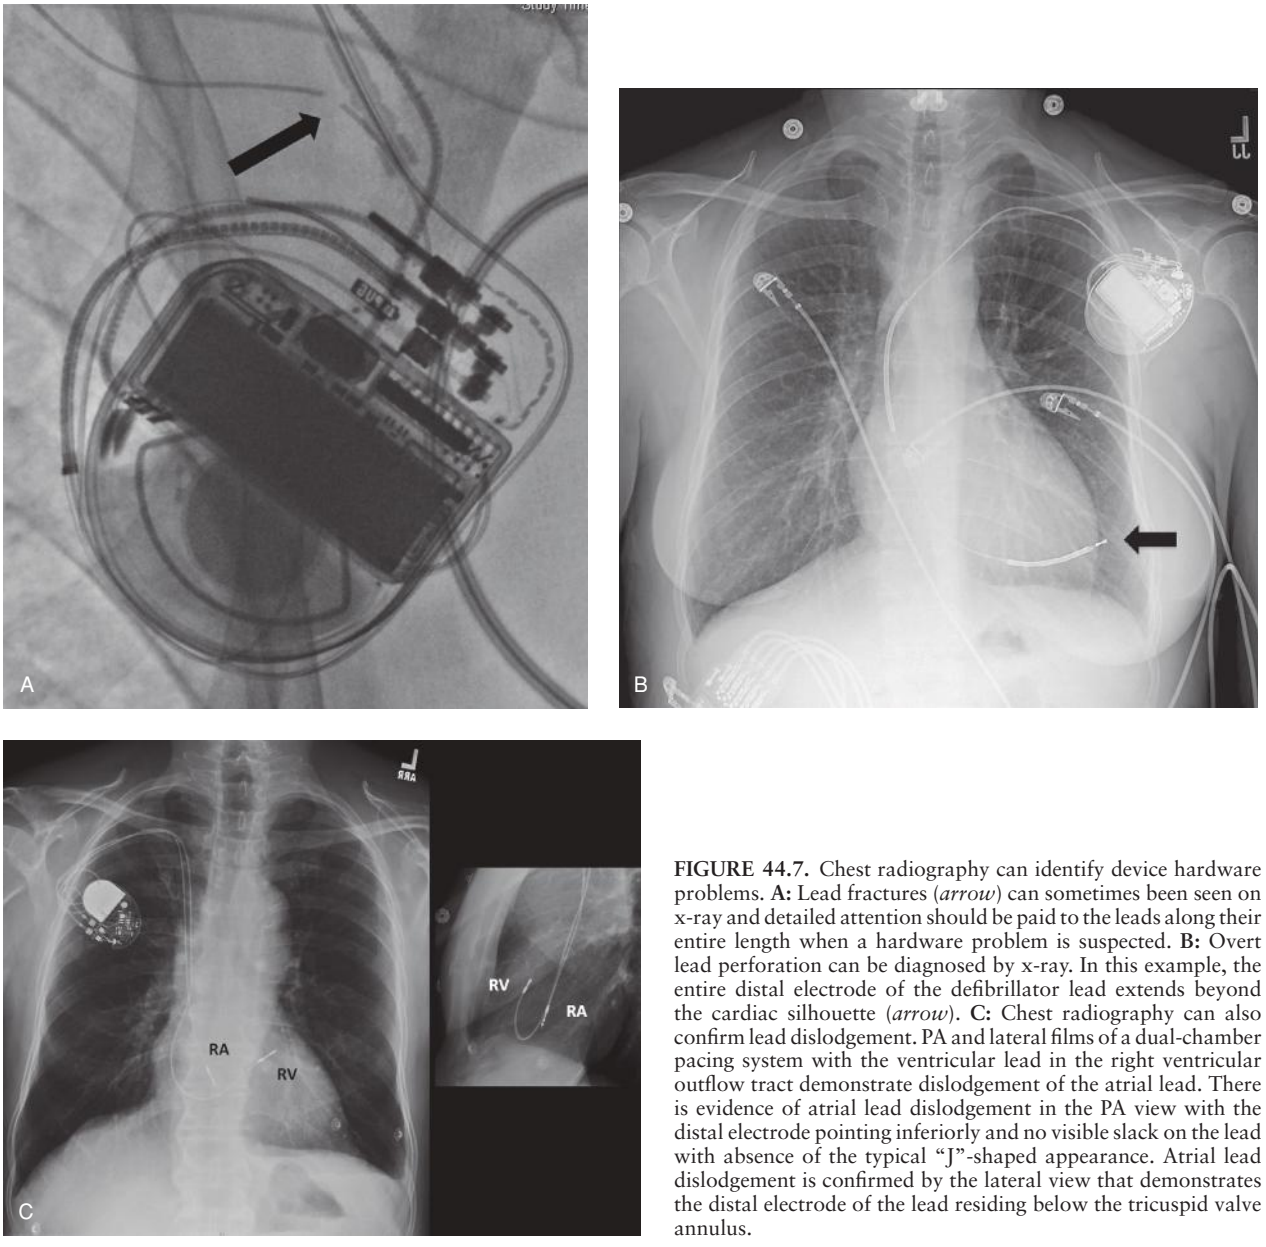

FIGURE 44.7. Chest radiography can identify device hardware problems. **A:** Lead fractures (*arrow*) can sometimes been seen on x-ray and detailed attention should be paid to the leads along their entire length when a hardware problem is suspected. **B:** Overt lead perforation can be diagnosed by x-ray. In this example, the entire distal electrode of the defibrillator lead extends beyond the cardiac silhouette (*arrow*). **C:** Chest radiography can also confirm lead dislodgement. PA and lateral films of a dual-chamber pacing system with the ventricular lead in the right ventricular outflow tract demonstrate dislodgement of the atrial lead. There is evidence of atrial lead dislodgement in the PA view with the distal electrode pointing inferiorly and no visible slack on the lead with absence of the typical "J"-shaped appearance. Atrial lead dislodgement is confirmed by the lateral view that demonstrates the distal electrode of the lead residing below the tricuspid valve annulus.

associated with significant morbidity and mortality [39,40]. Common causes of inappropriate therapies include SVT, ventricular sensing problems, lead failure, and EMI. The detection algorithms of ICDs are based primarily on heart rate, and any ventricular-sensed event that exceeds the programmed detection rate will trigger ICD therapy. Supraventricular discriminators related to arrhythmia onset, cycle length stability and electrogram morphology are also programmable but reduce inappropriate therapies only slightly [41,42]. Repeated inappropriate ICD therapies in hemodynamically stable patients should prompt magnet application or device deactivation with back-up external defibrillation available and definitive treatment directed at the underlying rhythm or problem.

The most common cause of inappropriate defibrillator therapy is atrial fibrillation although sinus tachycardia and other SVTs can result in inappropriate therapies. Surface electrocardiogram and clinical status may aid with the diagnosis if formal interrogation is not immediately available. The device should be inactivated and treatment directed at the underlying atrial arrhythmia. Ventricular sensing problems also

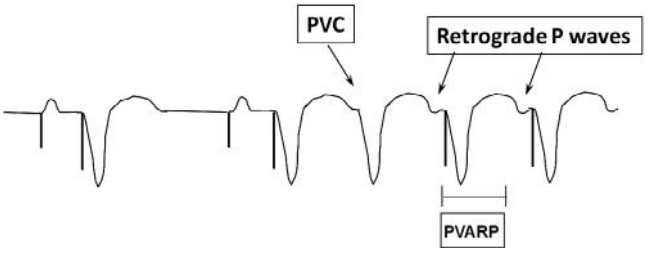

FIGURE 44.8. Pacemaker-mediated tachycardia (PMT). A premature ventricular complex (PVC) occurs in a patient with a dual-chamber pacemaker. The PVC results in retrograde conduction back to the atrium that is subsequently tracked by the ventricular lead and incessant tachycardia ensues. Retrograde atrial activation is sensed by the pacemaker because it falls outside the postventricular atrial refractory period (PVARP). One means of eliminating PMT is to extend the PVARP.

result in inappropriate therapies when other electrical events (P waves, T waves, wide QRS) are misinterpreted as a ventricular event. This "double counting" is erroneously interpreted as a tachyarrhythmia and prompts inappropriate ICD therapy. Ventricular oversensing may be transient as a result of metabolic derangements (e.g., peaked T waves with hyperkalemia) or may sometimes be successfully eradicated with reprogramming of the device although some sensing problems may require device revision. Hardware problems such as lead fracture, insulation break, lead dislodgement, or a loose setscrew may result in noise and short ventricular cycle lengths that can be mistakenly detected as VT. The surface electrocardiogram is extremely useful and will demonstrate sinus rhythm

or tachycardia at the time of defibrillation. Device hardware problems cannot be overcome with reprogramming. The ICD should be deactivated until the system can be revised. Similarly, EMI can produce noise and result in inappropriate therapies.

Withdrawal of Care

Patients with ICDs and end-stage heart failure or other fatal illness warrant special consideration. Successful defibrillation may prolong life but it cannot prevent death. In addition, repeated ICD shocks in a patient with end-stage disease may cause unnecessary pain and anxiety. Defibrillation can be deactivated in ICDs without deactivating pacemaking functions. Discussions regarding ICD deactivation occur rarely even in patients with do-not-resuscitate orders [43]. It is important that patients and their families understand that deactivation of defibrillator therapies is always an option [44].

Cardiac Resynchronization Therapy (Biventricular Pacing)

Cardiac resynchronization therapy (CRT) improves symptoms, decreases hospitalizations, assists with reverse remodeling of the left ventricle, and reduces mortality in patients with symptomatic heart failure, severe left ventricular dysfunction, and mechanical dyssynchrony (QRS >120 ms) [45–48]. Ventricular resynchronization aims to achieve myocardial coordination through left ventricular preexcitation ideally at the site of latest activation. This can be achieved through an endovascular approach with left ventricular lead placement via coronary sinus cannulation or epicardially with a direct surgical approach (typically via left lateral thoracotomy). Approximately 70% of CRT patients demonstrate clinical improvement with reduction in symptoms [49,50] and even fewer show improvement in left ventricular function [51].

Loss of Resynchronization

Achieving resynchronization appears dependent not only on stimulating the ventricle at the site of latest activation but also providing reliable biventricular pacing. There appears to be a threshold effect of CRT related to frequency of biventricular pacing. A recent retrospective analysis demonstrated a significant decrease in hospitalizations and mortality at biventricular pacing above 92% [52]. Among CRT responders, loss of resynchronization can result in recurrent symptoms, diminished functional capacity, repeat hospitalization, and significant hemodynamic alterations. Although formal device interrogation is necessary to assess the degree of biventricular pacing over the long-term, careful observation of the telemetry monitor often can provide significant insight. Similarly, the 12-lead electrocardiogram can identify the site of ventricular stimulation and can be used to detect loss of biventricular pacing (Fig. 44.9A, B). Atrial arrhythmias with intact ventricular conduction exceeding the programmed lower rate of the CRT device are the most common reason for failure to achieve sufficient resynchronization. Other potential reasons for suboptimal biventricular pacing include elevated pacing threshold, lead fracture, or lead migration to an unfavorable location. Common reasons for a lack of response to CRT are lead location, suboptimal programming and underlying narrow QRS [53]. If the left ventricular pacing lead is not stimulating a late activation site in the basal posterolateral left ventricle, the degree of biventricular pacing is irrelevant. The electrocardiogram and chest radiograph are useful in identifying issues with left ventricular lead placement.

Summary

In the modern era, patients with implantable pacemakers, defibrillators and cardiac resynchronization devices are increasingly commonly admitted to the care of an intensivist. Attention to and understanding of the implanted device as a critical portion of the patient's acute care is warranted. Early involvement of electrophysiologist colleagues in the care of critically ill patients especially with device malfunction or infection is prudent.

CHAPTER 45 ■ MECHANICAL SUPPORT FOR HEART FAILURE

JEFFREY J. TEUTEBERG AND FIRAS E. ZAHR

During the past two decades the incidence of cardiogenic shock has not significantly declined despite important progress in the management of patients with acute myocardial infarction and advanced heart failure [1,2]. Cardiogenic shock is characterized by persistent hypotension with systolic arterial pressures typically less than 80 mm Hg and marked reduction of cardiac index (<2 L per minute per m^2) in conjunction with elevated left ventricular (LV) filling pressures and evidence of end-organ hypoperfusion. Patients may present in shock as a complication of acute myocardial infarction, cardiac surgery, acute myocarditis, or an acute decompensation of chronic heart failure. Although the mortality of patients presenting with acute myocardial infarction and cardiogenic shock declined during the 1990s, the 1-month mortality remains nearly 50% despite aggressive efforts at reperfusion therapy [2–5]. In many cases of cardiogenic shock, medical therapy alone may be inadequate, and the patient may require temporary or even permanent mechanical support. The proper application of mechanical circulatory support (MCS) requires knowledge of the underlying mechanism of heart failure, understanding of the potential benefits and limitations of both medical and device therapy, familiarity with the full range of devices available for support, and perhaps most critically, careful selection of the appropriate timing for intervention.

MECHANICAL CIRCULATORY SUPPORT

Over the past five decades, mechanical circulatory support technology has evolved substantially from partial temporary support with intra-aortic balloon counterpulsation to a broad array of ventricular assist devices (VADs) capable of providing long-term complete support for one or both ventricles. In the 1990s, extensive experience with bridging patients to transplantation spurred the evolution from bulky extracorporeal devices to smaller, implantable designs, which allowed patients to be discharged from the hospital and have substantial improvements in functional status and quality of life. More recently, the prior generations of larger pulsatile pumps have been superseded by the introduction of smaller, more durable continuous flow devices with superior survival and fewer adverse events.

BENEFITS OF MECHANICAL CIRCULATORY SUPPORT

Hemodynamic

As the left ventricle begins to fail, cardiac output falls and intracardiac filling pressures rise. The main goals of MCS are to decompress the failing ventricle and augment systemic perfusion [6]. Mechanical unloading of the left ventricle leads to a decrease in the severity of mitral regurgitation, less pulmonary congestion, and a reduction in pulmonary arterial hypertension, all of which, in turn, can result in improved right ventricular (RV) function. Partial support pumps provide several liters of flow to augment the reduced native ventricular contribution to the total output, whereas full support pumps provide upwards of 6 to 7 L of flow with the native heart contributing little to the total output. Restoration of forward flow and the normalization of filling pressures also reduces neurohormonal activation, with attendant benefits on cardiorenal function; as a result, temporary VAD support may allow reverse ventricular remodeling and sufficient recovery of ventricular function to permit explantation in selected patients [7].

Biologic

The hemodynamic benefits of mechanical circulatory support with a LV assist device (LVAD) are also associated with favorable structural changes within the cardiac myocytes and extracellular matrix. In studies of isolated human cardiac myocytes, LVAD support increased the magnitude of contraction, shortened the time of peak contraction, and reduced the time to 50% relaxation. In addition, responses to beta-adrenergic stimulation were greater in isolated myocytes after LVAD support. This suggests that mechanical unloading might reverse the downregulation of beta-adrenergic receptors and improve cardiac responsiveness to inotropic stimulation [8–15]. In vivo, mechanical unloading with an LVAD is known to be associated with alteration of gene and protein expression within the cardiac myocyte [16,17], a reduction in nuclear size and DNA content, and a reduction in fibrosis and collagen content within the cardiac extracellular matrix [10,11].

SELECTION OF APPROPRIATE MECHANICAL SUPPORT

The clinical application of MCS grew from early experience with its application as temporary support in the operating room to supporting patients for months until transplant. A broad array of different ventricular support devices is now available (Table 45.1). Broadly speaking, the devices may be configured for isolated right ventricular (RVAD), left ventricular (LVAD), or biventricular (BiVAD) support and for short-term (bridge to recovery or bridge to decision), short-term (bridge to transplant), or long-term (destination therapy) support [18]. Some devices are extracorporeal or paracorporeal in location, with cannulae traversing the skin allowing for inflow and outflow of blood, whereas others are totally implantable with the pump and the cannulae housed in the thoracic and/or abdominal cavity with only a single percutaneous line supplying the power

TABLE 45.1

APPROVED MECHANICAL CIRCULATORY SUPPORT DEVICES

	Description	Approved devices	Advantages	Disadvantages
Temporary—LV support				
Extracorporeal pulsatile	Cannulated from LV apex to ascending aorta	• Abiomed BVS 5000	• Relatively easy to implant	• Unable to ambulate
Continuous flow	Catheter-based axial flow Centrifugal Often used emergently with resuscitation	• Impella 2.5 • TandemHeart System • Centrimag • ECMO	• Percutaneous placement in cath lab • Rapid placement • Place in catheterization lab without • Rapid surgical placement • Used with oxygenator when pulmonary concomitant pulmonary support required	• Partial support device • Current indication for high-risk PCI • Unable to ambulate • Leg ischemia from large bore cannula • Requires familiarity with transseptal cannula placement • Unable to ambulate • Usually surgically placed
Permanent—LV support				
	Description	**Approved devices**	**Advantages**	**Disadvantages**
Extracorporeal pulsatile	Inflow cannula from LV and outflow cannula to ascending aorta	• Thoratec PVAD • Abiomed AB5000	• Ease of implantation	• Total of two large cannula traversing skin • External pumps
Implantable pulsatile	Pump implanted in the abdomen or preperitoneally, allowing increased mobility and ability to discharge	• HeartMate XVE • Thoratec IVAD	• Requires only an aspirin, no Coumadin • Approved as DT • Durable	• Less durable if duration of support >9–12 months • BSA $\geq$1.5 m^2 • INR 2.5–3.5 • Less portable peripherals
Continuous flow	Pump implanted in the thoracic cavity with only one moving part.	• HeartMate II and MicroMed DeBakey	• Reduced size and noise • Much greater durability than pulsatile devices • Better adverse event profile than pulsatile pumps	• Difficult to assess BP and pulse due to lack of pulsatility • "Suck-down" caused by over unloading ventricle
Permanent—biventricular support/TAH				
Extracorporeal	Two pumps—one supporting the RV and one supporting the LV, but native heart remains in place	• Thoratec PVAD	• Easy to insert for unstable patients	• Two pumps with a total of four cannula transversing the skin • External pumps
Intracorporeal	Native heart removed completely	• AbioCor and SynCardia CardioWest	• Removes cardiac tissues which may contribute to inflammation and be susceptible to clots, arrhythmias or interference with pump	• Available only in select centers • Not applicable to most patients

LV, left ventricle; PCI, percutaneous coronary intervention; ECMO, extracorporeal membrane oxygenation; TAH, total artificial heart; BSA, body surface area; BP, blood pressure; RV, right ventricle.

and providing the connections to the external control systems. Early generation devices were volume displacement pumps, which had a volume chamber sequentially filled and emptied of blood, mimicking the native heart and providing pulsatile flow. However, the need for a volume displacement chamber resulted in a larger pump size and also required more moving parts resulting in mechanical wear and shorter pump life. The current generation of devices no longer has a displacement chamber, but rather has a continuously rotating impeller. This results in a continuous flow of blood and thus limited pulsatility, but allows for substantially smaller pump profiles and longer pump life.

Cannulation

VADs are typically implanted in parallel with the native right- or left-sided circulation. For long-term LVADs, the pump inflow is from a cannula placed directly into the LV apex and the pump outflow is a cannula that is anastomosed to the

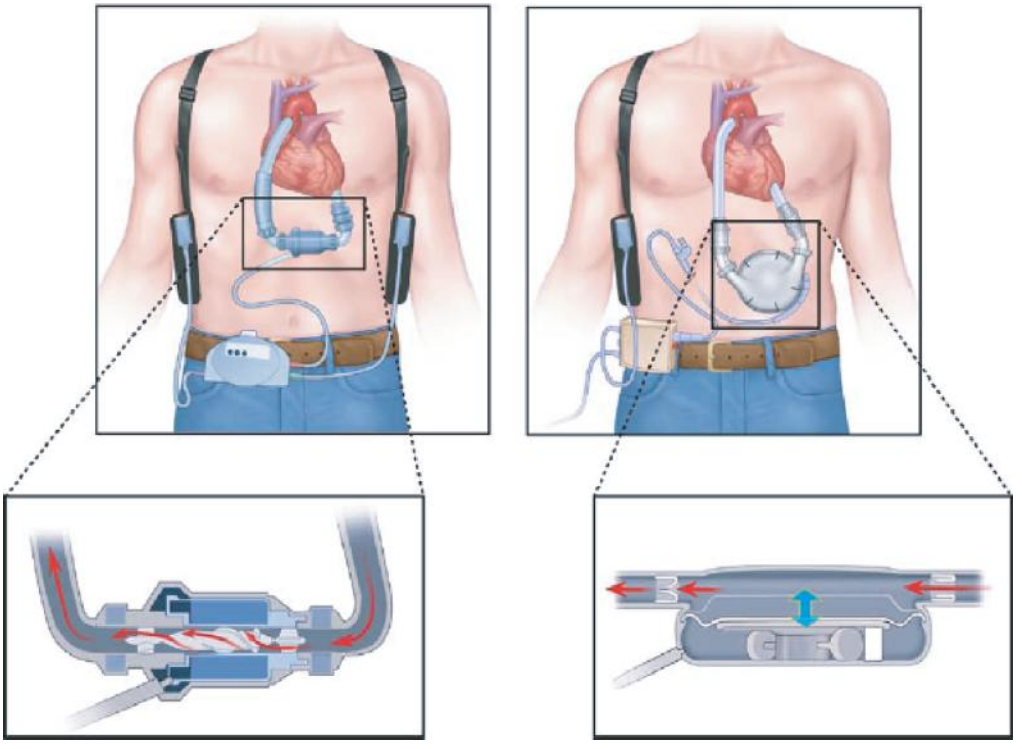

FIGURE 45.1. Representative left ventricular assist devices. (*Right*) Continuous flow LVAD (HeartMate II). Cardiac output is maintained by the continuous rotation of an impeller. (*Left*) Pulsatile flow LVAD (HeartMate XVE). Cardiac output is maintained by the sequential filling and emptying of a volume displacement chamber and unidirectional blood flow is provided with the use of valves before and after the displacement chamber. [From Wilson SR, Givertz MM, Stewart GC, et al: *J Am Coll Cardiol* 54:1647–1659, 2009, with permission.]

ascending aorta just distal to the aortic valve. Pulsatile systems typically have valves in the inflow and outflow cannulae, whereas continuous flow devices do not. For percutaneous systems, the pumps may be placed across the aortic valve and into the left ventricle or into the left atrium via transcatheter puncture of the interatrial septum. RVADs typically have inflow from the right atrium rather than the RV apex as RV apical cannulation typically provides less reliable flow. The venous blood may also be accessed from the cavae or femoral veins. Outflow is directed to the main pulmonary artery just distal to the pulmonic valve through either direct or transvenous cannulation.

Pulsatile Flow

Early-generation VADs are volume displacement pumps which fill and empty asynchronously with the cardiac cycle creating pulsatile arterial flow. The pulsatile pumps mostly fill passively or have limited ability to augment their filling; thus, the beat-to-beat filling of the pump depends partially on the cardiac cycle. Although most of the blood volume entering the left ventricle is diverted into the pump, the left ventricle does occasionally fill enough to eject and contribute to the total cardiac output. In settings of hypovolemia, the pump will fill less quickly and thus the pump rate will slow down, the converse is true in the setting of hypervolemia, thus maintaining a relatively constant state of decompression of the left ventricle.

Continuous Flow

In contrast to pulsatile flow pumps, continuous flow pumps have a continuously rotating impeller which produces forward flow. The left ventricle is continuously and actively unloaded and therefore the left ventricle rarely can fill to the point where it can eject blood during systole. Thus, the patient has little pulsatile contribution from their native ventricles and hence has little to no pulse pressure, but rather have a mean blood pressure. Patients supported with continuous flow LVADs therefore require Doppler ultrasound to assess their blood pressure. Continuous flow pumps are generally one of two major types: axial or centrifugal flow. Axial flow pumps have the impeller rotating in the same plane as the blood flow, whereas centrifugal pumps accelerate the blood perpendicularly to the axis of inflow. They typically have only one moving part (the impeller) which is magnetically or hydrodynamically suspended resulting in little wear over time. Given the size and wear considerations, among others, continuous flow pumps are now the pump of choice for long-term support. The internal and external components of representative pulsatile and continuous flow pumps are as seen in Figure 45.1.

Most recent data suggests that implantation of a continuous-flow LVAD, as compared with a pulsatile-flow device, significantly improved the probability of survival free of stroke and reoperation for device repair or replacement at 2 years in patients with advanced heart failure in whom medical therapy had failed and who were ineligible for transplantation. In addition, the 2 year actuarial survival with an LVAD was significantly better with a continuous-flow device than with a

pulsatile-flow device. The continuous-flow LVAD was also associated with significant reductions in the frequency of adverse events and the rate of repeat hospitalization, as well as with an improved quality of life and functional capacity [19–22].

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) can provide pulmonary or cardiopulmonary support for up to a week or more. Blood is withdrawn from the circulation via an inflow cannula to an extracorporeal continuous flow pump, an oxygenator, and then back to the patient through an outflow cannula. There are two basic types of ECMO: venovenous (VV) and venoarterial (VA). In VV ECMO, the blood is withdrawn from a large central or peripheral vein (jugular or femoral) and oxygenated blood is returned via another large vein. Thus, VV ECMO does not provide hemodynamic support, but rather pulmonary support. For VA ECMO the inflow is typically via the femoral vein and the outflow is typically through the femoral artery and thus provides both oxygenation and mechanical circulatory support. VA ECMO is most commonly used in the setting of severe shock in the setting of acute infarction, fulminant myocarditis or cardiac arrest or after a failure to wean from cardiopulmonary bypass. In the setting of a failure to wean from bypass, the intraoperative cannulation that was used for cardiopulmonary bypass can be attached to the ECMO circuit, rather than having new cannula placed peripherally. Outside the setting of the operating room, both VV and VA EMCO can be rapidly instituted even at the bedside, as either configuration can be achieved through peripheral access, but should only be performed by experienced personnel.

COMPLICATIONS

Although the focus of this chapter is the preoperative assessment and management of patients being considered for MCS, knowledge of some of the common postoperative complications of MCS are necessary to understand the implications of some of these preoperative considerations. The three most common are bleeding, infection, and thromboembolism.

Bleeding

Placement of an intracorporeal pump requires a sternotomy and cardiopulmonary bypass. The degree of perioperative bleeding can be affected by preexisting coagulopathy, liver congestion, and prior sternotomies or other concomitant corrective surgeries at the time of MCS. Most current-generation devices, whether temporary or permanent, require anticoagulation with heparin after post-operative bleeding subsides and then chronically with warfarin and, depending on the center, an antiplatelet agent(s). Most pulsatile devices have mechanical prosthetic valves requiring an INR of 2.5 to 3.5, whereas some of the current generation continuous flow devices may only require an INR of 1.5 to 2 [23]. Thus, there is a risk of continued or new onset bleeding throughout the duration of support, but current devices have a risk of bleeding requiring transfusion of about 0.85 per patient year beyond 30 days, which is a substantial improvement in comparison to previous generation pulsatile devices [24,25]. However, the continuous flow pumps present a unique risk for gastrointestinal bleeding. The high shear stress on the blood from the impeller can cause destruction of large multimers of von Willebrand factor (vWF), which results in a picture of acquired von Willebrand's disease [26,27]. Bleeding risk is mostly manifest from gastrointestinal arteriovenous malformation (AVMs), it is unknown if the loss of vWF multimers results in bleeding from pre-existing AVMs or the lack of pulsatile flow predisposes to the development of AVMs [27–29]. Although most patients have a demonstrable loss of vWF multimers, only a minority of patients develop bleeding. For those who are awaiting transplant, bleeding requiring transfusion carries the additional risk of sensitization to human leukocyte anitgen (HLA) antigens that may limit the pool of suitable donor organs [30].

Infection

Aside from the infection risks associated with surgery and indwelling lines postoperatively, there is the additional chronic risk associated with the presence of the VAD itself and the associated driveline or cannulae. However, sepsis from any source can result in seeding of interior of the VAD or its components, which may necessitate more urgent and higher risk transplant or even device replacement [31]. Vegetations on LVAD prosthetic valves may also be a source of thromboembolism [32].

Thromboembolism and Stroke

Embolism may result from the pump due to inadequate anticoagulation, the cardiac chambers due to arrhythmias such as atrial fibrillation, or may arise from the native vasculature as a result of the patients' preexisting vascular atherosclerosis. The overall incidence of ischemic stroke varies greatly with type of device, however with the current generation devices the rate is 0.09 per patient-year overall and 0.05 per patient-year after 30 days [33]. Maintenance of goal INR is critical to minimize the risk of thromboembolism.

INDICATIONS

MCS may be appropriate for either short-term (<1 week) or long-term support of patients with heart failure and shock. In the majority of cases, long-term MCS is intended as a hemodynamic 'bridge' to subsequent cardiac transplantation (BTT) [34]. For patients who are not candidates for transplant, an LVAD may be used for long-term support (destination therapy, DT) [19]. The only two devices that have been approved for DT in the United States are the HeartMate XVE, and more recently Thoratec's HeartMate II LVAD [19,22]. Occasionally, patients are placed on MCS in anticipation of ventricular recovery and device explantation (bridge-to-recovery), as in selected patients with postcardiotomy shock or acute heart failure due to potentially reversible causes (e.g., fulminant myocarditis) [34].

UNIVENTRICULAR VERSUS BIVENTRICULAR SUPPORT

Selection of the appropriate device for MCS depends initially on the type of support that is required. Most patients presenting with acute heart failure or shock predominantly have LV failure and may be candidates for isolated LV support with an LVAD. Successful LVAD implantation, however, relies heavily on confirmation of adequate native RV function, since RV function is required for LVAD filling [35]. For patients with concomitant, severe RV dysfunction, biventricular support may be necessary. Although recent experience suggests that selected BiVAD patients can be successfully discharged to home, outcomes are generally poorer than with LVAD alone, perhaps in part due to greater severity of illness and end-organ dysfunction amongst patients presenting initially with biventricular

failure [36]. Since BiVAD treatment is currently available only for patients who are candidates for eventual cardiac transplantation, up-front BiVAD support should only be considered in transplant-eligible patients with prolonged shock, giant cell-myocarditis, refractory ventricular tachyarrhythmias, or a high likelihood of postoperative RV failure. Even with the current generation of continuous flow LVADs, there is an approximately 7% incidence of RV failure requiring an RVAD postoperatively, highlighting the need for careful assessment of RV function prior to VAD implantation [37–42]. In select centers, explant of the native heart and implantation of a total artificial heart (TAH) may provide an alternative to the use of BiVADs [43].

URGENT VERSUS ELECTIVE SUPPORT

Urgent MCS

Urgent mechanical support may be necessary in a subgroup of patients presenting with acute, medically refractory cardiogenic shock (e.g., acute myocardial infarction, fulminant myocarditis, acute valvular incompetence). In these subjects, time for comprehensive medical and surgical evaluation is limited, and the focus is on rapid hemodynamic stabilization and restoration of end-organ perfusion. Historically, because of widespread availability and ease of implantation, the IABP has been a cornerstone of therapy; however, for many patients an IABP may be inappropriate (e.g., those with severe peripheral arterial disease or aortic insufficiency (AI)) or inadequate in the setting of profound cardiac dysfunction. Increasingly, stabilization for such patients may be accomplished with temporary or percutaneous VADs (e.g., TandemHeart, Impella, CentriMag) or with urgent institution of extracorporeal membrane oxygenation (ECMO) [44]. Particularly for those patients with cardiogenic shock complicated by progressive hypoxemia despite adequate ventilation, ECMO, if instituted early, can be a lifesaving measure [45,46]. As such, transfer to a specialized medical center with experience in cardiac transplantation or MCS should be considered as soon as medically feasible. Once stabilized with MCS, patients can be either weaned gradually over time or, as appropriate, be transitioned to more permanent devices for long-term support (if irreversible end-organ damage has not already occurred). In general, critically ill patients have better outcomes if they are stabilized and undergo implantation of long-term MCS on an urgent rather than emergent basis, largely due to the extremely high rate of perioperative complications amongst patients presenting multisystem organ failure [24].

Elective MCS

For patients with advanced heart failure, MCS on a more elective basis is becoming the preferred strategy for optimizing outcomes for patients whether they are BTT or DT. End-stage heart failure is characterized by progressive functional decline and repeated heart failure hospitalizations which significantly impacts both resource utilization and quality of life [47,48]. Although support with intravenous inotropic agents (in hospital or at home) may provide temporary relief, these agents are associated with an increased risk of adverse outcomes including arrhythmia and sudden death [20]. Furthermore, patients may still experience progressive functional decline and end-organ dysfunction during long-term inotropic support. Since elective VAD implantation is most successful when instituted prior to the onset of irreversible end-organ (e.g., liver or kidney) dysfunction, early referral and implantation of patients with accelerating heart failure symptoms despite medical therapy for evaluation is especially important.

SELECTION OF CHRONIC HEART FAILURE PATIENTS FOR LONG-TERM MCS

Cardiac

RV Function

Assessment of RV function is critical when considering MCS particularly in those who are being implanted with the intent of long-term support. An LVAD alone is preferred for long-term support and only LVADs are approved for DT, but it is not a viable strategy if the RV cannot adequately fill the LVAD [36]. RV function can be acutely affected by the primary etiology of the myopathy such as with ischemia in the presence of acute infarction, inflammation in the setting of myocarditis, or persistent ventricular arrhythmias. The RV can also become dysfunctional as a result of chronic elevations of LV filling pressures and/or mitral valve pathology, which results in pulmonary hypertension and thus increased RV afterload. Lastly, other processes that may exacerbate pulmonary hypertension, such as hypoxic lung disease, sleep apnea, chronic thromboembolic disease, or pulmonary vasculopathy, can also contribute to RV dysfunction. Chronic severe RV dysfunction with concomitant increases in right atrial pressures and tricuspid regurgitation further exacerbates liver and renal dysfunction, leads to gut edema with poor absorption of medications and nutrients, and results in hypotension and an inability to tolerate diuresis, beta-blockade, and ACE inhibition [49].

LV mechanical support is generally beneficial to RV function, with chronic unloading of the left ventricle resulting in a reduction in pulmonary pressures and thus, RV afterload. However there may be deleterious effects of an LVAD on RV function, particularly when RV function is marginal. Profound unloading of the LV, particularly with continuous flow devices, can result in shift of the septum away from the RV and thus decrease the septal contribution to RV output. The RV may also struggle to accommodate the increased venous return as a result of the improved cardiac output from the LVAD [50,51].

Echocardiography provides valuable information about overall RV size and function, the degree of tricuspid regurgitation and can give estimates of pulmonary arterial systolic pressures. However, functional assessments of RVEF are quite subjective and even a fairly normal appearing RV on echocardiography may have little functional reserve [52]. Invasive hemodynamic assessment with a pulmonary arterial catheter is therefore essential to decision making regarding the adequacy of RV function. The degree of elevation in the right atrial pressure (RA), especially in relation to the wedge (W) pressure can be quite revealing. One would expect high RA and W pressures in the setting of heart failure, but with a normally functioning RV, the RA pressures are relatively lower than the W and thus the RA/W ratio typically remains less than 0.5. With the onset of RV dysfunction, the RA pressures increase out of proportion to the left-sided pressures and the RA/W ratio increases. A high right atrial pressure in the setting of low pulmonary arterial pressures and low RV stroke work index are also concerning for the presence of severe RV failure [53].

Given the morbidity associated with RV failure post-LVAD, a number of investigators have sought risk factors for postimplantation RV dysfunction. Univariate predictors for RV failure include RV stroke work index, small BSA, and mechanical

ventilation [40,41]. Multivariate predictors include the need for preoperative circulatory support, female gender, and a nonischemic etiology of heart failure [40]. Researchers at the University of Michigan developed a risk score for RV failure based on vasopressor requirement, an AST ≥80 IU, total bilirubin ≥2 mg per dL, creatinine ≥2.3 mg per dL that is predictive of RV failure as well as overall survival [54]. However, there are many limitations to these studies including being based on single-center studies, small sample sizes, and are mostly based on prior generation pulsatile devices.

A recent study of 484 patients examined the predictors of RV dysfunction in patients receiving a current generation continuous flow device (HeartMate II) across multiple centers as a bridge to transplantation. Multivariate predictors of RV failure were preoperative ventilator support (OR 5.5), CVP/W > 0.63 (OR 2.3), and BUN > 39 (OR 2.1). Patients without RV failure also had significantly better survival at 6 months (89% vs. 67%, $p < 0.001$) and shorter lengths of stay (22 vs. 32 days, $p < 0.001$). This study, unlike other prior studies, also investigated the effects of intraoperative factors which might impact RV function. Those who required an RVAD required more units of packed red blood cells (14.3 vs. 5.6, $p < 0.03$) and had twice the incidence of reoperation for bleeding (40% vs. 19%, $p < 0.04$) [55].

Management of RV failure is similar to that of LV failure, decreasing excess preload, inotropy, and reducing afterload. RV preload should be reduced with aggressive diuresis and, if needed, mechanical volume removal if there is a renal limitation to diuresis. The dysfunctional RV may need slightly more preload to maintain output, but a goal should be to reduce the RA pressure to less than 13 mm Hg. Inotropy is often needed for LV support as well, but is often equally important to maintaining RV output [50]. Milrinone is typically the inotrope of choice for RV support in the setting of concomitant pulmonary hypertension due to its vasodilatory properties. Afterload is addressed through strategies to reduce elevated pulmonary pressures. Reducing the left sided filling pressures is the first and most important therapeutic targets and can be accomplished through a combination of diuresis, inotropy, IABP, and even a temporary LVAD. Patients must have adequate oxygenation to avoid hypoxic pulmonary vasoconstriction and if intubated positive end expiratory pressure should be minimized [56]. Nitric oxide may be considered in the intubated patient, but such patients may be too ill to consider LV support alone. There is little evidence for the use of other vasodilators such as prostaglandins and some evidence that such therapies may be deleterious in the setting of LV failure [57]. A summary of the management of RV function and the various organ systems discussed below is as seen in Table 45.2.

Arrhythmias

Ventricular tachyarrhythmias are reasonably common in the setting of acutely decompensated heart failure. Many patients with chronic heart failure will have a history of ventricular tachycardia or have an implantable cardioverter defibrillator (ICD) with or without resynchronization therapy [58]. Aside from their impact on the patient's stability in the acute phase of their presentation, the persistence of ventricular tachyarrhythmias has implications for outcomes on mechanical support. The presence of sustained ventricular tachycardia or ventricular fibrillation during LVAD support can substantially affect RV function, particularly in the setting of borderline RV function. Although ventricular tachyarrhythmias are not typically lethal in the setting of LVAD support alone, they will fairly routinely result in lower pump output, hypotension, and recurrent symptoms. For patients with an ICD they may also result in frequent ICD discharges. Preoperative ventricular tachyarrhythmias in the setting of substantially elevated filling pressures or acute ischemia often resolve after MCS as the heart failure state resolves. However, patients with persistent ventricular dysrhythmias despite reasonable filling pressures are at potentially higher risk of recurrence or persistence of these arrhythmias post-MCS and thus are more likely to need biventricular support.

Aortic Valve

The cardiac assessment of patients being considered for MCS should focus on other morphologic features of the heart other than the LV and RV function. The presence and quantification of AI is particularly important. Blood from the left ventricle empties into the device and is then pumped into the ascending aorta just distal to the aortic valve. The presence of significant AI will result in ineffectual forward flow as the blood that was pumped into the aorta is regurgitated back into the ventricle only to reenter the device, be pumped into the aorta, and regurgitate into the ventricle once again in a blind loop. Moderate or worse AI should prompt aortic valve repair, replacement with a tissue valve, or oversewing of the aortic valve. With adequate decompression by the LVAD, the left ventricle generates very little effective forward flow and hence rarely opens the aortic valve. In patients with mechanical aortic prostheses, this lack of flow across the valve may result in the formation of thrombosis and subsequent embolism [59]. Thus, mechanical aortic valves are either replaced with tissue valves at the time of surgery or are oversewn.

Other Cardiac Abnormalities

The presence of large atrial or ventricular septal defects should be ruled out as these will need to be addressed during the time of implantation. Mitral regurgitation essentially resolves post-MCS with adequate LV decompression, but significant mitral stenosis can impede LVAD filling and should be addressed at the time of implantation [60]. The degree of tricuspid regurgitation should be quantified as severe tricuspid regurgitation is a predictor of poor outcomes with LVAD alone [61]. LV thrombus can form in the setting of acute ischemia or with chronic LV dysfunction. Such thrombi are usually located in the LV apex, which is the site of cannulation for the LVAD. Although the ventricle is routinely inspected before insertion of the cannula, knowledge of the presence of thrombus preoperatively is nevertheless important as retained thrombus may systemically embolize or, more ominously, be sucked into the impeller of a continuous flow pump resulting pump dysfunction or failure. For patients with congenital heart disease it is important to establish the anatomical position of the systemic ventricle and aorta as well as the type and location of any previous corrective surgeries. Complex congenital heart disease may necessitate placement of the pump or inflow/outflow cannulae in atypical positions.

Noncardiac

Other chronic medical conditions, many of which are exacerbated by acute heart failure, should be optimized if possible prior to implantation of long-term MCS. Patients must be assessed for signs of infection and if found treated aggressively prior to implant. Active infection at the time of implantation can be catastrophic as septicemia can result in device infection which may be chronically suppressed but rarely cured with antibiotic therapy. If the pump or the pocket in which it sits becomes infected, the only recourse is urgent transplant, if indicated, as device exchanges in these situations often result in recurrent infection [62]. Renal dysfunction at the time of presentation is common from a variety of causes: poor renal perfusion, high right atrial pressures, preexisting renal dysfunction, high doses of diuretics, and the adverse neurohormonal milieu of heart failure. It is certainly advantageous if the

TABLE 45.2

ORGAN SYSTEM REVIEW OF CANDIDATES FOR MECHANICAL CIRCULATORY SUPPORT

Organ system	Review	Organ system	Review
LV dysfunction			
Preload	• Diuresis • Mechanical volume removal	Pulmonary disease	• Avoid hypoxia • Attempt to quantify extent/ severity of lung disease
Cardiac output	• Support with inotropy • IABP or temporary support as needed	Liver disease	• Occult liver disease in the presence of persistently high right atrial pressures • Ultrasound/CT scan to assess for cirrhosis
After load	• Treat hypertension, if present • IABP	Coagulation	• Stop any unneeded anticoagulants/antiplatelets • Review for history of hypercoagulable state
RV dysfunction	• Assess with invasive hemodynamics	Vascular disease	• Review history • Confirmatory ultrasound/CT scanning
Preload	• Diuresis • Mechanical volume removal	Nutrition	• Screen with prealbumin • Nutritional support
Inotropy	• Milrinone if concomitant pulmonary hypertension	Surgical	
Afterload	• Decreasing left-sided filling pressures • Milrinone • Avoiding hypoxia	Identify	• ASD/VSD • Number of prior sternotomies • Location and number of prior bypass grafts • Congenital abnormalities • Prior cardiac surgeries • Intracardiac thrombus • Mitral stenosis
Arrhythmias	• Rate control • Antiarrhythmics • Cardioversion if hemodynamically tenuous. • Persistent ventricular tachyarrhythmia despite adequate treatment of left heart failure may need consideration for BiVADs	Other limitations	
Aortic valve	• Assess for AI • Presence of mechanical valve?	Emotional	• Careful assessment and support
Noncardiac		Physical	• Ability to care for and utilize device
Infection	• Aggressive assessment and treatment	Cognitive	• Understanding device
Renal dysfunction	• Decrease high right atrial pressures • Inotropy or IABP • Avoid nephrotoxic agents, contrast	Social	• Support system available
		Financial	• Adequate resources as both inpatient and outpatient

patient can be stabilized with inotropy, IABP, or even temporary mechanical support to allow for renal recovery. Improvement of renal function is often seen with restoration of cardiac output and resolution of the heart failure state after MCS, but is not the rule, especially when the patients are implanted in the setting of significant renal dysfunction [63,64]. Renal failure requiring dialysis after MCS remains a highly morbid event, likely reflecting the level of illness entering the surgery as well as an additional, persistent nidus of infection due to the need for vascular access [65].

Intrinsic pulmonary disease also has a number of implications for long-term MCS. Advanced lung disease impacts mortality and morbidity from the implantation surgery itself as well as the ability to rehabilitate and post-operative functional status. Hypoxic pulmonary vasoconstriction from intrinsic lung disease may also exacerbate preexisting pulmonary hypertension. Severe chronic pulmonary disease with an FEV1 of less than 1 L is should raise concerns about a patient's suitability for MCS [60]. Intubation and mechanical ventilation prior to implantation is also a strong predictor of poor outcomes [38]. Hepatic dysfunction is occasionally a result of shock from acute decompensation, but chronic occult hepatic dysfunction is not uncommon with chronic heart failure, especially in the setting of poor RV function with persistently high right atrial pressures or those with Fontan circulation [60]. These patients may have significant hepatic dysfunction without substantial baseline abnormalities of AST, ALT, or total bilirubin. There should be a low threshold to screen such patients with ultrasonography or CT or even liver biopsy to assess hepatic architecture for signs of cirrhosis. If there is evidence of cirrhosis then early involvement of hepatologists is essential. Patients with marginal hepatic function frequently have massive transfusion requirements during implantation and not infrequently have acute hepatic failure postoperatively. Careful management of antiplatelet and anticoagulant therapy around the time of VAD implant may be critical to minimizing the risk of perioperative bleeding. Extensive carotid or peripheral vascular disease may increase the risk of extracardiac vascular events following MCS, and must be evaluated appropriately with preoperative noninvasive testing [60]. In patients who present acutely, nutrition is not often a pressing issue, but nutritional impairment in patients with chronic heart failure can be quite profound and low BMI is a risk factor for poor outcomes [66]. Poor nutrition impacts T-cell function and is another risk factor for infection and poor

wound healing postoperatively. For patients at nutritional risk supplemental feeding may be of some use, but should not delay implantation when MCS is indicated.

SURGICAL

Whenever patients are being considered for MCS the surgical team should be involved, not only to help assess a patient's suitability for support, but also allow them time to properly survey the patient for additional factors which may impact outcomes. The number of prior sternotomies will impact the ease of surgical approach, the operative time, the risk of postoperative bleeding, and perhaps even the overall candidacy for MCS. The presence and degree of AI, the presence of mechanical valves, the number and location of prior bypass grafts, the presence of intraventricular thrombus, and the details of congenital abnormalities and subsequent surgical corrections should be determined and communicated to the surgical team as previously noted. The details of past surgical ventricular reconstruction should be sought, as these surgeries usually involve the LV apex, the site of inflow cannulation for all long-term LVADs, and may present significant technical challenges.

OTHER CONSIDERATIONS

Aside from the many and varied medical and surgical considerations are emotional, physical, and social considerations. The acute nature of many patients' illness often precludes a detailed assessment of such issues, but for nonemergent situations addressing these issues prior to implantation is ideal. Physical limitations that may impact the patient's ability to care for the device such as the manual dexterity to change batteries or hear alarms are a critical part of such a review. Adequate cognitive ability is needed to understand the importance of the device and its components, the ability to troubleshoot problems, and recognize when to ask for assistance. The emotional wherewithal to adapt to the device, its implications, potential limitations, and adverse events is also important to maximizing long-term outcomes and quality of life. Lastly, patients must have an adequate social support network; although having an implanted VAD does not typically involve around the clock supervision, there must be a background of reliable support for assistance in an emergency and for long-term emotional support.

TIMING

When patients present to the intensive care unit with shock and are subsequently stabilized with aggressive medical therapy the decision to transition to MCS rests on the expectation of improvement in the patient's condition. For those who received an intervention, such as revascularization, waiting to see the impact of this intervention on the patient's clinical status is reasonable in the absence of further clinical deterioration. Many patients, however, will not have a readily identifiable or treatable proximate cause of their deterioration. For those who are eligible or are already listed for transplantation, the risk of continued medical therapy awaiting transplantation must be weighed against the risk of proceeding with MCS [67]. The advantages of waiting for transplantation in the setting of stable, yet critical illness are an increased likelihood of receiving an organ due to a higher status, avoiding a second surgery, and the potential morbidity and mortality of MCS itself. Disadvantages to delaying MCS include the high-risk nature of transplant during acute illness, further decompensation prior

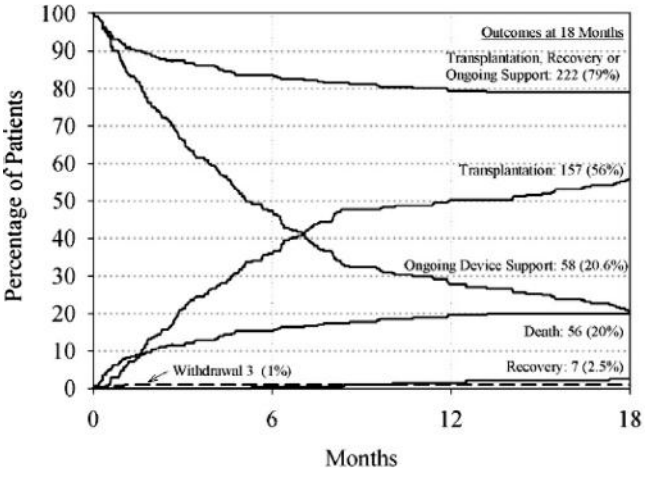

FIGURE 45.2. Competing outcomes analysis of patients with a continuous flow left ventricular assist device as a bridge to transplant. [From Pagani FD, Miller LW, Russell SD, et al: Extended mechanical circulatory support with a continuous-flow rotary left ventricular assist device. *J Am Coll Cardiol* 54:312–321, 2009, with permission.]

to transplant that may require a higher risk, emergent LVAD or biventricular support, becoming too ill for either transplant or mechanical support, or death. Proceeding with MCS early allows for surgery to be performed when the patient is less ill followed by a lower risk transplant once the patient is rehabilitated. Certain patients may be expected to have a short wait for transplantation based on their size, blood type, and level of sensitization and therefore the disadvantages of waiting for transplant may be minimized. Others may have clear indications for early MCS such as persistent pulmonary hypertension not responsive to medical therapy [68]. Unfortunately most patients do not have such a clear delineation of risk and determining the optimal timing of MCS can be quite difficult. However, there is an emerging evidence base that supports the earlier institution of MCS.

Prior reticence to institute MCS was based upon results using the prior generation of pulsatile LVADs with 6- and 12-month survival of approximately 75% and 60%, respectively. In contrast, the newer generation nonpulsatile pumps have 6- and 12-month survival of 82% and 73%, respectively [33] (Fig. 45.2). Furthermore, these devices are also associated with a much more favorable adverse event profiles and given their smaller size are applicable to almost the entire cohort of transplant eligible patients. When examining the survival of patients supported with MCS much of the mortality is early and attributable to patient selection, with the sickest patients preimplantation having the worst outcomes [36]. This has lead researchers to attempt to quantify this operative risk to improve patient selection.

Several risk prediction models are available for patients with chronic systolic heart failure. The Heart Failure Survival Score is comprised of clinical, laboratory data, and exercise data [69]. The Seattle Heart Failure Model incorporates a much wider array of clinical and laboratory variables and does not require an exercise test. However, these models were derived from a much less critically ill population and have not been validated in patients who are being considered for mechanical circulatory support [70]. Risk prediction models for patients undergoing LVAD exist, but are limited in that they describe risk attributable to device that is no longer used [71], are from a previous era of MCS support [72], or only examined patients implanted as destination therapy with a pulsatile device [73]. However, the factors associated with higher risk in these studies such as signs of RV failure, mechanical ventilation, infection,

TABLE 45.3

INTERMACS PROFILES

Profile	Description
1	Acutely decompensating
2	Failing inotropes
3	Inotrope dependent, stable
4	Recurrent, but not refractory advanced heart failure
5	Exertion intolerant, but no dyspnea at rest
6	Exertion limited, dyspnea with only mild activity
7	Advanced NYHA class III

NYHA, New York Heart Association.

and renal and hepatic dysfunction are also generally seen in patients who are more ill at the time of implantation.

The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) is large national registry of approved support devices that was recently established and has provided a means by which to risk assess patients undergoing MCS by their preimplant acuity of illness. INTERMACS has established seven different profiles for patients being implanted with MCS from advanced NYHA class III patients, through inotrope dependence, to acute shock despite maximal medical management (Table 45.3) [74]. Data from INTERMACS have shown that risk stratification based solely upon the preimplant profiles does indeed predict outcomes when applied to both pulsatile and continuous flow devices (Fig. 45.3) [33]. There is a substantial difference in survival at 1 year between even those who were profiles 1 and 2. A recent study of 101 patients who received current generation continuous flow devices stratified patients based on their preimplant INTERMACS category: group 1 was profile 1; group 2 was profiles 2 to 3; and group 3 was profiles 4 to 7. Survival at 18 months was 50% versus 73% versus 96% ($p < 0.01$) for groups 1, 2, and 3 respectively [75]. The implication for patients in the ICU who are stabilized and are being considered for long-term support is that there is an emerging consensus that earlier institution of mechanical support is preferable to waiting, as further decompensation will yield worse outcomes with both MCS and transplantation.

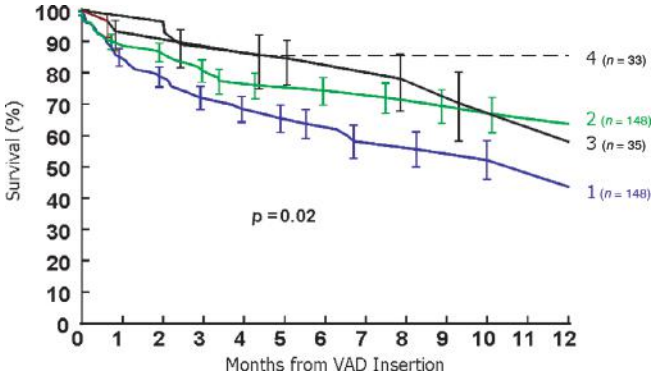

FIGURE 45.3. Survival after VAD stratified by INTERMACS profile. 1—Profile 1; 2—Profile 2; 3—Profile 3; 4—Profile 4. FUTURE DIRECTIONS

Mechanical circulatory support has evolved over the past 25 years from an investigational strategy reserved only for the moribund to a standard therapy supporting patients with stable advanced heart failure. Today, a wide variety of devices are available for short-term, medium-term, and long-term support at numerous centers worldwide.

A number of newer MCS devices are now in clinical use or clinical trials. Advances in pump technology are moving toward smaller pumps that still allow for full support, pumps that can be either implanted percutaneously or through minimally invasive surgeries, increased durability, totally implantable systems with transcutaneous energy transfer, and an improved device-patient interface. Research is also focused on improving biocompatibility, lowering risk of thrombosis, and better responsiveness to physiologic demands.

The role of MCS as an alternative to transplantation, that is, destination therapy, is likely to increase in the future. It is hoped that with advances in device design, patient selection, and medical management, MCS will be applicable to a greater proportion of patients with advanced heart failure, result in continued improvement in outcomes, and a reduction in adverse events and cost.

CHAPTER 46 ■ RESPIRATORY FAILURE PART I: A PHYSIOLOGIC APPROACH TO RESPIRATORY FAILURE

THADDEUS C. BARTTER, MELVIN R. PRATTER, WISSAM ABOUZGHEIB AND RICHARD S. IRWIN

OVERVIEW

Respiration serves to oxygenate blood and to remove the volatile waste product of metabolism, carbon dioxide and results in hypoxemia, hypercapnia, or both combined. Although it is traditional to define respiratory failure with abrupt boundaries [i.e., arterial carbon dioxide tension ($PaCO_2$) greater than 49 mm Hg or arterial oxygen tension (PaO_2) less than 50 to 60 mm Hg] [1,2], this is too simplistic for the understanding and management of respiratory insufficiency. This chapter discusses the physiologies leading to the different presentations of respiratory failure and briefly discusses management.

The alveolar PO_2 and PCO_2 are determined by the relationship between alveolar ventilation and perfusion ($\dot{V}/\dot{Q}$ ratio). The ratio of $\dot{V}$ to $\dot{Q}$ is approximately 0.8 under normal resting conditions. In $\dot{V}/\dot{Q}$ mismatch, the ratio is altered and the exchange of gaseous O_2 and CO_2 becomes inefficient. There are two $\dot{V}/\dot{Q}$ mismatch scenarios, termed "high $\dot{V}/\dot{Q}$ mismatch" and "low $\dot{V}/\dot{Q}$ mismatch." High-$\dot{V}/\dot{Q}$ mismatch occurs in a lung region that receives a disproportionate increase in ventilation or decrease in blood flow. Low $\dot{V}/\dot{Q}$ mismatch occurs in a lung region that receives a disproportionate decrease in ventilation or increase in blood flow. As will be seen, low $\dot{V}/\dot{Q}$ mismatch plays a major physiologic role in respiratory failure.

In many cases of respiratory failure, a low PaO_2 is coupled with an elevated $PaCO_2$, but the physiology of oxygenation is different from that of CO_2 removal. The differences stem in part from the differences in the capacity of blood to carry each of the two gases. Oxygen must bind to hemoglobin for effective transport. Saturated hemoglobin can carry 1.39 mL of O_2 per gram, whereas plasma can carry only 0.003 times the PaO_2; only approximately 1% of oxygen transport is independent of hemoglobin. The amount of O_2 that blood can carry is thus limited by hemoglobin concentration (and function). Once hemoglobin is saturated, a doubling of the alveolar oxygen concentration has no meaningful impact on oxygen transport. For this reason, alveoli with high $\dot{V}/\dot{Q}$ mismatch cannot add extra oxygen to the pulmonary capillary blood to compensate for alveoli with low $\dot{V}/\dot{Q}$ mismatch in which the hemoglobin of the associated pulmonary capillary blood is not fully saturated [3].

The biochemistry of CO_2 is very different. CO_2 diffuses readily into blood; its quantity increases almost linearly as the $PaCO_2$ increases. The mechanisms for CO_2 transport include a buffering system mediated by carbonic anhydrase and the formation of carbonyl compounds. The net result is that a doubling of alveolar ventilation essentially doubles CO_2 elimination. For this reason, unlike the physiology of O_2 transport, lung units with normal or high $\dot{V}/\dot{Q}$ relationships can compensate for areas with low $\dot{V}/\dot{Q}$ relationships. Because of these differences between the two gases, abnormalities in their values are not always linked, and it is useful to approach the factors that can cause each to be abnormal.

Normal Blood Gas Values

"Normal" PaO_2 can be shown to decrease with age and with the supine position [4]. There is significant standard deviation, and in clinical practice the normal range for most laboratories, 80 to 100 mg Hg, suffices.

In normal human homeostasis, the $PaCO_2$ is tightly regulated by respiration at or close to 40 mm Hg. Unlike the PaO_2, the normal $PaCO_2$ remains at 40 mm Hg throughout life. It is unaffected by age [4] or position [5].

The normal pH of human arterial blood is at or close to 7.40. Like the $PaCO_2$, there is no predicted change with age.

HYPOXEMIA AND HYPERCAPNIA

There are six basic pathophysiologic mechanisms that can lead to hypoxemia. Some also cause hypercapnia [1,6,7]:

1. Low partial pressure of inspired O_2 (PIO_2)
2. Diffusion impairment
3. Right-to-left shunt
4. Low $\dot{V}/\dot{Q}$ mismatch
5. Hypoventilation
6. High partial pressure of inspired CO_2

Only three are clinically important: low $\dot{V}/\dot{Q}$ mismatch, right-to-left shunt, and hypoventilation. $\dot{V}/\dot{Q}$ mismatch and hypoventilation can cause both hypoxemia and hypercapnia.

Low Partial Pressure of Inspired Oxygen

Low PIO_2 is a potential cause of hypoxemia. A low PIO_2 occurs only at high altitudes and in conditions when other gases are present; it is not in the differential diagnosis of normal clinical management.

Diffusion Impairment

It was once thought that thickening of alveolar walls could lead to an increase in the diffusion distance great enough to prevent equilibrium of the partial pressure of oxygen between the alveoli and the associated pulmonary capillary blood. This

physiologic concept is known as "alveolar–capillary block syndrome," [8]. Subsequent data, however, indicated that even radiographically "homogeneous" pulmonary disease rarely alters alveolar–capillary membranes uniformly throughout the lung. In addition, the efficiency of gas exchange within any single alveolus is such that even with a barrier to diffusion, diffusion impairment is not a factor; by the time blood leaves the alveolar capillaries, alveolar and capillary gas partial pressures are equal. Thus, hypoxemia at rest in patients with pathologies such as interstitial disease is due not to "alveolar–capillary block" but rather to areas of low $\dot{V}/\dot{Q}$ mismatch. In contrast, there may be a component of "alveolar–capillary block" in exercise; as the transit time of blood through alveolar capillaries decreases, there may be some true physiologic impairment of capillary/alveolar gas equilibrium that could result in hypoxemia [9].

Right-to-Left Shunt

In right-to-left shunt, blood from the right heart does not come into contact with oxygenated air before reaching the left heart; ventilation and perfusion are uncoupled [5]. Three kinds of shunt are recognized: cardiac, pulmonary vascular, and pulmonary parenchymal [10]. In a cardiac shunt, a defect allows blood to pass directly from the right atrium or ventricle into the left-sided chamber. For cardiac shunt to occur, there must be some relative increase in right-sided pressures. In a pulmonary vascular shunt, the shunting of blood occurs through arteriovenous malformations within the pulmonary vascular bed. These arteriovenous malformations can be small and not visible on chest imaging (as in some cases of cirrhosis), or large and visible as parenchymal densities (as with hereditary hemorrhagic telangiectasia) [11]. In pulmonary parenchymal shunt, alveolar consolidation or atelectasis prevents gases from reaching alveoli while blood flow continues through their capillary beds. Examples of conditions that cause parenchymal shunt are pneumonia, lobar collapse, and acute respiratory distress syndrome.

Note that right-to-left shunt is listed as a cause of hypoxemia but not of hypercapnia because of the capacity of alveoli with normal or high $\dot{V}/\dot{Q}$ ratios to compensate for the lack of clearance of CO_2 from shunted blood [6]. If the only gas exchange defect present is shunt, increased ventilation to the perfused alveoli leads to a normal $PaCO_2$ [6]. This increased ventilation has no effect on the PaO_2; as already noted, the dependency on hemoglobin for blood to carry oxygen results in an inability of areas with normal or elevated $\dot{V}/\dot{Q}$ ratios to compensate for areas with low $\dot{V}/\dot{Q}$ ratios. Thus, shunt is a cause of nonhypercapnic hypoxemic respiratory failure.

$\dot{V}/\dot{Q}$ Mismatch

Low $\dot{V}/\dot{Q}$ mismatch is the dominant physiology in abnormalities of gas exchange. Mild to moderate degrees of low $\dot{V}/\dot{Q}$ mismatch can cause hypoxemia alone, whereas more severe $\dot{V}/\dot{Q}$ mismatching leads to hypoxemia with hypercapnia. (For a patient breathing room air, $\dot{V}/\dot{Q}$ mismatch never causes hypercapnia in the absence of hypoxemia.) There are two reasons why a substantially greater amount of low $\dot{V}/\dot{Q}$ mismatch must be present to cause hypercapnia than to cause hypoxemia. The first reason is the higher solubility of CO_2 in blood as discussed earlier [6]; there is no saturation limit for CO_2. Thus while normal alveoli cannot increase oxygen uptake significantly after hemoglobin saturation, they can increase CO_2 removal as venous CO_2 content rises. The second reason is that, just as with shunt, patients with low $\dot{V}/\dot{Q}$ mismatch increase their minute ventilation to compensate for the potential elevation in CO_2 that the low $\dot{V}/\dot{Q}$ areas would otherwise generate [6]. With severe $\dot{V}/\dot{Q}$ mismatch, there are not enough normal and high $\dot{V}/\dot{Q}$ alveoli to compensate for the hypercarbia of those with low $\dot{V}/\dot{Q}$ mismatch; hypercapnia occurs in addition to hypoxemia.

Hypoventilation

Hypoventilation refers to conditions in which minute ventilation is reduced relative to the metabolic demand present for oxygen uptake and CO_2 production. By necessity, when minute ventilation is reduced alveolar ventilation must also be abnormally low, resulting in decreased gas exchange between the external environment and the alveoli [6]. Hypoventilation by definition causes both arterial hypoxemia and a raised arterial PCO_2. Some physicians use the terms "hypoventilation" and "carbon dioxide retention" interchangeably, a usage that confuses physiologies. Pure hypoventilation represents decreased minute ventilation with normal lungs. In contrast, other conditions that cause carbon dioxide retention (low $\dot{V}/\dot{Q}$ mismatch) are caused by airway or parenchymal lung disease and usually are associated with increased minute ventilation.

In hypoventilation as defined earlier, the alveolar PCO_2 can rise to the point that the partial pressure of O_2 is significantly reduced. The disorders that cause hypoventilation are called the *extrapulmonary* causes of respiratory failure because they do not involve abnormality of the pulmonary gas exchange mechanisms [7,12,13]. A defect leading to hypoventilation can occur anywhere in the normal physiologic linkages that affect minute ventilation; the differential diagnosis of extrapulmonary respiratory failure is listed in Table 46.1. Note that in this categorization, obstruction at or above the trachea and other large airways is classified as an extrapulmonary disorder because of the fact that the gas exchange mechanisms of the lung remain intact.

High Partial Pressure of Inspired Carbon Dioxide

The inhalation of a gas containing CO_2 can cause hypercapnia although it is not usually part of the differential diagnosis in clinical medicine. It does occur occasionally in iatrogenic situations; patients on a t-piece with extended tubing attached to the expiratory port may be forced to re-breathe exhaled CO_2 to the point of hypercapnia.

TABLE 46.1

DIFFERENTIAL DIAGNOSIS OF EXTRAPULMONARY RESPIRATORY FAILURE[a]

Site of abnormality	Disease
Central nervous system	Respiratory center depression owing to overdose, primary alveolar hypoventilation, myxedema
Peripheral nervous system	Spinal cord disease, amyotrophic lateral sclerosis, Guillain–Barré syndrome
Respiratory muscles	Muscle fatigue, myasthenia gravis, polymyositis, hypophosphatemia
Chest wall	Ankylosing spondylitis, flail chest, thoracoplasty
Pleura	Restrictive pleuritis
Upper airway obstruction	Tracheal stenosis, vocal cord tumor

[a]This table is not an exhaustive listing; it includes the more common causes for each involved compartment of the respiratory system.

Overlapping Factors

Several comments are in order. First, more than one mechanism may be operant in any individual case. For example, a high ventilatory requirement needed to compensate for areas of low $\dot{V}/\dot{Q}$ mismatch in a patient with chronic obstructive pulmonary disease may lead to muscle overload with fatigue and therefore add an extrapulmonary etiology of hypercapnia to primary pulmonary disease. Another common coupling would be the coexistence of $\dot{V}/\dot{Q}$ mismatch and pulmonary parenchymal shunt in a patient with pneumonia and underlying chronic obstructive pulmonary disease (COPD).

Second, a decrease in cardiac output may worsen hypoxemia primarily due to marked $\dot{V}/\dot{Q}$ abnormalities, a large right-to-left shunt, or both. A decrease in cardiac output forces a compensatory increase in oxygen extraction at the tissue level, leading to a decreased mixed-venous oxygen content. Isolated reduction in the mixed-venous oxygen content is not a cause of hypoxemia, but it can exacerbate the hypoxemia generated by any of the primary mechanisms described above.

Third, as mentioned, shunt alone is not a cause of hypercapnia, but if a significant shunt is present in conjunction with one of the primary causes of hypercapnia, then the capacity to compensate for the shunt is reduced and hypercapnia is worsened.

Finally, the $PaCO_2$ represents a balance between CO_2 production and CO_2 clearance; in patients with an impaired capacity to clear CO_2, increases in production may gain clinical relevance [14]. Fever increases CO_2 production by 13% for each 1°C temperature elevation above normal. Thus, lowering temperature to normal may have an impact on $PaCO_2$ in a febrile patient with a large amount of $\dot{V}/\dot{Q}$ mismatch. Nutritional support with excessive total calories or proportionally high-carbohydrate loads also increases CO_2 production [15]. It follows that decreasing total caloric load may influence the degree of hypercapnia in patients with limited ventilatory reserve.

ANALYTICAL TOOLS FOR HYPOXEMIA AND HYPERCAPNIA

Several tools can be used to categorize type and severity of the different causes of hypercapnia and hypoxemia. Simple calculation, maneuvers, and tests can give the clinician a better understanding of the underlying physiology.

Calculation of Alveolar–Arterial PO_2 Gradient and PaO_2/FIO_2 Ratio

The A–a PO_2 gradient, although a conceptual simplification, is clinically useful. It allows separation of extrapulmonary from pulmonary causes of respiratory failure [16,17]. It presents a mathematical model as though the lung were one large alveolus and the entire blood flow of the right heart passed around that alveolus. Rules of partial pressure and the respiratory exchange ratio, R, are used to calculate the theoretical alveolar PO_2 (PAO_2). The PIO_2 is reduced first by water pressure in the airways and then at the alveolar level by the alveolar $PaCO_2$. Exchange of oxygen and CO_2 at the alveolar level is reflected in the respiratory exchange ratio, R. This is the basis for the alveolar air equation [18],

$$PAO_2 = PIO_2 - PaCO_2/R$$

Ambient air at sea level has a total pressure of 760 mm Hg, 21% of which is oxygen. As air is inhaled it is humidified by water vapor, which has a partial pressure of approximately 47 at normal body temperature. The partial pressure of O_2 after inhaled air is humidified is therefore 0.21 (760 − 47), or 150. In a steady state, *R* can be assumed to be 0.8, even in patients with significant lung disease [18]. Given the previous assumptions and a normal $PaCO_2$ of 40 mm Hg, one gets an idealized PAO_2 of 100:

$$PAO_2 = 150 - 40/0.8 = 100$$

The A–a gradient is then obtained by subtracting the measured arterial PO_2 from the calculated PAO_2. $PCO_2/0.8$ is the same as the $PCO_2 \times 1.25$. Thus, for a person breathing room air at sea level,

$$\text{A–a gradient is equal to} = 150 - (1.25 \times PaCO_2) - PaO_2$$

In reality, the lung is not a single large alveolus, and there is not an oxygen gradient between the alveolus and the capillary. The calculated "gradient" represents a mixture of blood from alveoli with ideal characteristics with blood from alveoli that have low $\dot{V}/\dot{Q}$ mismatch and with shunted blood. The greater the contribution from alveoli with low $\dot{V}/\dot{Q}$ mismatch and from shunt, the greater the A–a "gradient."

One value of the concept of the A–a gradient is that it can be used to separate the extrapulmonary causes of respiratory failure from those that involve parenchymal lung disease [12] as long as the patient is breathing room air. With extrapulmonary failure, the A–a gradient remains normal. With shunt or $\dot{V}/\dot{Q}$ mismatch, the gradient is usually elevated. $\dot{V}/\dot{Q}$ mismatch and extrapulmonary respiratory failure are the two causes of hypercapnia encountered in clinical practice, and the A–a gradient is a useful tool for distinguishing between them. Gray and Blalock have noted that the A–a gradient is an imperfect tool; with very high $PaCO_2$, the gradient can narrow [19]. This is rarely an issue in clinical management. At any age, an A–a gradient exceeding 20 mm Hg on room air should be considered abnormal and indicative of pulmonary dysfunction [16].

When the FIO_2 is above 0.21, the A–a gradient becomes a less accurate measure of the efficiency of gas exchange and therefore a less valuable tool for the measurement of shunt, $\dot{V}/\dot{Q}$ mismatch, or the lack thereof. The PaO_2 divided by the FIO_2 (PaO_2/FIO_2 ratio) can be used to assess the severity of the gas exchange defect. For calculation, the FIO_2 is expressed as a decimal ranging from 0.21 to 1.00. The normal PaO_2/FIO_2 is 300 to 500. A value of <300 is indicative of gas exchange derangement and a value below 200 is indicative of severe impairment. Although the PaO_2/FIO_2 is felt to be a more reliable measure of degree of gas exchange impairment at higher FIO_2s, it too has the potential to be unreliable, particularly in the presence of a large shunt or a low FIO_2 [20–22].

100% Oxygen Inhalation Challenge

A trial of 100% oxygen inhalation can be used to separate low $\dot{V}/\dot{Q}$ mismatch from shunt as the cause of respiratory failure. In areas of low $\dot{V}/\dot{Q}$ mismatch, the alveolar PO_2 is low. If 100% oxygen is delivered via a closed system, even a poorly ventilated alveolus in theory soon contains 100% oxygen diluted only by the partial pressures of water and CO_2 [1]. Thus, with low $\dot{V}/\dot{Q}$ mismatch, the PaO_2 rises dramatically if the FIO_2 is increased. In contrast, areas of shunt are never exposed to O_2, and there is no response to an increase in FIO_2. If the PaO_2 with the patient breathing 100% O_2 is greater than 500 mm Hg, then prior hypoxemia is largely due to $\dot{V}/\dot{Q}$ mismatch [1]. If the PO_2 on 100% O_2 is less than 350 mm Hg, then major shunting is present.

Nuclear Scanning and Echocardiography

Nuclear scanning and echocardiography can be used to determine the etiology of a shunt. As previously stated, a right-to-left shunt can be pulmonary parenchymal, pulmonary vascular, or intracardiac. Nuclear perfusion scanning for evaluation of

shunt takes advantage of the fact that the technetium-labeled macroaggregated albumin used for the scan is a relatively large particle that does not pass through capillaries. This characteristic can help to separate shunt with normal vasculature from shunt due to abnormal vascular connections. If vascular anatomy is normal (and shunt is produced by blood flow through normal capillaries traversing consolidated lung), the technetium-labeled molecules of the nuclear scan are filtered by the pulmonary capillaries and remain in the lung. In contrast, with abnormal connection(s) between the right and left heart vasculatures, significant amounts of technetium-labeled particles bypass pulmonary capillaries and are then filtered by systemic capillaries (e.g. brain and kidneys). Thus, a nuclear scan obtained to classify and quantify shunt shows immediate renal and cerebral uptake if the shunt is cardiac or pulmonary vascular and only pulmonary uptake if the shunt is of pulmonary parenchymal origin [10]. If the shunt is not pulmonary parenchymal, the final step to differentiate intracardiac from pulmonary parenchymal is contrast echocardiography. Contrast echocardiography can document right-to-left cardiac shunting if present [17,23,24]; immediate transit (within four cardiac cycles) to the left heart can be seen with intracardiac shunt. If there is no cardiac shunt or if contrast appears after five cardiac cycles, then the abnormal vascular connection is in the pulmonary circulation.

RESPIRATORY ACID–BASE DISORDERS

Acid–base analysis can be used to understand the nature and acuity of a respiratory disturbance, both essential for clinical management. Relationships between $PaCO_2$, pH, and bicarbonate concentration (HCO_3^-) can be used first to determine whether there is a primary respiratory or metabolic process, whether it is simple (one acid–base disturbance) or complicated (more than one), and whether it is acute or chronic [25]. A respiratory disturbance is defined by a primary change in $PaCO_2$, whereas a metabolic disorder involves a primary change in the HCO_3^- (see Chapter 72). An acute process is one occurring in minutes to hours, whereas a chronic process has persisted for several days or longer. This chapter concentrates on acute and chronic simple respiratory disorders.

Acid–base balance is assessed clinically from the arterial hydrogen ion (H^+) concentration and may be expressed either in nanoequivalents per liter or as the negative logarithm of that number, pH_a. H^+ concentration can be assessed with knowledge of the concentration of any of many potential hydrogen donors and the dissociation constant for that donor. The mass action equation that demonstrates the capacity of CO_2 to act as an acid ($CO_2 + H_2O \Leftrightarrow H_2CO_3 \Leftrightarrow H^+ + HCO_3^-$), is of clinical relevance and also convenient, given that $PaCO_2$ and HCO_3^- are easily measured. An increase in CO_2 drives the equation to the right, increasing H^+ concentration. An increase in HCO_3^- drives the equation to the left, decreasing the H^+ concentration. The Henderson version of the Henderson–Hasselbalch equation [3], $H^+ = 24\ (PaCO_2/HCO_3^-)$, calculates actual H^+ concentration using those measurements. Clinically, all acid–base disorders can be evaluated using this basic equation [4].

Calculation of H^+ Concentration

In clinical practice, the pH is the value reported, but knowledge of the H^+ concentration can often facilitate the diagnosis of respiratory acid–base disturbances. The relationship between H^+ and pH and how to predict H^+ from pH, essential to the following discussion, is covered in Chapter 11.

TABLE 46.2

THE DIFFERENTIAL DIAGNOSIS OF HYPERCAPNIA

Low $\dot{V}/\dot{Q}$ mismatch COPD	Extrapulmonary respiratory failure (see Table 46.1) Obesity/hypoventilation syndrome Rebreathing CO_2

$\Delta H^+/\Delta PCO_2$ Ratio

Ability to calculate the H^+ concentration allows calculation of the $\Delta H^+/\Delta PCO_2$ ratio that is of value in understanding respiratory acid-base disorders. The $\Delta H^+/\Delta PCO_2$ is calculated as the change in H^+ from baseline (baseline assumed usually to be 40 nanoequivalents per liter that corresponds to a pH of 7.40) divided by the change in $PaCO_2$ from baseline (baseline again 40). For example, for the theoretical blood gas (pH, $PaCO_2$, PaO_2), 7.32/50/60, the change in PCO_2 is 10 and the change in H^+ concentration is 8 (48 − 40); the ratio is therefore 0.8.

An acute change of PCO_2 in either direction causes an immediate and predictable change in H^+ and thus a predictable $\Delta H^+/\Delta PCO_2$ [25,26]. If a respiratory alteration persists, however, renal mechanisms increase or decrease serum HCO_3^- in a direction that pushes the H^+ back toward normal; maintenance of H^+ homeostasis is a primal physiologic function. Thus, after renal compensation occurs, the $\Delta H^+/\Delta PCO_2$ ratio is altered. This alteration represents the chronic state.

Respiratory Acidosis/Respiratory Alkalosis

Respiratory acidosis is defined as an acidosis associated with and caused by an elevation of the $PaCO_2$. By definition therefore, respiratory acidosis is a product of hypercapnia (See Table 46.2). Knowledge of the H^+ concentration in addition to the $PaCO_2$, however, allows for calculation of the $\Delta H^+/\Delta PCO_2$ ratio. A ratio of 0.8 (as in the earlier example) implies an acute respiratory acidosis [26]. A ratio of 0.3 implies a chronic (and compensated) respiratory acidosis [26]. Values for the $\Delta H^+/\Delta PCO_2$ ratio between 0.3 and 0.8 correspond to an acute-on-chronic respiratory acidosis (as often occurs with an exacerbation of chronic obstructive pulmonary disease) [26].

Respiratory alkalosis is defined as an alkalosis caused by a decrease in $PaCO_2$ that drives the CO_2 in the mass action equation to the left: H^+ and HCO_3^- concentrations decrease. The differential diagnosis for respiratory alkalosis is listed in Table 46.3. When the $\Delta H^+/\Delta PCO_2$ ratio is used to analyze a pure respiratory alkalosis, a ratio of 0.8 corresponds to an acute respiratory alkalosis and a ratio of 0.17 corresponds to a chronic respiratory alkalosis [26].

CLINICAL APPROACH TO RESPIRATORY FAILURE

Respiratory failure occurs when gas exchange becomes significantly impaired. It is impossible to accurately predict PaO_2 and $PaCO_2$ using clinical criteria [27,28]; the diagnosis of respiratory failure depends on arterial blood gas (ABG) analysis. Various clinical signs and symptoms, including those reflecting the effects of hypoxemia or hypercapnia, or both, on the

TABLE 46.3

CAUSES OF RESPIRATORY ALKALOSIS[a]

Elevated A–a gradient	Normal A–a gradient
Sepsis and capillary leak syndrome	Central nervous system disorder
Hepatic failure with hepatopulmonary syndrome	Hepatic failure with normal lungs
Chronic interstitial lung diseases	Analeptic overdose drugs
Pulmonary edema	Salicylates
Cardiogenic	Catecholamines
Noncardiogenic (acute respiratory distress syndrome)	Progesterone
Pulmonary embolism	Thyroid hormone excess
Pneumonia	Pregnancy
Asthma	High altitude
Right-to-left shunt	Severe anemia (approximately 3 g/dL hemoglobin)
	Psychogenic hyperventilation
	Endotoxemia
	Mechanical hyperventilation with normal lungs
	During menses after ovulation

$P(A–a)O_2$, alveolar–arterial oxygen tension gradient.
[a]The differential diagnosis of respiratory alkalosis with an elevated $P(A–a)O_2$ gradient is the same as that of nonhypercapnic, hypoxemic respiratory failure.

central nervous system and cardiovascular system, may lead to suspicion of the diagnosis, but the ABG must be obtained for confirmation. A clinical approach to respiratory failure begins with analysis of the ABG for the severity, type, and acuity of the gas exchange disturbance. These factors and the expected duration of the process guide interventions.

Acute hypercapnia should be evaluated for reversible causes. If none is found, mechanical ventilatory support, invasive or noninvasive, is needed. This can take the form of intubation, but other options such as continuous positive airway pressure and noninvasive positive-pressure ventilation now have a documented role in the management of acute respiratory compromise [29]. Hypercapnia with a $\Delta H^+/\Delta PCO_2$ ratio of 0.3, indicating chronicity, uncommonly requires urgent ventilatory support.

CLINICAL EXAMPLES

Scenario 1

A 29-year-old man is brought to the emergency department in a stuporous state. ABGs drawn on room air at the time of arrival demonstrate a PaO_2 of 52, $PaCO_2$ of 68, and pH of 7.21. On calculation, the A–a gradient is 13 and the $\Delta H^+/\Delta PCO_2$ ratio is 0.8. You therefore know that you are dealing with an acute respiratory acidosis of extrapulmonary origin. The narcotic antagonist naloxone is administered, and the patient wakes up, with normalization of blood gases.

Scenario 2

The same patient, given naloxone and flumazenil, has no change in blood gases or mental status. Your differential diagnosis is now acute extrapulmonary respiratory failure other than narcotic or benzodiazepine respiratory suppression. You intubate and start mechanical ventilation.

Scenario 3

The patient arrives with a PaO_2 of 42, $PaCO_2$ of 68, and pH of 7.21. Calculation of the A–a gradient yields a value of 23. You administer naloxone and the patient does awaken, but he remains hypoxemic. This was anticipated owing to the elevated A–a gradient; you evaluate for an additional process such as aspiration of gastric contents.

In an acute-on-chronic situation, the trend of the acidosis is most crucial in deciding whether mechanical ventilatory support is necessary [7]. Although these ratios are strictly correct only for simple respiratory acid–base disturbances, the authors believe they should be applied therapeutically even in a complicated disturbance. If the ratio is consistent with an acute respiratory acidosis, the patient who fails to improve with treatment should receive ventilatory support (see Chapters 58, 59).

Fear of causing greater hypercapnia should not be a deterrent to the use of supplemental oxygen in an acutely ill hypoxemic patient. Although $PaCO_2$ predictably increases with the use of supplemental oxygen in patients with hypercapnia due to $\dot{V}/\dot{Q}$ mismatch, CO_2 narcosis is very uncommon. It does, however, make sense to start supplemental oxygen at a low concentration and then to slowly increase the FIO_2 until adequate oxygenation is achieved. The uncommon case of resultant severe hypercapnia can be treated with mechanical ventilatory support.

Respiratory alkalosis is not itself a cause of respiratory failure unless the increased work of breathing cannot be sustained by the respiratory muscles. Management therefore depends on diagnosis of the underlying stimulus for hyperventilation and on treatment specific to that condition (e.g., heparin for pulmonary embolism). When respiratory alkalosis continues to worsen in critically ill patients on mechanical ventilatory support, however, it may become necessary to treat the respiratory alkalosis directly. In such a setting, sedation with or without paralysis of skeletal muscles can be useful.

Hypoxemia that responds only minimally to large increases in FIO_2 involves significant shunt. (In many clinical situations, such as chronic obstructive pulmonary disease with pneumonia, the physiology involves a coupling of shunt and $\dot{V}/\dot{Q}$ mismatch.) Cardiac shunt or large pulmonary arteriovenous shunts may require an invasive intervention to correct them. Diffuse pulmonary parenchymal shunt, as can occur in acute respiratory distress syndrome, may be amenable to positive end-expiratory pressure.

Noninvasive ventilation has been studied extensively. In clinical scenarios in which reversal or amelioration of the underlying process may be possible within the short term, noninvasive ventilation may provide a therapeutic bridge that allows avoidance of the possible disadvantages of intubation and mechanical ventilation [29].

CONCLUSION

The basic physiologic mechanisms underlying all abnormalities of gas exchange have been delineated. Of these, the most clinically relevant are low $\dot{V}/\dot{Q}$ mismatch, hypoventilation, and shunt. A series of tools that can be used to analyze and differentiate these physiologic possibilities has been presented along with an analysis of how $H^+/PaCO_2$ relationships can help to define the acuity of a disorder. Analysis of the type and acuity of a process should lead to an attempt to define the responsible disease process(es) and to intervene specifically. The decision of when or whether to institute mechanical ventilatory support, especially with intubation, is not always clear from numbers alone; this decision involves the art as well as the science of medicine.

CHAPTER 47 ■ RESPIRATORY FAILURE PART II: ACUTE RESPIRATORY DISTRESS SYNDROME

GILMAN B. ALLEN AND POLLY E. PARSONS

INTRODUCTION

Acute lung injury (ALI) and the acute respiratory distress syndrome (ARDS) represent a continuum of severity for the same pathologic condition, both being defined by noncardiogenic pulmonary edema and hypoxemia in the setting of direct or indirect lung injury. Because ARDS, by definition, simply represents a more severely advanced form of ALI, the term "ALI" can be used as a comprehensive term for both conditions. ALI represents a common pathologic endpoint of various potential insults to the lung that almost invariably lead to hypoxemic respiratory failure requiring support with mechanical ventilation. Despite the confirmed success of protective mechanical ventilation strategies in lowering mortality [1,2] and ongoing efforts to discover other effective interventions [3–6], treatment of this condition remains largely supportive, and ALI continues to be a major source of morbidity and mortality in the intensive care unit [7,8]. Fortunately, an enormous body of research already exists on the pathogenesis of this condition, and advances continue to develop with regard to our understanding of ALI, its prognostic implications, and how to best manage the condition medically.

DEFINITION

ALI is defined as a diminished arterial oxygen pressure (PaO_2) to fractional inspired oxygen (FiO_2) ratio (P to F (P:F) ratio less than 300), bilateral airspace disease on chest radiograph, and pulmonary edema from increased permeability, the latter defined by evidence of normal cardiac function [9]. ARDS is simply a subset of ALI having a more severely diminished P:F ratio (less than 200). However, because the P:F ratio can be affected by arbitrary ventilator settings [10], and because many

TABLE 47.1

RECOMMENDED CRITERIA FOR ACUTE LUNG INJURY (ALI) AND ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS)

	Timing	Oxygenation	Chest radiograph	Pulmonary artery wedge pressure
ALI Criteria	Acute onest	PaO_2/FiO_2 ≤300 mm Hg (regardless of PEEP)	Bilateral infiltrates seen on frontal chest radiograph	≤18 mm Hg when measured OR no clinical evidence of left atrial hypertension
ARDS Criteria	Acute onset	PaO_2/FiO_2 ≤200 mm Hg (regardless of PEEP)	Bilateral infiltrates seen on frontal chest radiograph	≤18 mm Hg when measured OR no clinical evidence of left atrial hypertension

From Bernard GR, Artigas A, Brigham KL, et al: The American-European Consensus Conference on ARDS. Definitions, mechanisms, relevant outcomes, and clinical trial coordination. *Am J Respir Crit Care Med* 149:818–824, 1994.

studies have shown that indices of oxygenation are not strongly predictive of outcome [11–13], this differentiation may be of limited clinical relevance. Furthermore, the definition of ALI and ARDS has undergone significant evolution over the years, and limitations of this definition still exist [14], which can confound the interpretation of older research results and contribute added challenges to the design of new studies.

In response to the recognized limitations in determining the incidence and outcomes of ALI, a committee of leading investigators in the field met in 1994 to develop a consensus between the American Thoracic Society and the European Society of Intensive Care Medicine. The most current definition of ALI derives from this consensus [9] and defines the condition as the acute onset of hypoxemia and noncardiogenic pulmonary edema (see Table 47.1). Although the source of hypoxemia in ALI is multifactorial, it is one of the most easily gauged markers of "lung injury" in the intensive care unit and thus an important component of the definition. Despite its limited prognostic value, the more inclusive P:F ratio of less than 300 can serve to identify patients earlier in their course [11], thus expediting delivery of critical life saving interventions before progression to ARDS. In ALI, the pulmonary edema is the result of capillary leak, a parameter that is difficult to measure in the clinical setting. Accordingly, noncardiogenic pulmonary edema is defined using clinical parameters, which include the presence of "bilateral infiltrates" consistent with pulmonary edema on chest radiograph and either a pulmonary artery wedge pressure (PAWP) less than 18 mm Hg (when measured) or no clinical evidence of left atrial hypertension [9]. However, because the group recognized that ALI does not always exist exclusively without heart failure, the consensus more explicitly defines ALI as "a syndrome of inflammation and increased permeability that is associated with a constellation of clinical, radiologic, and physiologic abnormalities that cannot be explained by, but may coexist with, left atrial or pulmonary capillary hypertension"[9].

Despite the great lengths taken to clarify the current definition of ALI, it is not without its shortcomings, particularly because it does not delineate the cause of hypoxemia (i.e., alveolar damage) or clearly establish the presence of increased permeability [14]. Unfortunately, easily employed tests for microvascular permeability are not yet available, and what degree of permeability is needed to reliably predict the presence of alveolar damage is not known [14]. The boundaries for the P:F ratio are also arbitrary. The consensus committee recognized the difficulty in interpreting this ratio in the setting of different levels of positive end-expiratory pressure (PEEP) [15], and thus decided to not include this parameter in their definition. It would also be impractical to base the clinical definition of ALI upon histologic findings given the often critical condition of patients and their poor candidacy for biopsy by the time of clinical diagnosis. Nevertheless, the histopathology of ALI has been well characterized and is, in many ways, descriptive of its pathogenesis.

HISTOPATHOLOGY

Despite having many different potential etiologies [16–18], the histologic findings of ALI are fundamentally uniform and are collectively described by the term, *diffuse alveolar damage* (DAD) [19]. DAD represents a continuum of changes that can be temporally divided into *exudative*, *proliferative*, and *fibrotic* phases [19,20], between which considerable overlap exists. The *exudative* phase of DAD is the earliest phase, during which clinical symptoms first develop and lung mechanical changes become manifest [21]. This phase typically occupies the first week and is characterized by epithelial and endothelial cell death, neutrophil sequestration, platelet–fibrin thrombi, interstitial edema, and exudates within the airspaces, which consist of fluid, protein, and cellular debris [19]. These exudates compact into dense, protein-rich hyaline membranes that stain strongly with eosin and line the alveoli and alveolar ducts (Fig. 47.1A). During the second week of injury, the *proliferative* phase ensues, which is characterized by organization of the intra-alveolar exudates and proliferation of type II alveolar cells, fibroblasts, and myofibroblasts. During this phase, it is common to find areas of squamous metaplasia and granulation tissue occluding alveolar ducts in a manner similar to that of organizing pneumonia (Fig. 47.1B) [22].

The *fibrotic* phase has classically been considered the later phase of remodeling that occurs in patients who survive past 3 or 4 weeks [19]. However, studies suggest an increase in the *fibrotic* response to ALI as early as 24 hours from presentation [23], and histologic evidence can be seen within the first 2 weeks of diagnosis [24]. Because such overlap exists between the fibrotic and proliferative phases, the two are often described together as the *fibroproliferative* phase. On histology, alveolar septa are expanded and airspaces filled with sparsely cellular connective tissue [19]. Such airspace connective tissue formation can either resolve or progress to the point of complete airspace obliteration [24], fibrosis, and even honeycombing [22]. Regardless of severity, there is evidence that increased fibroproliferative signaling [23] and fibrosis [24] predict worse outcomes.

RADIOGRAPHIC FINDINGS

The diagnostic criteria of ALI require bilateral infiltrates on frontal chest radiograph [9]. These infiltrates will often initially appear as heterogeneous opacities, but later become more homogenous over hours to days [25] (see Fig. 47.2A). Although some have recommended using criteria such as cardiac

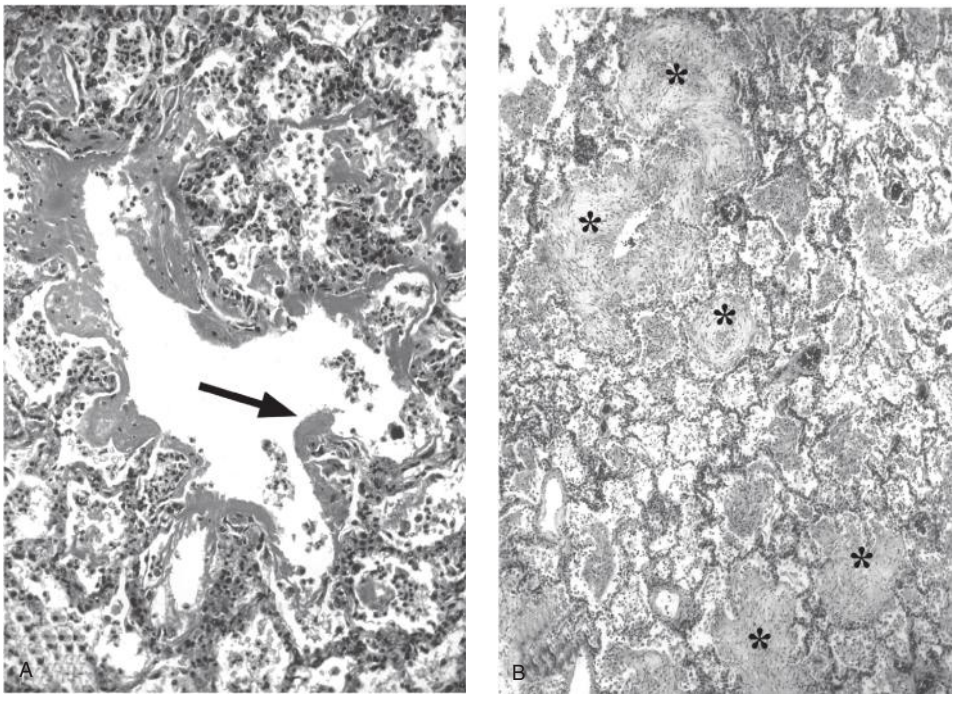

FIGURE 47.1. A: Histologic lung specimen from ARDS patient, showing red blood cells and neutrophils within the alveolar space and characteristic hyaline membranes (*arrow*) consistent with diagnosis of diffuse alveolar damage (DAD). **B:** Hematoxylin and eosin stained, 60×; demonstrates distal airspace granulation tissue (*asterisks*) consistent with organizing pneumonia. [Images were graciously provided by Dr. Martha Warnock.]

silhouette size and vascular pedicle width to differentiate cardiogenic from noncardiogenic edema, this differentiation has proven difficult [26]. Furthermore, the seemingly straightforward interpretation of bilateral infiltrates can be obscured by factors such as atelectasis, effusions, or isolated lower lobe involvement, all of which contribute to low interobserver agreement [27].

Prior to computed tomography (CT) scanning, the pulmonary edema seen on chest radiograph was widely believed to be a diffuse process. However, CT imaging has demonstrated

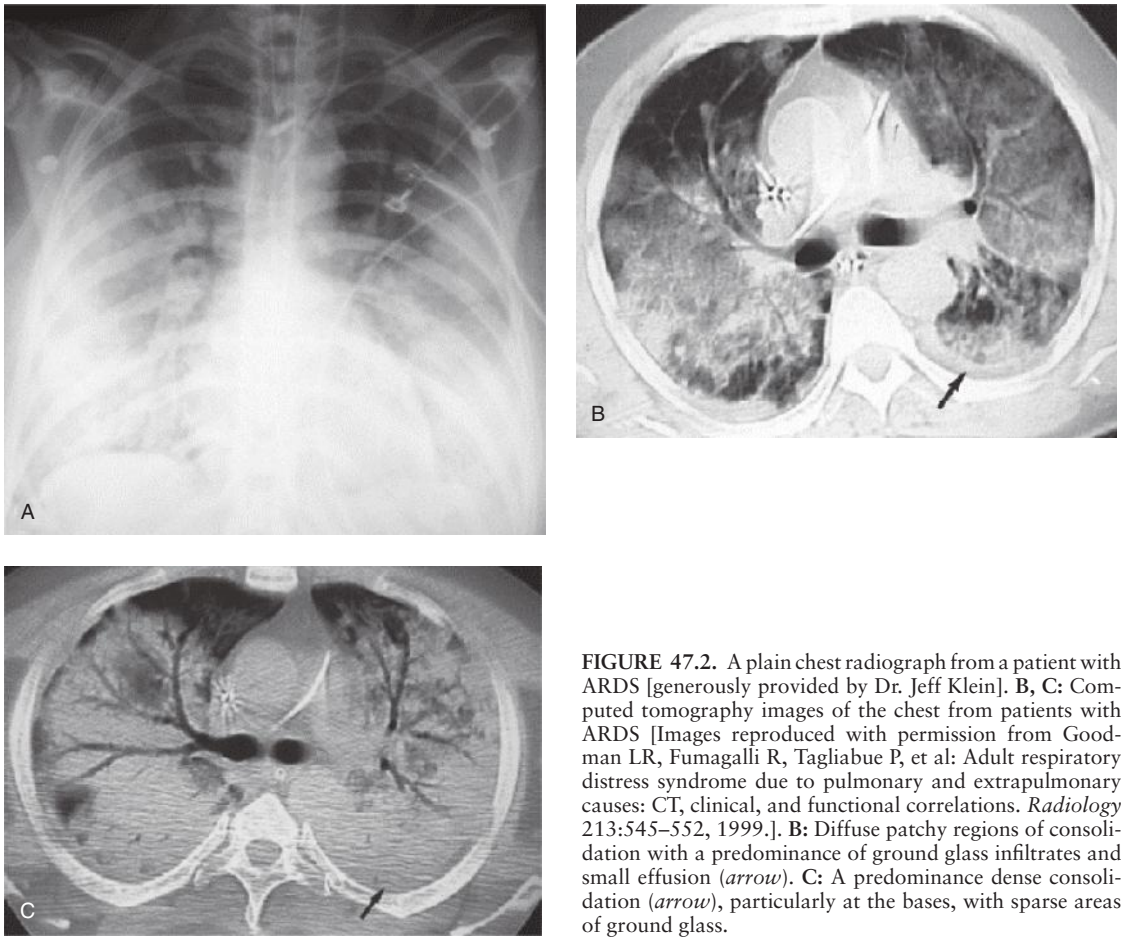

FIGURE 47.2. A plain chest radiograph from a patient with ARDS [generously provided by Dr. Jeff Klein]. **B, C:** Computed tomography images of the chest from patients with ARDS [Images reproduced with permission from Goodman LR, Fumagalli R, Tagliabue P, et al: Adult respiratory distress syndrome due to pulmonary and extrapulmonary causes: CT, clinical, and functional correlations. *Radiology* 213:545–552, 1999.]. **B:** Diffuse patchy regions of consolidation with a predominance of ground glass infiltrates and small effusion (*arrow*). **C:** A predominance dense consolidation (*arrow*), particularly at the bases, with sparse areas of ground glass.

the distribution of ALI to oftentimes be heterogeneous and patchy, with areas of normal-appearing, aerated lung interspersed among areas of mixed ground glass opacity and consolidation, the latter being concentrated in the more gravitationally dependent regions of the lung [28] (see Fig. 47.2B, C). Despite this pattern, a recent study using positron emission tomography (PET) to map cellular metabolic activity demonstrated that diffuse inflammatory change can be detected even in areas of the lung that appear spared radiographically [29]. Some investigators have also used PET imaging and magnetic resonance imaging (MRI) to estimate pulmonary microvascular leak and assist in the differentiation between high permeability and hydrostatic pulmonary edema [30–32], but these methods have yet to be adopted in clinical practice.

EPIDEMIOLOGY

The estimated incidence of ALI worldwide has been variable in the past due to its wide range of causes and previously nonuniform definition. The first estimate by the National Institutes of Health (NIH) projected an annual incidence of 75 cases per 100,000 in the United States [33]. Two subsequent cohort studies in Scandinavia and Australia, respectively, estimated an annual incidence of 18 and 34 cases per 100,000 [34,35], but these studies were limited in size and case inclusion. A much lager pool of prospective cases from the NHLBI-sponsored ARDS Network yielded a conservative estimate of 64.2 cases per 100,000 person-years [36]. A more recent and significantly larger prospective cohort study from King County in Washington State estimates an annual incidence of 78.9 cases per 100,000 person-years [7], which is more in accordance with the ARDS Network and original NIH estimates, and is likely to be the most accurate estimate to date for incidence in the United States.

In patients at risk of developing ALI, the onset of ALI is typically swift, with a median duration of 1 day (interquartile range 0 to 4 days) from the time of risk factor development to the time of diagnosis [37]. The known causes and risk factors for the development of ALI have been well characterized [16–18] (see Table 47.2), and can be categorized as ensuing from either direct or indirect injury to the lung [16,38]. This differentiation is justified by the demonstration of differing physiologic properties between ALI of a direct or indirect nature [38], and by the varied outcomes associated with different causes of ALI [7,11,13]. It is now well established that sepsis is the most commonly identified cause of ALI, and is associated with the worst outcome overall [7,13,18], while trauma-related ALI has a significantly lower mortality [7]. These differences in mortality may be in part due to differences in pathogenesis [39]. Other risk factors for the development of ALI following a known insult include a history of alcoholism [40–42], recent chemotherapy [41], delayed resuscitation [41], and transfusion with blood products [43–46]. The latter condition, commonly referred to as "transfusion-related ALI" (i.e., TRALI), may be more likely to develop following transfusion with fresh frozen plasma and platelets than with packed red blood cells (PRBCs) [44]. Curiously, in those at clinical risk for developing ALI, the diagnosis of diabetes mellitus has been shown to confer protection from ALI, providing about half the relative risk as that of nondiabetic patients [41,47].

TABLE 47.2

CLINICAL DISORDERS ASSOCIATED WITH THE DEVELOPMENT OF ALI AND ARDS, SUBCATEGORIZED INTO THOSE COMMONLY ASSOCIATED WITH DIRECT AND INDIRECT INJURY TO THE LUNG

Direct injury	Indirect injury
Common causes	**Common causes**
Pneumonia	Sepsis
Aspiration of gastric contents	Severe trauma with shock and multiple transfusions
Uncommon causes	**Uncommon causes**
Pulmonary contusion	Cardiopulmonary bypass
Fat emboli	Drug overdose
Near drowning	Acute pancreatitis
Inhalation injury	Transfusion of blood products
Reperfusion injury after lung transplantation or embolectomy	

Adapted from Ware LB, Matthay MA: The acute respiratory distress syndrome. *N Engl J Med* 342:1334–1349, 2000, with permission.

PATHOGENESIS

An understanding of the pathogenesis of ALI is perhaps best imparted through a reflection on the predominant pathologic findings on histology. First and foremost, ALI is a condition triggered by injury to the alveolar epithelium and capillary endothelium. The insult can be initially isolated to either the epithelium, as in the case of aspiration, or to the endothelium, as in most forms of indirect ALI such as sepsis. However, injury is generally detected in both the endothelium and epithelium by the time of diagnosis [19,48]. This injury invariably leads to a leakage of plasma proteins into the alveolar space. Many of these plasma proteins in turn activate procoagulant and proinflammatory pathways that lead to the fibrinous and purulent exudates seen on histology. Through increased transcription and release of proinflammatory cytokines, and an increased expression of cell surface adhesion molecules, a profound acute inflammatory response ensues. This is heralded by epithelial cell apoptosis and necrosis [49], further activation of inflammatory cascades, and a robust recruitment of neutrophils [50]. The increased expression of tissue factor and other procoagulant factors ultimately leads to coagulation within the microvasculature and airspaces, accompanied by a suppression of fibrinolysis, which helps perpetuate the microthrombi and fibrinous exudates that are pathognomonic for ALI.

Injury to the alveolar epithelium plays a critical role in the pathogenesis of ALI. Through the loss of tight junctions and barrier function, plasma proteins and edema fluid seep into the alveolar space, leading to increased shunt fraction, higher alveolar surface tension, and a greater propensity for alveolar collapse. Clearance of both protein and fluid are crucial to the resolution of ALI. Indeed, a greater alveolar fluid clearance (AFC) rate is associated with fewer days of mechanical ventilation and lower mortality in patients with ALI [51]. The type I alveolar epithelial cell (pneumocyte) plays an important role in barrier function, while the type II pneumocyte is the primary source of surfactant production and is known to participate in AFC. Although type I pneumocytes comprise 99% of the alveolar surface area and are presumed to participate in AFC, their exact role in this process remains undefined [52]. AFC occurs by fluid following a sodium concentration gradient established by active sodium transport at the basolateral membrane via Na, K-ATPase activity [53]. Despite the demonstrated impairment of AFC in the setting of lung injury [54], areas of preserved AFC can coexist with injury and epithelial barrier disruption [55], making AFC a potential target for interventional therapy (see "Management" section).

The resorption of protein from the alveolar space is believed to occur more slowly than AFC, and is differentially regulated

depending on the burden of protein present. Alveolar albumin transport occurs primarily via receptor-mediated endocytosis at low concentrations, but occurs primarily via passive paracellular diffusion when present in higher concentrations, as in the case of ALI [56]. Removal of larger insoluble proteins such as fibrin can take much longer and require degradation [56].

On the other side of the alveolar capillary interface, injury to the endothelium results in increased permeability, release of inflammatory molecules, expression of cell adhesion molecules, and activation of procoagulant pathways. Although endothelial injury is detectable under electron microscopy [19], gross endothelial damage may be seen only sparingly [48,57]. Increased microvascular permeability has been widely demonstrated in ALI [32,58,59], but this may be more due to a functional alteration or activation of intact endothelium than due to actual cell lysis or necrosis. Endothelial cells can be activated by factors such as thrombin or endotoxin to increase surface expression of the potent neutrophil-tethering molecules called selectins [60] or to release preformed von Willebrand factor (vWF) [61] and potent neutrophil activating factors [62]. Endothelial cell activation of binding molecules on neutrophils can in turn promote their binding to the endothelium and transmigration into areas of injury. Furthermore, when endothelial cells are tethered to activated neutrophils, such interaction can promote neutrophil degranulation [63], further contributing to local injury and inflammation. The important role of endothelial activation in ALI is highlighted by the finding that elevated plasma levels of vWF have been shown to predict the development of ALI in patients at risk [64] and are associated with worse outcomes [65] and fewer organ failure-free days in established ALI [65].

Although widely accepted to play a key role in the pathogenesis of ALI [50,66,67], the neutrophil is not essential for the development of ALI, as evidenced by the development of ALI in the setting of neutropenia [68]. However, ALI can worsen during the recovery from neutropenia and after administration of the neutrophil growth and releasing factor, G-CSF [69]. Furthermore, neutrophil recruitment to the lung has been shown to be a crucial factor in experimentally induced ALI as demonstrated by attenuated pathology under neutrophil-depleted conditions [70,71].

Activated leukocytes and endothelial cells can also contribute to another recognized pathologic manifestation of ALI: dysregulated intravascular and extravascular coagulation [72,73]. Surface expression of tissue factor by alveolar macrophages and endothelial cells can activate the extrinsic coagulation cascade through factor VII [73], activating thrombin and generating fibrin [72]. Extravascular alveolar fibrin arising from increased procoagulant activity and impaired fibrinolysis [74,75] has been well described in ALI [48]. Fibrin formation and clearance in the lung is in part governed by the differential activity of fibrinolysis promoters and inhibitors [74–76]. Plasminogen activators enzymatically convert plasminogen to active plasmin, the key protease involved in fibrinolysis. Plasminogen activator inhibitor-1 (PAI-1) can prevent fibrinolysis via direct binding and inhibition of plasminogen activators [77]. PAI-1 inhibition of fibrinolysis in the BAL fluid of ALI patients was first recognized in 1990 [75]. Since then the importance of PAI-1 in ALI has been further recognized in that elevated plasma and edema fluid levels of PAI-1 are associated with higher mortality in ALI patients [78]. However, studies examining the direct role of PAI-1 in animal models of ALI have yielded mixed results [79,80]. With respect to the initial process of coagulation and fibrin generation, the activation and expression of tissue factor (TF) has received notable attention due to its known interaction with factor VIIa and downstream generation of thrombin. TF expression has been shown to be increased on the surface of alveolar epithelial cells and macrophages in patients with ALI, and is accompanied by increased procoagulant activity in the edema fluid [81].

Numerous additional pathways have been implicated in the pathogenesis of ALI, but an attempt to cover each in depth would extend beyond the intended breadth of this chapter. In brief, lipopolysaccharide (i.e., endotoxin) has long been recognized as a reliable initiator of ALI [82], particularly in the settings of sepsis and pneumonia, and the mechanisms of its action have been extensively elaborated [83]. Oxidant-mediated injury through the generation of reactive oxidant species is also a well-recognized pathway for injury in ALI [84]. The cytoprotective role of the heat-shock response in ALI, particularly through heat shock protein 70, is also widely acknowledged [85,86]. Dysregulated cell death and apoptosis through the release and accumulation of soluble Fas ligand is also thought to contribute to ALI and may also become a potential future target for therapeutic intervention [49,87]. The role of mechanical ventilation in contributing to the development and worsening of ALI is now also widely recognized and its mechanisms extensively researched [88,89].

PATHOPHYSIOLOGY

Because of the accumulation of extravascular lung water (i.e., pulmonary edema), the physiologic derangements of ALI invariably manifest as refractory hypoxemia [90], decreased respiratory compliance [91], and a propensity for alveolar closure [92]. As alveolar edema fluid and protein accumulate within the alveoli, physiologic shunt develops as blood flows through capillary units and perfuses alveoli that are either filled with fluid, or have collapsed from the resulting increase in surface tension (see Fig. 47.3A). Hypoxic vasoconstriction, the normal autoregulatory reflex that helps match ventilation and perfusion by shunting capillary blood flow away from poorly ventilated regions of the lung, is severely impaired within the diseased regions of the lung [93]. Hence, physiologic shunt is accentuated by an imbalance of flow to the poorly ventilated lung regions [93]. Increased vasoconstriction and scattered microthrombi within well-ventilated lung regions contribute to physiologic dead space or "wasted ventilation" via diminished blood flow to aerated lung [93] (see Fig. 47.3B). The combined effects of these derangements result in refractory hypoxemia and increased minute ventilation requirements, which explain the often challenging demands of managing these patients in the intensive care unit.

Overall, the average pulmonary vascular resistance is commonly elevated in patients with ALI [94,95], likely the result of a reduction in total luminal diameter of the vascular bed, stemming from hypoxia and thrombotic obstruction [95,96]. This in turn leads to the common finding of pulmonary

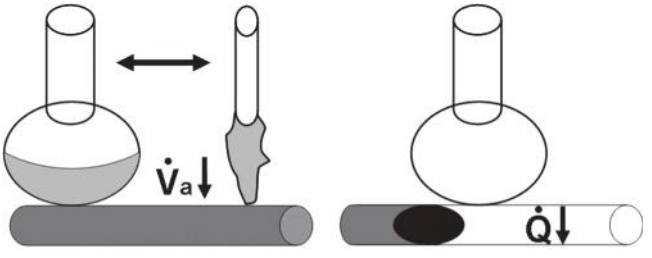

FIGURE 47.3. A: The edema fluid-filled alveolus and a neighboring collapsed alveolus, both with unrestricted blood flow, contributing to physiologic shunt. Double-headed (*arrow*) represents potential for fluid-filled alveolus to collapse and re-expand during normal tidal ventilation. **B:** The effect of a microthrombus (*black oval*) obstructing blood flow to a functioning alveolus, contributing to physiologic dead space.

hypertension in these patients, which can alter right ventricular loading and function [94,97], and predicts higher mortality in afflicted patients [97]. Because elevated pulmonary artery pressures could in theory contribute to increased pulmonary edema [94,98] and right heart strain, it is unclear whether pulmonary hypertension is directly contributing to mortality or simply a marker of disease severity [95].

The mechanical manifestations of ALI present mainly as a decrease in respiratory compliance. This is primarily due to a decrease in lung compliance, particularly in the more direct forms of ALI such as pneumonia. However, contribution from the chest wall and abdominal compartment can be significant under conditions such as trauma and peritonitis [38]. The reduction in lung compliance reflects the collective contribution of changes in the intrinsic elastic properties of the remaining aerated lung and a reduction in resting lung volume via alveolar flooding and collapse. The increased elastic properties of the aerated lung result from increased tissue stiffness due to interstitial edema and increased alveolar surface tension, but the contribution from interstitial edema is thought to be negligible relative to that from alveolar edema [99]. The increase in alveolar surface tension is thought to develop from the increased surface forces generated by a greater abundance of alveolar lining fluid and a decrease in surfactant activity [100]. This loss in surfactant activity is believed to result from inhibitory binding of surfactant by plasma proteins [101] and cholesterol [102], and decreased production of functionally active surfactant by type II pneumocytes [3,103]. To further complicate matters, the biomechanical effects of mechanical ventilation alone can alter the structure and biophysical properties of surfactant [104,105], an unfortunate consequence of a typically mandatory intervention for this condition.

Lower resting lung volumes in ALI result from persistently fluid filled or collapsed alveoli, leading to what has been colloquially referred to as "baby lung" [106]. The affected regions of the lungs are often so diseased that they may remain fluid-filled or collapsed throughout each tidal inflation [107] and hence contribute negligibly to compliance. In fact, CT imaging has demonstrated respiratory compliance to be more closely linked to the amount of aerated lung [108], lending some to assert that compliance is more of a direct measure of aerated lung volume than tissue stiffness [106]. As a result, tidal volumes delivered to the heterogeneously fluid-filled and atelectatic lung are shunted preferentially to more compliant, aerated regions of the lung [109]. This is one of the main postulated mechanisms through which mechanical ventilation can overdistend and injure the remaining regions of "normal lung" and lead to ventilator-induced lung injury (VILI) [88].

At the bedside, the reduction in compliance is typically observed as an increase in peak and plateau airway pressures but can also be seen as an expansion in the hysteresis of pressure–volume (PV) curves obtained during graded inflation of the lung (see Fig. 47.4). The decrease in slope of the inspiratory limb of the PV curve represents a decrease in volume obtained for any given change in pressure, and hence a decrease in compliance.

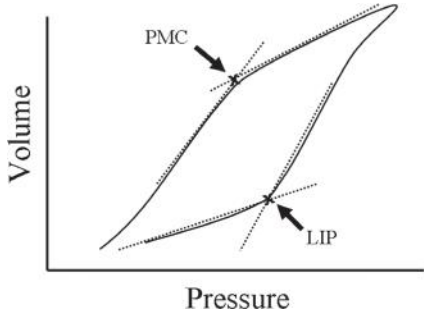

FIGURE 47.4. Simulated pressure volume curve obtained from typical acute lung injury patient, with pressure recorded during slow inflation to total lung volume. Lower inflection point (LIP) marked at point of sudden change in slope of inflation curve. Point of maximal curvature (PMC) also marked at point of maximal change in slope of deflation curve.

MANAGEMENT

Mechanical Ventilation

Mechanical Ventilation and Low Tidal Volumes

The early presentation of ALI is chiefly characterized by hypoxemic respiratory failure and the almost invariable need for support with mechanical ventilation. Because the greatest danger posed to patients with ALI is the development of multiorgan failure [110], establishing supportive ventilation modes that optimize hemodynamic function and oxygen delivery remain important objectives in the management of these patients. Prior to the late 1960s, endotracheal intubation and positive pressure mechanical ventilation were primarily used for supporting patients during general anesthesia. It was during this time that investigators first noted that larger tidal volumes could reduce the shunt associated with atelectasis during general anesthesia [111]. Soon afterward, the benefits of a larger tidal volume on shunt were demonstrated in animal models of ALI [112]. Because many of the techniques used for the support of patients with acute respiratory failure were originally adopted from general anesthesia practice, employing tidal volumes of 10 to 15 mg per kg became the standard for improving oxygenation and ventilation in patients with ALI [113,114].

We now know that idealized oxygenation and normal physiologic pH and $PaCO_2$ can come at a cost when employing higher tidal volumes in patients with ALI. After VILI was induced with higher tidal volumes in animal models [88,115], small retrospective and prospective uncontrolled trials suggested a benefit from limiting tidal volume and peak airway pressures in patients with ALI [116,117]. Numerous larger, randomized trials comparing traditional and lower tidal volumes have since been conducted, each trial differing in its methodology and results [1,2,118–120]. The largest randomized, multicenter trial to date, conducted by the ARDS Network, ultimately demonstrated a significant reduction in mortality when using a tidal volume of 6 mL per kg of predicted ideal body weight and a target plateau pressure of 30 cm H_2O or less (mortality 31.0%) as opposed to a tidal volume of 12 mL per kg and a target plateau pressure less than 50 cm H_2O (mortality 39.8%) [1].

In an effort to better understand the protection conferred by low tidal volumes, investigators have studied how this strategy modulates the inflammatory cascades associated with ALI and VILI. Evidence now exists to support the theory that low tidal volume ventilation improves outcomes at least in part through reduced activation of the inflammatory cascades associated with VILI and multiorgan failure. For instance, among patients enrolled in the ARDS Network trial of low tidal volume, it was found that higher plasma levels of soluble receptors for tumor necrosis factor-α (TNF-α) were associated with higher mortality and fewer organ-failure free days [121]. Furthermore, the lower tidal volume strategy was associated with lower levels of soluble TNF-α receptor I [121]. In another study from the same patient population, elevated plasma levels of interleukin (IL)-6, 8, and 10 were also linked to increased mortality while lower tidal volume was associated with a greater drop in IL-6 and IL-8 by day 3 of enrollment [122].

Many studies of low tidal volume ventilation adopted a strategy of permissive hypercapnia, in which investigators

tolerated a reduction in minute volume and an ensuing increase in $PaCO_2$ to achieve lower target tidal volumes and airway pressures [117,118,120]. Most studies suggest that this strategy is safe [117,118], but the actual safety of this practice is not yet entirely known. Although some animal studies have demonstrated a potential protection by hypercapnic acidosis [123,124], others suggest that hypercapnic acidosis may worsen ALI and VILI [125,126]. Some guidelines acknowledge permissive hypercapnia as an acceptable practice when necessary to limit tidal volumes, but also stress that its use is limited in patients with preexistent metabolic acidosis, and contraindicated in patients with increased intracranial pressure [127]. Because no firm guidelines have been established, current options range from a allowing for an arterial pH as low as 6.8 [117], to increasing respiratory rate up to 35 and buffering with intravenous bicarbonate when pH drops below 7.3 [1]. Despite ongoing controversy [128] and the delayed adoption low tidal volume strategy in clinical practice [129,130], the current evidence has led professional societies to recommend the use of lower tidal volumes at goal plateau pressures less than 30 cm H_2O in patients with established ALI [127]. Because calculations based on total body weight may be partly responsible for the documented underuse of lower tidal volumes for patients with ALI [129], the importance of using predicted ideal body weight (IBW), based upon measured height and sex, cannot be overstressed. IBW (in kg) for males is calculated as $50 + 0.91$ ((height in cm)—152.4), and for females as $45.5 + 0.91$ ((height in cm)—152.4) [1]. Although no firm guidelines exist regarding patients without established ALI, there is clinical evidence that a low tidal volume strategy may help prevent progression to ALI in patients at risk [131,132]. Yet to be determined is whether a more optimal or "best" strategy exists beyond that employed in the ARDS Network sponsored study. Although data suggest that tidal volumes lower than 6 mL per kg may confer even greater protection from VILI [133], there is no general consensus on this practice. However, the authors note that in the original ARDS Network trial, the lower tidal volume assignment started with a goal of 6 mL per kg, but patients in this arm were oftentimes adjusted to as low as 4 mL per kg as needed to maintain plateau pressures less than 30 cm H_2O [1].

Recruitment

The physiologic abnormalities in ALI can, in some patients, be reversed by a recruitment maneuver (RM), typically delivered as a sustained deep inflation with the intention of reopening collapsed regions of the lung. However, because of the unusually high surface tension within affected alveoli, the benefit is often transient [134,135], especially if not followed by sufficiently high levels of PEEP [136]. The potential impact of RMs on morbidity and mortality is not trivial. In fact, because derecruitment leads to an effectively smaller ventilated lung, investigators have proposed the use of "open lung" strategies [137] with periodic delivery of RMs to limit regional overdistention and minimize injury from atelectasis and cyclic alveolar reexpansion [88]. The long-term effect of atelectasis in humans is unclear, but prolonged periods of atelectasis have been shown to promote vascular leak and right ventricular failure in rodents [138]. On the other hand, periodic RMs also have the potential to worsen oxygenation by shunting blood flow to poorly aerated regions [139] and impair cardiac output by limiting venous return and cardiac preload [140,141]. Furthermore, RMs could conceivably contribute to lung injury through excessive overdistention [142] or repeated opening of collapsed lung.

Despite encouraging findings from animal studies [143, 144], clinical studies have yielded mixed results regarding beneficial effects of RMs on oxygenation and lung function [134,141,145]. Although earlier clinical studies demonstrated the benefits of recruitment to be negligible or short-lived [134,140], recent larger trials have demonstrated more promising improvements in lung function and oxygenation but still failed to demonstrate any reduction in mortality [146,147]. Although no guidelines currently exist, it is important to note that patients with ALI of differing origin [38,136,148] and stages of injury [141] vary in their response to RM, and it may help to first differentiate responders from nonresponders [141,148]. When performed, RMs are traditionally delivered as sustained inflations with peak inflation pressures limited to between 30 and 40 cm H_2O, and held for a period ranging from 15 to 40 seconds [2,141,144].

Positive End-Expiratory Pressure

PEEP is another widely employed strategy shown to retard alveolar derecruitment in the injured lung. Several studies have demonstrated the ability of PEEP to prevent or delay alveolar derecruitment [149,150] and attenuate VILI [115,151]. However the protective effect of higher PEEP was called into doubt after a multicenter randomized trial failed to demonstrate an improvement in outcomes using a higher PEEP strategy during low tidal volume ventilation in ALI patients [152]. In this NHLBI-sponsored trial, higher levels of PEEP were arbitrarily coupled to each step-wise increment in FiO_2 requirement during low tidal volume ventilation [152]. The study failed to demonstrate any benefit in mortality or ventilator-free days with higher PEEP [152], but potential underpowering of this study has left room for continued debate [153]. In addition, since the amount of recruitable lung varies significantly among ALI patients [154], some have suggested that setting PEEP levels without first determining the level of recruitable lung may offset the potential benefits of PEEP. In a recent randomized trial, the selection of PEEP was more patient-directed and set at a level required to maintain plateau pressures of 28 to 30 cm H_2O [147]. This higher PEEP strategy again failed to demonstrate a reduction in mortality, but did demonstrate lasting improvements in oxygenation and compliance and an increase in ventilator-free and organ failure-free days [147]. Others have shown that more directly targeting PEEP to transpulmonary pressure by measuring esophageal pressures may be a safer and more effective means of determining optimal PEEP [155].

This raises the question of how one determines the "optimal" setting of PEEP. The often observed lower inflection point (LIP) on the inspiratory limb of the PV curve obtained from ALI patients is the point beyond which the slope of the curve dramatically increases (see Fig. 47.4). This dramatic increase in compliance at the LIP was initially believed to represent a sudden increase in lung volume and hence maximal alveolar recruitment. Thus, many have advocated using the LIP to guide the setting of "optimal" PEEP [2,156]. However, several studies have demonstrated significant recruitment beyond the LIP [157,158], a concept supported by mathematical models [159] and CT imaging [108,160]. Data from CT imaging in ALI patients has recently lent strong support to setting "optimal PEEP" at the point of maximal curvature (PMC) along the deflation limb of the PV curve [160] (see Fig. 47.4). Nevertheless, the concept of "optimal PEEP" has likely been oversimplified and controversy remains over how alveolar recruitment is best served by PEEP.

High-Frequency Ventilation and Extracorporal Membrane Oxygenation

With the data demonstrating a reduction of mortality with a low tidal volume strategy in humans and animal studies showing that even lower tidal volumes offer additional protection [133], high-frequency oscillation ventilation (HFOV), with very small tidal volumes equal to or less than dead space and delivered at a very high rate, would seem to be an ideal

ventilatory strategy in ALI. How adequate ventilation is achieved with tidal volumes less than or equal to dead space is unknown. Proposed mechanisms include a pendelluft effect of mixing gases between lung regions of differing impedances, coaxial flow with net center inflow and net peripheral outflow, mixing of fresh and residual air along the leading edge of gas flow, and simple molecular diffusion through relatively still air [161]. HFOV first demonstrated clinical benefits among infants with respiratory distress syndrome [162,163]. Although early smaller studies of HFOV in adult ALI were promising [164,165], a larger multicenter-controlled trail failed to demonstrate any reduction in mortality from HFOV over conventional ventilation [166]. Nevertheless, newly developing strategies and equipment allow room for ongoing investigation of HFOV for adult ALI.

Extracorporeal membrane oxygenation (ECMO), used alone or in combination with HFOV, uses cardiopulmonary bypass to facilitate gas exchange while minimizing ventilation of the lung to limit barriers to healing. Despite demonstrated efficacy in neonates with severe respiratory distress syndrome [167], ECMO had until recently failed to demonstrate any reduction in adult mortality [168,169]. The largest controlled trial to date in ECHO for severe adult ARDS recently demonstrated an improvement in 6-month survival without disability when compared to conventional ventilatory support [170]. Despite noted strengths in study design, the lack of protocolized ventilator and critical care management in the control group, along with prohibitive issues of cost and availability has led experts to predict negligible resulting change in clinical use of this still controversial intervention [171].

Noninvasive and Partial Support Ventilation

As described earlier, the physiologic shunt responsible for refractory hypoxemia in ALI is attributed in part to alveolar collapse without adequate compensatory decrement in perfusion within the gravitationally dependent lung [172]. Noninvasive ventilation (NIV) and partial support ventilation modes such as pressure support ventilation, allow for patient triggering and cycling of breaths, resulting in more spontaneous breathing. The potential advantages of spontaneous breathing over controlled mechanical ventilation include improved patient–ventilator synchrony, lower sedation requirements, and improved hemodynamics and ventilation/perfusion ($\dot{V}a/\dot{Q}$) matching [173,174]. Partial assist modes of ventilation can still effectively help unload respiratory workload while allowing for variable degrees of spontaneous breathing [175,176]. These modes have also been shown to improve aeration and ventilation/perfusion matching within dependent lung regions [177], presumably due to more pronounced transpulmonary pressures generated within these regions by an actively moving diaphragm [178].

When these modes are applied noninvasively by face mask, an added benefit is the potential reduction in infectious complications, namely nosocomial pneumonia [179]. Studies have shown that NIV can be used safely for the treatment of ALI [180,181]. In a recent multicenter nonrandomized trial, the use of NIV as first line treatment for ALI helped to avoid intubation in 54% of cases and led to a reduction in the incidence of VAP [182]. However, authors could not recommend NIV in patients with a SAPS (Simplified Acute Physiology Score) II of greater than 34 due to a high rate of failure in this group.

Prone Positioning

Prone positioning was shown to improve oxygenation in patients with hypoxic respiratory failure as early as the mid-1970s [183], but how prone positioning improves oxygenation is still not entirely clear. Proposed mechanisms have centered around the potential reversal of gravitationally distributed perfusion to the better ventilated ventral lung regions [184] and improved ventilation of previously dependent dorsal lung [185], both of which would improve ventilation/perfusion matching. Curiously, however, prone positioning exerts limited gravitational effects on regional perfusion in either normal or injured lung [186] but can sufficiently increase dorsal transpulmonary pressures to improve ventilation within previously dependent dorsal regions of the lung [185]. Proposed mechanisms for this improvement in dorsal ventilation include a reduction in dependent lung compression by the heart and mediastinum [187] and regional changes in chest wall mechanics [188].

In animal models, prone positioning reduces physiologic shunt [187], protects against VILI [189], reduces PEEP requirements [190], and attenuates perfusion imbalances imposed by added PEEP [191]. Despite these known physiologic benefits, the first large randomized clinical trial of prone positioning demonstrated a significant improvement in oxygenation but no improvement in survival [192]. Post hoc analysis suggested an early survival advantage in the most severe subgroup of patients, which has also been suggested by subsequent studies [193]. The largest randomized clinical trial to date also demonstrated an improvement in oxygenation and a reduced incidence of ventilator-associated pneumonia with prone positioning, but again no benefit in survival [194]. This study, however, brought greater attention to safety concerns by demonstrating a higher incidence in pressure sores and inadvertent endotracheal tube displacement. Some experts still advocate an investigation of prone positioning in patients with severe ARDS [195], but the indiscriminant use of prone positioning for the general ALI population is not well supported by the current literature [192,194].

Fluid Management

Fluid management in ALI is an ongoing topic of controversy. Because pulmonary edema is the hallmark of ALI, it seems reasonable to aspire to keep patients relatively "dry." However, because the development of multiple organ dysfunction syndrome (MODS) increases mortality from ALI, the critical maintenance of adequate peripheral perfusion may require liberal administration of intravenous fluid. The type of fluid to administer is also controversial. As pulmonary edema is dependent on both hydrostatic and oncotic forces, the issues of optimal fluid balance and replacement of plasma colloid are not trivial. Diuretic therapy with combined albumin and furosemide has been shown to improve oxygenation and hemodynamics in hypoproteinemic ALI patients but does not reduce mortality [196]. In another study comparing the administration of albumin and furosemide with furosemide alone, a greater improvement in oxygenation was seen with albumin plus furosemide [197]. This suggests that albumin may either potentiate the effects of furosemide, allow for better tolerance of diuresis, or confer other favorable effects on oxidant balance [198] or endothelial permeability [199]. The NHLBI ARDS Network trial of conservative versus liberal fluid management demonstrated no difference in 60-day mortality between the two different strategies [200]. However, the patients in the conservative strategy group had a lower 7-day cumulative fluid balance with improved lung function and a reduced duration of mechanical ventilation without an increase in nonpulmonary organ failure [200].

An additional controversy is what parameter should be used to guide fluid management. Whether the indwelling pulmonary artery (PA) catheter is vital to the management of ALI depends upon two important considerations. First, optimal fluid balance must be crucial to preventing the progression of lung

injury. Although this seems defensible in theory, it has yet to be proven. Second, these indwelling catheters must provide a critical and unique understanding of this balance that sufficiently and appropriately modifies clinical practice. This has also yet to be proven. The use of PA catheters came into question after a large observational study of 5,700 critically ill patients actually suggested a higher mortality rate associated with PA catheter use [201]. However, subsequent prospective trials have contradicted these findings [202,203]. Unfortunately, the lack of any clear protocol regarding when to place these lines, and how to interpret and adjust management according to the information provided, leaves ongoing uncertainty regarding their use in patients with ALI [204]. Results from the ARDS Network trial suggest that PA catheter-guided therapy does not improve survival in ALI patients and is associated with more complications than the use of central venous catheters alone [205].

Pharmacologic Intervention

As in any other medical disease or syndrome, it would seem that the "Holy Grail" among clinicians is the discovery of some novel agent that can either break the cycle of disease pathogenesis or help restore physiologic homeostasis and reduce disease severity and morbidity. The field of pharmacologic intervention has been exhaustively explored in the field of ALI, often yielding promising results in animal models and periodically demonstrating modest improvements in lung function and oxygenation in patients, but rarely translating into improved outcomes.

Pulmonary Vasodilators

Given the advanced endothelial injury, physiologic shunt, and commonly observed pulmonary hypertension in ALI, there has been extensive investigation into the therapeutic benefit of pharmacologic pulmonary vasodilatation. Initial studies examined the use of intravenously administered vasodilators such as nitroglycerin and prostacyclin [98,206], but simultaneous and nonselective reductions in systemic and pulmonary vascular resistance led to systemic arterial hypotension with increases in cardiac output and shunt. After the once described "endothelial-derived relaxing factor" was discovered to be nitric oxide (NO) [207], it was found that inhaled NO (iNO) could selectively dilate the pulmonary vasculature within well-ventilated regions of the lung [208], helping reverse both hypoxic vasoconstriction and physiologic shunt. Subsequently, two small-randomized controlled trials demonstrated a significant but transient improvement in oxygenation and shunt in ALI patients in response to iNO, but these benefits did not last past 24 hours, and there was no improvement in outcomes [209,210]. A larger multicenter trial failed to demonstrate a reduction in mortality or ventilator-free days when pooled data from all iNO dosing groups were compared with placebo [211], but the subgroup receiving 5 ppm iNO showed improvement in these parameters. A larger European trial of iNO has since demonstrated a reduction in the development of severe respiratory failure but no reduction in mortality [212].

Most studies have demonstrated minimal adverse effects of iNO other than dose-dependent methemoglobinemia [211]. At the present time, iNO has been approved by the Food and Drug Administration for use in neonates with hypoxic respiratory failure accompanied by pulmonary hypertension but is not approved for use in adult ALI. Experts have concluded that iNO can improve oxygenation in the early phase of its application with minimal adverse effects and is a feasible rescue therapy in severe and refractory ARDS [93]. Given the demonstrated benefits at lower doses, experts recommend using iNO at doses less than 10 ppm when used as rescue therapy.

Surfactant Replacement

Not long after ALI was first described [213] investigators demonstrated a reduction in the amount of surfactant retrieved from the lung and a derangement in the retrieved surfactant's biophysical properties [100]. Since then, numerous studies have supported these findings. The chief surface-tension lowering components of surfactant are phospholipids that align their hydrophilic polar heads along the surface of the alveolar lining fluid and reduce surface tension by interfering with the lateral forces imposed upon the alveolus by water tension. Phosphatidylcholine (PC) makes up the majority of the phospholipid fraction, followed in abundance by phosphatidylglycerol (PG) [214]. The large aggregate fractions consist of large lamellar structures, tubular myelin, and surfactant-associated proteins, and possess the primary surface-tension lowering properties, while the smaller aggregates contain smaller lipids, less surfactant protein, and have limited surface activity [215,216]. In ALI, the relative amount of large-to-small aggregates is reduced [215], as are amounts of bioactive PC and PG [215].

Surfactant-associated proteins also play varied and important roles in surfactant function. Surfactant protein A (SP-A) has been implicated in formation of tubular myelin and antimicrobial defense [217]. SP-B helps to enhance the distribution and stability of phospholipids within the air–liquid interface [218]. SP-C is hydrophobic and believed to closely interact with the surfactant film [219]. Bronchoalveolar lavage fluid (BAL) levels of SP-A and SP-B are reduced in patients with established ALI and those at risk [220]. At the same time, serum levels of SP-A and SP-D are typically elevated in these patients [220] and such elevations are associated with more severe disease and increased risk of mortality [221].

The fundamental rationale for surfactant replacement is to help restore the natural surfactant film and reduce surface tension at the air–liquid interface, thus reducing the tendency for alveolar collapse and improving oxygenation through a reduction in shunt. The evidence in support of surfactant replacement therapy for neonatal RDS is abundant [222,223]. Results from its investigated use in adult ALI patients have been less promising [3,224,225]. Some have speculated that the failure to demonstrate an improvement in mortality is due to the lack of a direct relationship between mortality and severity of respiratory failure alone [110,226]. However, under the assumption that alveolar collapse promotes progression of ALI during mechanical ventilation, many believe that restoring surfactant function holds promise in reducing morbidity and mortality by attenuating VILI. In fact, there is evidence from animal models that surfactant replacement therapy may help prevent VILI [227,228]. Current obstacles to demonstrating this benefit in patients are imposed by intricacies of surfactant administration and its potential inactivation by plasma proteins following delivery. For example, although there is improvement in lung function following surfactant replacement [229], the response is transient. This has been, at least in part, attributed to the tendency for the administered surfactant to be inactivated by plasma proteins in the airspace following [230,231]. This obstacle has been addressed, with mixed results, by adding surfactant proteins [231,232] or polyethylene glycol [233] to block serum protein binding of surfactant.

Despite ostensibly warranted enthusiasm, the largest multicenter randomized clinical trial in adult ALI failed to demonstrate any improvement in mortality with continuous aerosol delivery of the synthetic surfactant, Exosurf [224]. Another large-scale, randomized investigation of intratracheally delivered, recombinant SP-C in ALI patients demonstrated

improvement in oxygenation but again no reduction in mortality or duration of mechanical ventilation [3]. Nevertheless, many investigators believe that a strong case can still be made for further research in surfactant replacement strategies [226].

Corticosteroids

Given the well-characterized acute inflammatory response of ALI and evidence that a fibroproliferative response can predict worse outcomes [23,24], considerable effort has been spent determining the therapeutic role of corticosteroid therapy for this condition. The use of steroids for ALI dates back to the original report of this condition in 1967, when Ashbaugh and Petty suggested a potential role for corticosteroids in fat-embolism and viral-related ALI [213]. Ashbaugh later drew parallels between the features of persistent ALI and idiopathic pulmonary fibrosis, and noted the potential for treating these patients with corticosteroids [234]. Numerous uncontrolled trials had initially suggested a potential benefit of corticosteroids for late or persistent ARDS [235–237]. However, treatment with corticosteroids during the acute phase of ALI has since been proven ineffective [238,239]. The first randomized controlled trial of corticosteroids for late ARDS demonstrated improved lung injury scores and oxygenation, decreased multiorgan dysfunction scores, and reduced ICU and in-hospital mortality in the group receiving steroids [240], but this study drew criticism for its small size and baseline differences between the treatment groups [241]. Since then, a significantly larger NHLBI sponsored multicenter trial completed by the ARDS Network exploring the use of corticosteroids for late persistent ARDS demonstrated more ventilator-free days and improved oxygenation in the group treated with methylprednisolone compared with placebo, but no reduction in 60-day mortality [242]. Furthermore, a higher 60- and 180-day mortality was observed when steroid therapy was initiated after 14 days of onset, suggesting a serious risk from this therapy for late ARDS.

Anticoagulation/Fibrinolysis

The importance of microvascular coagulation and thrombosis in ALI is underscored by the physiologic dead space, or "wasted ventilation," observed in ALI patients [243]. Minimizing microvascular thrombosis could conceivably improve oxygenation through improved ventilation–perfusion matching [244] and increase survival through prevention of multiorgan failure [245]. Thus, the importance of coagulation in the pathogenesis of ALI has become widely appreciated [72], and the use of anticoagulant therapy in ALI has in turn gained attention [246]. Although it has been shown that fibrin and its degradation products can promote inflammation [247], vascular leak, and wound remodeling [72], the detriment imposed by alveolar fibrin has also been accredited to its recognized in vitro capacity to bind with and inhibit the surface-tension lowering capacity of surfactant [248,249]. This has led to considerable interest in limiting in situ fibrin deposition as a means of preserving lung function [246]. As a result, several different anticoagulating agents have been investigated in animal models, some of which have been shown to attenuate lung injury and improve survival [244,250,251].

The most encouraging clinical evidence to support this therapeutic target initially came from a multicenter trial demonstrating a mortality benefit from activated protein C (APC) in severe sepsis [245]. However, because randomized trials of other potent anticoagulants, such as antithrombin III and tissue factor pathway inhibitor (TFPI), yielded no mortality benefit in sepsis [252,253], the postulated benefits from APC may be unrelated to its anticoagulant activity. Consequently, investigators have focused on the use of APC for ALI that is not accompanied by sepsis. Despite promising results in a rat model [251], the most recent phase II clinical trial failed to demonstrate a reduction in ventilator-free days with the use of APC [254]. Critics expressed concern about the study's statistical power and a priori likelihood of success [255], but in a similar vein, despite a promising animal studies [244,250], a recent multicenter Phase II trial of Tissue Factor inhibitor (site-inactivated VIIa) in ALI was terminated prematurely due to higher projected mortality rates in the high-dose treatment arm [256]. There was also an increased risk of adverse bleeding events with escalating doses of this drug [256]. Thus, it seems that the benefits of potent anticoagulation in ALI may ultimately be outweighed by risks of adverse bleeding, but further investigation is warranted.

β-Agonists

As discussed in the pathogenesis section, AFC often remains intact in the setting of injury. AFC can be directly increased by β-agonists in animal models [6,257], presumably through upregulated activity of Na, K-ATPase at the basolateral membrane [258]. In human subjects, the use of exogenous catecholamines has been retrospectively linked to increased AFC [51], but, until recently, the greatest support for pharmacologic AFC modulation in ALI came indirectly from findings of lower mortality in ALI patients having preserved/maximal AFC [51]. An early study demonstrated reduced extravascular lung water in patients receiving intravenous salbutamol, but treatment was complicated by supraventricular tachyarrhythmias [259]. A large multicenter randomized trial investigating the use of the aerosolized β-agonist, albuterol, for the treatment of ALI, was recently halted on the basis of projected futility [260]. In the wake of findings, there is currently no support for the use of β-agonists in the treatment of ALI.

Nutritional Supplementation

Over the past decade, enthusiasm has arisen over the use of nutritional supplements in sepsis and ALI, particularly with the use of omega-3 fatty acids and other natural antioxidants such as vitamin E. The rationale for supplementing patients with omega-3 fatty acids, such as eicosapentaenoic acid (EPA), in the setting of inflammatory disorders comes from the notion they can directly suppress monocyte production of inflammatory cytokines and incorporate into cell membrane phospholipids to compete with omega-6 fatty acids to promote the production of more favorable prostaglandins and leukotrienes [261]. Perhaps the most encouraging earlier data supporting omega-3 fatty acids in ALI came initially from small randomized trials comparing a standard isonitrogenous, isocaloric enteral diet with one supplemented with a proprietary mixture of EPA, gamma-linolenic acid (borage oil), and other antioxidants [262–264]. These studies demonstrated an improvement in gas exchange and lung function [262,264], a reduction in BALF levels of IL-8, leukotriene B_4, and neutrophils [263], and a reduction in ICU stay and mechanical ventilation days [262] with the EPA-rich supplement.

An effort was made to better clarify the effects of omega-3 fatty acids alone in a randomized controlled trial comparing the use of EPA and docosahexanoic acid with a nonnutrient saline supplement. This study failed to demonstrate any associated benefit in their a priori primary outcome (BALF IL-8 and LTB_4 levels), but it did show a yet unexplained trend toward a reduction in ICU length of stay and days on mechanical ventilation [265]. The largest trial of supplemental omega-3 fatty acids to date, conducted by the ARDS Network, was recently halted early due to projected futility [266], but the other component of this study investigating early versus delayed enteral feeding in ALI remains ongoing. Reasons for these negative findings are not yet well understood.

PROSPECTIVE FUTURE THERAPIES

Airway Pressure Release Ventilation

"Airway pressure release ventilation" (APRV) is a mode of ventilation that uses sustained high airway pressures and spontaneous breathing to maximize lung recruitment, with brief periods of "pressure release" to facilitate ventilation while minimizing derecruitment during exhalation [267]. Proponents assume that the periods of pressure release are brief enough to avoid alveolar closure and reexpansion [268], and efficacy relies heavily on the presence of spontaneous ventilation [269], which is believed to generate regionally variable transpulmonary pressures that favor recruitment of dependent lung regions [174]. Although APRV can be equally efficacious and safe when compared with SIMV and pressure support modes [174,270], most published experience in ALI with this mode has been in the surgical and trauma population [174,271,272], and the same findings may not hold true for more unstable forms of ALI resulting from direct pulmonary injury, such as pneumonia and aspiration.Fortunately, two studies comparing APRV with conventional low tidal volume ventilation in ALI are currently enrolling patients (ClinicalTrials.gov Identifiers NCT00750204 and NCT00793013).

Stem Cell Therapy

Recent attention has been given to use of bone marrow derived and circulating stem cells in an effort to expedite tissue regeneration through engraftment and suppress inflammation through immunomodulation [273]. Enthusiasm first came from findings suggesting a favorable rate of engraftment and epithelial differentiation of infused bone marrow derived stem cells in the injured lungs of mice [274]. Important clinical findings followed with the discovery that circulating epithelial progenitor cells (EPCs) are elevated in the plasma of patients with ALI, and that increased circulating EPCs are associated with reduced ALI mortality [275]. Newer studies suggest that the rates of stem cell engraftment and differentiation are not as robust as initially hoped, but many are examining ways of promoting engraftment [273]. This field has found added momentum in the discovery that infused bone marrow derived stem cells may also down regulate inflammation and dampen ALI progression, independent of engraftment [276].

HMG-CoA Reductase Inhibitors (The "Statins")

Recent animal experiments and observational human studies have provoked interest in the treatment of ALI with HMG-CoA Reductase Inhibitors (also called "statins"), a class of drugs originally developed for the treatment of dyslipidemia. In addition to reducing atherosclerotic inflammation, these drugs may also reduce morbidity in other inflammatory conditions such as rheumatoid arthritis [277], influenza [278], sepsis [279], and ALI [280]. The mechanisms through which statins are believed to provide benefit [281] include reduced expression of leukocyte and endothelial adhesion molecules [282,283], reduced production of acute phase reactants (C-reactive protein) and inflammatory cytokines (IL-6, IL-8 and TNF-α) [284,285], and impaired coagulation via platelet stabilization [286], reduced TF and thrombin activity [287,288], and suppressed PAI-1 expression [289]. These drugs have also been shown to promote the mobilization of circulating EPCs [290]. There is experimental data from animal models of ALI arising from ischemia-reperfusion [291] and endotoxemia [280] demonstrating an amelioration of lung inflammation and vascular permeability associated with statin therapy. To date, the only clinical data supporting statin use in ALI comes from a retrospective study of patients on statin therapy at the time of ALI diagnosis that demonstrated a 73% reduction in odds of death, but this did not reach statistical significance [292]. A large, randomized placebo-controlled trial is currently being conducted by the NHLBI ARDS Clinical Trials Network (ClinicalTrials.gov Identifier: NCT00979121).

Preemptive Intervention Protocols

The search for an effective pharmacologic intervention or management algorithm in ALI has thus been extensive and has now spanned decades. Despite this effort, with the exception of low tidal volume ventilation, the reward from most interventions has been limited to improvements in oxygenation [3,192] or fewer days of mechanical ventilation [147,200] (see Table 47.3). One important lesson from the work to date is that much of what we once thought was critical to the management of these patients, although grounded in sound rationale, is not only often ineffective, but can also be potentially harmful. We have become more aware of how sound basic and simple principles of ICU care, such as hand hygiene and protocols for ventilator-associated pneumonia prevention can substantially reduce overall morbidity in the ICU [293,294]. In keeping with this philosophy of preemptive intervention, two studies have recently demonstrated that something as simple as early intervention with physical therapy in mechanically ventilated patients is not only safe and cost-effective, but can also reduce the duration of delirium, mechanical ventilation, ICU and hospital length of stay, and promote greater functional independence by the time of discharge [295,296]. Investigators have also discovered reductions in ALI incidence following the enforcement of conservative transfusion policies (prevention of TRALI) and preemptive low tidal volume ventilation (prevention of VILI) in the care of patients "at risk" for the development of ALI [131,132]. Such practice seems compatible with an emerging theme that if clinicians are still limited to supportive care for ALI patients, then they should at least be doing "less harm" by delivering lower tidal volumes [1], limiting transfusion of blood products, [132,297], conservatively limiting fluids in stable resuscitated patients [298], and fastidiously preventing iatrogenic infections [299].

PROGNOSIS AND OUTCOMES

Prognosis

Numerous clinical factors have been shown to predict a higher mortality rate in ALI patients. These include male sex, African American race, advanced age, alcoholism, malignancy, liver disease, chronic steroid use, infection with human immunodeficiency virus, and ALI secondary to sepsis or aspiration [13,310]. Curiously, although patients of advanced age, particularly older than 70 years, are at a significantly higher risk of death from ALI, those who survive recover at the same rate as their younger counterparts [311,312]. Chronic alcoholism has been shown to not only increase the risk of developing ALI in patient at risk [42], but to also increase the risk of developing multiorgan dysfunction after the development of ALI [40]. Plasma granulocyte colony stimulating factor (G-CSF) levels [313] and body-mass index (BMI) [314] both exhibit a U-shaped distribution of relative risk for mortality in ALI, with higher risk falling on both the low and high ends of the curve. In the case of BMI, although it is somewhat intuitive that patients with either an exceedingly low or excessively high BMI would be at greater risk of death, investigators were somewhat surprised to find the lowest risk belonging to those considered "obese," with a BMI between 30 and 40 [314]. Investigators

TABLE 47.3

TABLE SUMMARIZING ALL RANDOMIZED TRIALS OF PHARMACOLOGIC TREATMENTS AND VENTILATION STRATEGIES FOR ACUTE LUNG INJURY AND ACUTE RESPIRATORY DISTRESS SYNDROME[a]

Intervention	Year	Study	No. of patients	Findings	Reference
High levels of positive end-expiratory pressure	1975	Observational	28	High incidence of pneumothorax	[300]
Extracorporeal membrane oxygenation	1979	Phase 3 multicenter	90	No benefit	[169]
High frequency ventilation	1983	Phase 3 multicenter	309	No benefit	[301]
Preventative PEEP (8 cm H_2O)	1984	Phase 3 single center	92	No benefit in patients at risk of ALI	[302]
Glucocorticoids (during acute phase)	1987	Phase 3	87	No benefit	[239]
Glucocorticoids (during acute phase)	1988	Phase 3	59	No benefit	[238]
Alprostadil: Intravenous	1989	Phase 3	100	No benefit	[303]
Liposomal	1999	Phase 3	350	Stopped for lack of efficacy	[304]
Extracorporeal membrane oxygenation	1994	Phase 3 single center	40	No benefit	[168]
Surfactant (aerosolized)	1996	Phase 3	725	No benefit	[224]
"Open-lung" approach (recruitment maneuver and "ideal PEEP")	1998	Phase 3 single center	53	Decreased 28-day but not in-hospital mortality	[2]
Low tidal volume ventilation (7 vs. 11 ml/kg)	1998	Phase 3	120	No benefit in patients at risk for ALI/ARDS	[120]
Low tidal volume ventilation (7 vs. 10 mL/kg)	1998	Phase 3	116	No benefit	[118]
Glucocorticoids during late fibrosing alveolitis	1998	Phase 3	24	Decreased mortality, but study small	[240]
Inhaled nitric oxide	1998	Phase 2	177	No benefit	[211]
Inhaled nitric oxide	1999	Phase 3	203	No benefit	[305]
Ketoconazole	2000	Phase 2	234	No benefit	[306]
Low tidal volumes (6 vs. 12 mL/kg)	2000	Phase 3, multicenter	861	Decreased mortality from 40% to 30%	[1]
Prone positioning during mechanical ventilation	2001	Phase 3, multicenter	304	Improved oxygenation, but no benefit in mortality	[192]
Partial liquid ventilation	2002	Phase 3, multicenter	90	Lower progression to ARDS, but no benefit in mortality	[307]
Recombinant surfactant protein C-based surfactant	2004	Phase 3, multicenter	448	Improved oxygenation at 24 hours but no benefit in mortality	[3]
Prone positioning for hypoxemic acute respiratory failure	2004	Phase 3, multicenter	791	No benefit in 28 or 90 day mortality and some safety concerns	[194]
Higher versus lower PEEP during low tidal volume ventilation	2004	Phase 3, multicenter	549	No benefit in mortality or days on the ventilator	[152]
Low and high dose partial liquid ventilation	2006	Phase 3, multicenter	311	No benefit in mortality and some safety concerns	[308]
Glucocorticoids for late/persistent ARDS	2006	Phase 3, multicenter	180	No benefit in mortality; increased mortality if started after 2 weeks	[242]
Conservative versus Liberal Fluid Management in ALI	2006	Phase 3, multicenter	1,000	No benefit in mortality; conservative strategy improved lung function and reduced ventilator days	[200]
Prolonged prone positioning for severe ALI	2006	Phase 3, multicenter	136	Nonsignificant reduction in mortality (43% vs. 58%, p = 0.12)	[193]
Low tidal volumes, recruitment maneuvers and high PEEP	2008	Phase 3, multicenter	983	No mortality benefit; less refractory hypoxemia and rescue therapy	[146]
Low tidal volumes with plateau pressure directed, high PEEP	2008	Phase 3, multicenter	767	No mortality benefit; higher organ failure free and ventilator free days and improved lung function	[293]
Activated Protein C	2008	Phase 2, multicenter	75	No benefit in ventilator-free days or mortality; reduced dead space	[254]

TABLE 47.3

CONTINUED

Intervention	Year	Study	No. of patients	Findings	Reference
L-2-oxothiazolidine-4-carboxylic acid	2008	Phase 2, multicenter	215	Terminated early due to higher 30 day mortality & reduced vent-free days	[309]
Early mobilization in ICU for patients with respiratory failure	2008	Multicenter prospective	330	Decreased intensive care unit and hospital length of stay in survivors	[296]
Early physical therapy in ICU for patients with respiratory failure	2009	Randomized, two centers	104	Decreased days on mechanical ventilation and ICU length of stay; increased functional independence at time of discharge	[297]
Site-inactivated factor VIIa	2009	Phase 2, multicenter	46	Terminated early due to higher 28 day mortality in high dose group and trend toward increased bleeding	[256]
ECMO vs. conventional ventilatory support for severe adult respiratory failure (CESAR)	2009	Randomized multicenter	180	Reduced death or severe disability at 6 months	[170]
Albuterol to treat acute lung injury (ALTA)	2009	Phase 2 and 3, multicenter	282	Terminated early due to projected futility by DSMB	[260]
Fish oil in patients with ALI	2009	Phase 2 multicenter	90	No difference in BALF IL-8 or LTB_4; trend toward reduced ICU stay	[265]
Omega-3 fatty acids supplementation for ALI (EDEN-Omega)	2009	Phase 3, multicenter	272	"Omega" arm terminated early due to project futility	[266]
Neuromuscular blockade in early severe ARDS	2010	Phase 3, multicenter		48 hours cisartacurium reduced mortality and increased ventilator-free days without prolonged weakness	[338]

[a]Results of randomized clinical trials of pharmacologic treatments and ventilatory strategies for acute lung injury and acute respiratory distress syndrome.
Table partially adapted from Ware LB, Matthay MA: The acute respiratory distress syndrome. *N Engl J Med* 342:1334–1349, 2000, with updated additions.

are also uncovering genetic polymorphisms and phenotypes among ALI patients that lead to an increased risk of mortality. Individuals carrying specific haplotypes for IL-6 [315] or an endogenous inhibitor of NF-kB [316] have an increased susceptibility to ALI and mortality is increased in patients with ALI, with specific polymorphisms for surfactant protein B [317], pre-B-cell colony enhancing factor [318], or VEGF [319].

Outcomes

Estimates of mortality from ALI once ranged as high as 70% [110,320]. Despite a documented decline between the early 1980s and late 1990s [110,320], mortality from ALI appears to have now plateaued between 30% and 40% for all patients, [1,7,110,320]. As mortality has slowly improved for ALI, there has been growing interest in the long range consequences of this condition. In particular, ALI survivors have been shown to suffer from a prolonged disturbance in lung function [321,322], an impairment in neurocognitive skills [323,324], and a perception of poor quality of life [324,325]. By as far out as one year from recovery, although many have recovered spirometric lung function [326], the majority of ALI survivors have a diminished diffusing capacity and exercise tolerance [321,326]. One report noted less than half of all ALI survivors returning to work after 1 year [326], and many survivors suffer from depression and anxiety as far as 2 years out from recovery [324]. In a recently published study, symptoms of moderate to severe depression were reported by 41% of survivors within 6 to 48 months following discharge [327]. Posttraumatic stress disorder (PTSD) has been another growing concern among survivors [328] and delusional memories of ICU stay have been shown to correlate with the development of PTSD symptoms [329].

A regimented sedation protocol designed to promote daily awakenings and lower overall sedation in critically ill patients was associated with decreased days in the ICU and fewer days on mechanical ventilation [330]. Furthermore, to help raze the myth that daily awakening be traumatic for patients, this strategy has since been found to actually reduce PTSD-related symptoms following recovery [331]. The feasibility and importance of establishing clear sedation goals and using validated tools for sedation assessment in critically ill patients has been firmly established [332,333], and this standard of care is now a part of established professional society guidelines for sedation in the ICU [334]. It remains to be seen whether these guidelines will be adapted to accommodate recent findings showing a reduction in ARDS mortality with 48 hours of early neuromuscular blockade [338].

CONCLUSION

Since its first published description in 1967 [213], our understanding of the pathogenesis and pathophysiology of ALI has grown appreciably, and ongoing research efforts continue to provide hope for exciting new therapies in the future. Our improved understanding of this condition has already translated into improved outcomes for patients suffering from ALI [320], but it's still ominous prognosis for those acutely afflicted in the hospital [7], and those fortunate enough to survive [324], leaves room for ongoing progress in the management of these patients. Aside from the obvious importance of reducing mortality from this condition, a reduction in days on the ventilator and subsequent stay in the intensive care unit represent some of the other tangible and intangible benefits to both patients and society in general [335,336].

CHAPTER 48 ■ RESPIRATORY FAILURE PART III: ASTHMA

J. MARK MADISON AND RICHARD S. IRWIN

Asthma is an inflammatory disease of the airways characterized by reversible airway obstruction [1,2]. Inflammation causes airway obstruction by making airway smooth muscle more sensitive to contractile stimuli [3], by thickening the airway wall with edema and inflammatory cell infiltration, by stimulating glands to secrete mucus into the airway lumen, by damaging the airway epithelium [4], and by remodeling the architecture of the airways [5]. Typically, intermittent worsening or exacerbation of asthma is triggered by exposure to environmental factors such as inhaled allergens, irritants, or viral infections of the respiratory tract. These exacerbations represent acute or subacute episodes of increased airflow obstruction that may be mild to life threatening in severity. Assessment, management, and prevention of exacerbations of asthma, especially those leading to respiratory failure, are the critical challenges of caring for adult patients with asthma [6,7], the focus of this chapter.

EPIDEMIOLOGY

Worldwide, asthma ranks among the most common chronic diseases, with a prevalence ranging from a low of 0.7% in Macau, 6.7% in Japan, 10.9% in the United States, and a high of 18.4% in Scotland [8]. In general, asthma prevalence increases with urbanization and westernization of societies. In the United States, from 1980 to 1996, self-reported asthma prevalence increased 73.9% but then stabilized from 1997 to 2004 [9].

Asthma exacerbation rates vary by season with peaks in emergency room visits and hospitalizations coinciding with respiratory viral infections, especially rhinovirus, in late summer and early autumn [10]. In 2002, annual rates of hospitalization for asthma in the United States were 27 per 10,000 population-age 0–17 years and 13 per 10,000 population-age 18 and over. Although there remain important racial and gender differences in the rates of hospitalization, this represents an overall decline in hospitalizations from 1995 to 2002 and this suggests the possibility of better management and prevention of asthma exacerbations in ambulatory settings over these years [11].

In 2002 there were 4,261 deaths due to asthma in the United States indicating a death rate of 1.5 per 100,000 population of all ages [9]. Asthma mortality rates also have an annual cycle, but do not strictly parallel the cycle for exacerbations. In children, mortality peaks in the summer months, but, with increasing age, asthma mortality becomes more common in winter months [10]. In 2002, the death rate for ages 18 years and older was 1.9 deaths per 100,000 population, but it is notable that there are very large racial differences in the risk of death due to asthma. Blacks aged 25 to 34 years are six times more likely to die from asthma than whites of the same age group [9]. Deaths among patients hospitalized for asthma do account for one third of asthma related mortality, but potential differences in hospital care do not appear to account for the striking racial disparities and this suggests that prehospitalization factors are more important [12].

PATHOPHYSIOLOGY

Pathology

Bronchial biopsy specimens of patients with asthma are pathologically abnormal [13–15], with collagen deposition beneath the epithelial basement membranes, mucosal infiltration by eosinophils and neutrophils, mast cell degranulation, and epithelial damage. These findings occur in both severe and mild asthma, suggesting that airway inflammation is of primary importance in the pathogenesis of asthma.

Asthma exacerbations show variable pathology, reflecting at least two recognized subtypes of exacerbation—slow onset and rapid onset. Slow onset exacerbations are the most common (approximately 80% of exacerbations) and the patient presents with more than 2 to 6 hours of symptoms—often days or weeks of symptoms [16–18]. This suggests that most such patients should have sufficient time to seek medical attention for worsening shortness of breath [19]. At autopsy, the lungs of patients who die of "slow-onset" asthma exacerbations are hyperinflated with thick tenacious mucus filling and obstructing the lumens of the airways [4]. Microscopically, there is an eosinophilic bronchitis, with pronounced areas of mucosal edema and desquamation of the epithelium. Typically, hypertrophy and hyperplasia of smooth muscle are present and the muscle appears contracted [4].

The patient with the rapid-onset type of exacerbation presents with severe symptoms that have rapidly progressed over 2 to 6 hours [16–18]. These rapid-onset exacerbations may represent 8% to 14% of asthma exacerbations in general and can be fatal, leading to death in only a few hours after symptom onset [16,18]. Pathologically, airway obstruction by mucus is not prominent, and there is a neutrophil, rather than eosinophil, predominance of inflammatory cells in the airway submucosa [20]. There are no specific clinical characteristics that reliably predict which patients are prone to these rapid-onset asthma exacerbations. However, patients with rapid onset asthma exacerbations may more commonly report sensitivity to nonsteroidal anti-inflammatory drugs (NSAIDs) [18].

Pathogenesis

Asthma is a disease or group of diseases with complex underlying genetics [21]. Why airway inflammation develops in the asthmatic patient is not understood entirely, but much evidence suggests an important role for Th2 cytokines [22]. Inhaled allergens, pollutants, smoke, and viral infections all may play a role in augmenting the baseline airway inflammation present in the asthmatic airway [1,23]. When these environmental

triggers interact with the asthmatic airway, the inflammation is intensified and the released mediators have potent effects on smooth muscle cell function, epithelium and microvascular integrity, neural function, and mucus gland secretion. All these factors contribute to increased narrowing of the asthmatic airway with smooth muscle contraction, mucus secretion, epithelial cell sloughing into the lumen, and edema and inflammatory cell infiltration of the airway wall. The resulting acute increase in airway obstruction is commonly referred to as an *acute exacerbation of asthma*.

Physiology

The major physiologic consequences of airway obstruction are hypoxemia and increased work of breathing. Understanding these physiologic disturbances is important for management of severe exacerbations of asthma.

Narrowing the caliber of airway lumens causes hypoxemia by two mechanisms. First, increases in the resistance to flow in the conducting airways result in uneven distribution of ventilation to the alveoli. Hypoxic vasoconstriction of vessels that supply underventilated alveoli partially compensates for this uneven ventilation, but overall ventilation–perfusion ($\dot{V}/\dot{Q}$) ratios remain abnormal and are the principal cause of hypoxemia in asthma [24]. Consequently, even patients with severe exacerbations of asthma usually respond well to supplemental oxygen. A second, less common cause of hypoxemia in asthma is right-to-left shunt due to atelectasis of lung distal to airways that are completely occluded by mucus or due to interatrial shunt [25–27].

The second physiologic consequence of severe airway obstruction is increased work of breathing. During acute exacerbations, respiratory muscles must expend increased energy, generating large changes in pleural pressure to overcome high airway resistance [28]. The resulting discordance between respiratory effort and the change in thoracic volume also plays a role in the patient's sensation of dyspnea and central drive to increase minute ventilation. The ensuing rapid respirations further increase the work of breathing and worsen air trapping behind narrowed airways that prematurely close during expiration. The dynamic hyperinflation of the lung itself leads to increased respiratory muscle energy costs because it restricts vital capacity to high thoracic volumes where alveolar dead space is increased, the respiratory muscles are at suboptimal mechanical advantage, and the lung is less compliant. All of these factors contribute to the enormous increase in the work of breathing. Thus, the respiratory muscles must expend more energy to achieve the same alveolar ventilation. Initially, the respiratory muscles may be able to exert the force needed to maintain alveolar ventilation but the muscles may fatigue if airway resistance increases rapidly, is sustained, or if there is inadequate oxygen delivery to theses muscles [29,30]. Dynamic hyperinflation due to severe airway obstruction also may impair cardiac performance by increasing afterload, decreasing venous return to the heart, and causing diastolic dysfunction [7,27].

DIFFERENTIAL DIAGNOSIS

Not all wheezing is due to asthma (Table 48.1). Obstruction of the airway at any level can produce wheezing and dyspnea that can be confused with asthma. For example, vocal cord dysfunction syndrome [31–35] is an extrathoracic cause of upper airway obstruction that can be confused with acute asthma. This diagnosis is suggested by the presence of stridor and wheeze in the absence of increased alveolar-arterial oxygen tension difference, extrathoracic variable obstruction on flow-volume loop, and observing paradoxic closure of vocal cords during inspiration on laryngoscopy.

TABLE 48.1

DIFFERENTIAL DIAGNOSIS OF WHEEZING

- Upper airway obstruction
  - Extrathoracic
    - Anaphylaxis
    - Arytenoid dysfunction
    - Bilateral vocal cord paralysis
    - Laryngeal edema
    - Laryngostenosis
    - Laryngocele
    - Mobile supraglottic soft tissue
    - Neoplasms
    - Postextubation granuloma
    - Postnasal drip syndrome
    - Relapsing polychondritis
    - Retropharyngeal abscess
    - Supraglottitis
    - Vocal cord dysfunction syndrome
    - Wegener granulomatosis
  - Intrathoracic
    - Acquired tracheomalacia
    - Airway neoplasms
    - Foreign body aspiration
    - Goiter
    - Herpetic tracheobronchitis
    - Right-side aortic arch
    - Tracheal stenosis due to intubation
    - Tracheobronchomegaly
- Lower airway obstruction
  - Aspiration
  - Asthma
  - Bronchiectasis
  - Bronchiolitis
  - Carcinoid syndrome
  - Chronic obstructive pulmonary disease
  - Cystic fibrosis
  - Lymphangitic carcinomatosis
  - Pulmonary edema
  - Parasitic infections
  - Pulmonary embolism

Furthermore, many disease processes other than asthma can obstruct the lower airways to produce wheezing and dyspnea (Table 48.1). Systemic anaphylaxis can cause wheezing and should be considered in the differential diagnosis especially when respiratory symptoms have been of rapid onset and progress [36]. A diagnosis of anaphylaxis is suggested by acute-onset wheezing, stridor, urticaria, nausea, diarrhea, and hypotension (especially after insect bites, drug administration, or intravenous contrast). Exacerbations of chronic obstructive pulmonary disease (COPD) present similarly to acute asthma, but chronic bronchitis or emphysema, or both, can usually be distinguished from asthma historically. Pulmonary thromboembolism can masquerade as an exacerbation of asthma because the mediators released by platelets in thromboemboli sometimes cause bronchoconstriction and wheezing. However, hemoptysis, pleuritic pain, and pleural effusions rarely are seen in acute exacerbations of asthma.

Pulmonary edema, either cardiogenic or noncardiogenic, can obstruct small airways with mucosal swelling to produce acute wheezing. However, in these cases the clinical history, physical examination, and chest radiograph changes that show

vascular redistribution of blood flow and alveolar filling help exclude asthma as a diagnosis. Notably, however, acute, reversible left ventricular dysfunction has been described as a possible complication of severe exacerbations of asthma; the underlying mechanism for this is unclear [37]. Aspiration can present with acute dyspnea and wheezing. In this case, a history of impaired consciousness or inability to protect the airway suggests that the diagnosis and chest radiograph may show pulmonary infiltration.

ASSESSMENT

Physician failure to appreciate the severity of airway obstruction in acute asthma is not uncommon and contributes to mortality [1]. The cornerstone of evaluation of patients with asthma exacerbations is the objective measurement of airflow. However, because some patients, especially those with severe exacerbations, may be unable to perform the necessary testing maneuvers, the physician also must be adept at recognizing certain historical features and physical findings that strongly suggest high risk for severe airway obstruction.

History

Baseline pulmonary function tests that show persistent decreases in the forced expired volume of air in 1 second (FEV_1), loss of lung elastic recoil, and hyperinflation at total lung capacity are associated with increased risk of near-fatal asthma [38]. A recent history of poorly controlled asthma (increases in dyspnea and wheezing, frequent nocturnal awakenings due to shortness of breath, increased use of beta-adrenergic rescue medications, increased diurnal variability in peak expiratory flow, and recent hospitalizations or emergency department visits) and any history of a prior near-fatal asthma exacerbation (prior admission to an intensive care unit or intubation for asthma) are the two most important predictors of a patient's propensity for severe life-threatening asthma exacerbations [39–44]. Patient complaints of severe breathlessness or chest tightness or difficulty walking more than 100 feet (30.48 m) also suggest severe airway obstruction. Cigarette smoking also has been associated with higher in-hospital and posthospitalization mortality [43]. In general, patients are somewhat better judges of the severity of their airway obstruction during an attack of asthma than are physicians who elicit their history at the bedside [45]. However, the patient's own assessment of airway obstruction should never be the exclusive means of assessing the severity of airway obstruction. Notably, patients with a history of severe asthma often have a blunted perception of dyspnea [46–49]. In assessing risk for fatal asthma, other important historical details include identification of current medications and coexisting illnesses, such as psychiatric disease, that interfere with medical follow-up and cardiopulmonary disease. A history of known coronary artery disease is important because the patient may be more sensitive to the stimulatory effects of β_2-adrenergic agonists and to the cardiac complications of hypoxemia [50]. These patients may also be receiving β_2-adrenergic antagonists that are making control of their asthma worse.

Physical Examination

Physical examination is important for excluding other causes of dyspnea (see Differential Diagnosis section) and assessing the degree of airway obstruction [44]. Tachycardia (greater than 120 beats per minute), tachypnea (greater than 30 breaths per minute), diaphoresis [51], bolt-upright posture in bed, pulsus paradoxus greater than 10 mm Hg, and accessory respiratory muscle use all should be regarded as signs of severe airway obstruction [52]. However, because the absence of these signs does not rule out severe obstruction, physical examination cannot be relied on exclusively to estimate the severity of airway obstruction. The amount of wheezing heard on auscultation of the chest is a notoriously poor method of assessing the severity of airway obstruction [53]. Cyanosis is a late, insensitive finding of severe hypoxemia. Abnormal thoracoabdominal motion (e.g., respiratory muscle alternans, abdominal paradox) and depressed mental status due to hypoxemia and hypercapnia are ominous indicators and can herald the necessity for mechanical ventilation [54].

Pulmonary Function Tests

To evaluate patients who are having an acute exacerbation of asthma, an objective measure of maximal expiratory airflow should be performed. An exception to this is the patient who is unable to perform a testing maneuver due to a severe, life-threatening exacerbation with obvious airway compromise and cyanosis [44]. Peak expiratory airflow rate (PEFR) and FEV_1 are equally good bedside measures to quantify the degree of airway obstruction [55]. These tests are invaluable for the initial assessment and for following responses to therapy [44,56]. In general, a PEFR or FEV_1 of less than 40% of baseline (either the predicted value or the patient's best-known value) indicates severe obstruction and a severe exacerbation of asthma (Table 48.2).

Arterial Blood Gas Analysis

Analysis of arterial blood gases (ABGs) have a role in assessing and managing severe asthma exacerbations (see Chapter 11) and should be performed for suspected hypoventilation, severe respiratory distress, or when spirometric test results are less than 25% predicted [44]. Also, any patient who fails to respond to the first 30 to 60 minutes of intensive bronchodilator therapy should have an ABG analysis performed. Although ABG values are not predictive of overall patient outcome [55], there is some correlation between hypoxemia and hypercapnia and the degree of airway obstruction measured by FEV_1 [57]. A partial pressure of arterial oxygen (PaO_2) less than 60 mm Hg or a pulse oximeter oxygen saturation value less than 90% on room air should be regarded as additional evidence of severe airway obstruction. Therefore, although ABG analysis is not recommended as routine in the initial evaluation of asthma, it should be done for the evaluation of severe cases. One study found that the frequency of ABG analysis in cases of severe asthma actually decreased from 1997 to 2000, a trend needing improvement [58].

TABLE 48.2

OBJECTIVE ASSESSMENT OF AIRWAY OBSTRUCTION AFTER INITIAL INTENSIVE THERAPY

PEFR or FEV_1	Interpretation
≥70% predicted	Good response
≥40% but ≤69% predicted	Incomplete response
<40% predicted	Poor response

FEV_1, forced expired volume in 1 second; PEFR, peak expiratory flow rate.

Understanding the expected changes in the partial pressure of arterial carbon dioxide ($PaCO_2$) during an asthma exacerbation is important for recognition of a rapidly deteriorating course. With modest airway obstruction, the patient's mild dyspnea stimulates an increase in minute ventilation that meets or exceeds the level required to maintain normal alveolar ventilation. Thus, patients with modest obstruction have a normal or slightly below normal $PaCO_2$. As airway obstruction worsens, dyspnea becomes more severe and the central nervous system drive to increase minute ventilation becomes intense. Typically, the increase in minute ventilation exceeds the level required to maintain constant alveolar ventilation; consequently, patients with moderate-to-severe obstruction have lower than normal $PaCO_2$ and respiratory alkalosis. As the airway obstruction becomes more severe and prolonged, high minute ventilation can no longer be maintained by the respiratory musculature and alveolar ventilation decreases. As a result, the $PaCO_2$ rises toward normal and then continues to climb, resulting in hypercapnia and respiratory acidosis. Thus, a normal or high $PaCO_2$ (greater than 40 mm Hg) during a severe exacerbation of asthma is a potentially ominous finding, often signifying the impending need for mechanical ventilation. Any coexisting conditions (malnutrition, advanced age) or medications (sedatives) that weaken respiratory muscle function or depress respiratory drive should be expected to accelerate the onset of hypercapnic ventilatory failure during acute exacerbations of asthma.

Other Laboratory Studies

For acute exacerbations of asthma, routine chest radiographs reveal few abnormalities other than hyperinflation [59]. However, although not recommended for routine assessment, for severe exacerbations chest radiography can be helpful when there is clinical suspicion of other causes of dyspnea and wheezing (see Differential Diagnosis section) or complications of severe airway obstruction [44]. Chest radiographs should be examined for evidence of enlarged cardiac silhouette, upper lung zone redistribution of blood flow, pleural effusions, and alveolar or interstitial infiltrates because any one of these findings suggests a diagnosis other than or in addition to acute asthma. In addition, chest radiography allows the early detection of common complications of severe airway obstruction, including pneumothorax, pneumomediastinum, and atelectasis. Also, lung infiltrates on chest radiographs can be compatible with a diagnosis of asthma complicated by either allergic bronchopulmonary aspergillosis or Churg–Strauss syndrome.

In the elderly, in patients with severe hypoxemia, and in individuals with suspected cardiac ischemia or arrhythmia, an electrocardiogram should be performed. Sinus tachycardia is common during acute exacerbations of asthma, but less common and transient findings include right-axis deviation, right ventricular hypertrophy and strain, P pulmonale, ST- and T-wave abnormalities, right bundle-branch block, and ventricular ectopic beats [60].

THERAPEUTIC AGENTS

Optimal management of an acute exacerbation of asthma begins with a careful assessment of the degree of airway obstruction. This initial assessment and repeated objective measures of airway obstruction guide treatment that combines supportive measures, bronchodilator therapy, and anti-inflammatory therapy (Table 48.3).

Because the dominant causes of airway obstruction during an acute exacerbation of asthma are the result of airway inflammation, the cornerstone of treatment is anti-inflammatory therapy with systemic corticosteroids [61]. Because corticosteroids take at least 4 to 6 hours to begin to have a beneficial effect and the inflammatory causes of airway obstruction may take days to resolve, the medical challenge is to support patients until the inflammatory processes have responded to corticosteroids.

TABLE 48.3

TREATMENT OF SEVERE ACUTE EXACERBATIONS OF ASTHMA

- Pharmacologic agents
  - Anti-inflammatory agents
    - Systemic corticosteroids (oral preferred unless impaired intestinal absorption)
  - Bronchodilators
    - Inhaled β_2-adrenergic agonists
    - Inhaled cholinergic antagonists
    - $MgSO_4$ (not routine; consider in severe, refractory cases)
    - Oral or intravenous methylxanthines (not routine or recommended)
    - Systemic β_2-adrenergic agonists (not routine or recommended)
    - General anesthetics (not routine)
- Supportive measures
  - Frequent reassessment
  - Supplemental oxygen
  - Fluid management
  - Invasive mechanical ventilation if needed (controlled hypoventilation)
  - Helium-oxygen mixtures to drive nebulizer (not routine; consider in severe, refractory cases)
  - Lavage by bronchoscopy (not routine, intubated patients only)
- Education
  - Avoidance of asthma triggers
  - Medication use
  - Access to medical follow-up
  - Home monitoring of airway obstruction

β_2-Adrenergic agonists relieve airway obstruction due to airway smooth muscle contraction, and this is an important therapeutic maneuver in initial treatment. Although these bronchodilators relieve only one component of the airway obstruction during severe exacerbations of asthma, even small improvements in airflow can lead to important clinical benefits in the acute setting. Of the available bronchodilators, β_2-adrenergic agonists are the most effective and rapidly acting and, therefore, most useful during that critical time before the onset of corticosteroid action [62]. Other measures that support the patient until the inflammatory processes in the airways have resolved include supplemental oxygen, judicious fluid administration, and, when indicated, mechanical ventilation.

β_2-Adrenergic Agonists

β_2-Adrenergic agonists bind to β_2-adrenergic receptors on airway smooth muscle cells and cause relaxation of the muscle cell. Although the primary cellular target of β_2-adrenergic agonists is airway smooth muscle, other cell types in the airways also express β_2-adrenergic receptors that may regulate mediator release by mast cells, epithelial cells, and nerves.

There are two general classes of β_2-adrenergic agonists. Short-acting β_2-adrenergic agonists (SABA) have bronchodilatory effects that last for 3 to 5 hours. They include

epinephrine, isoproterenol, terbutaline, metaproterenol, albuterol, and fenoterol. These short-acting agents have an onset of action less than 5 minutes and are the mainstay of bronchodilator therapy for acute asthma. These agents differ in their selectivity for β_2-adrenergic receptors, the rank order of selectivity being epinephrine < isoproterenol < metaproterenol < fenoterol, terbutaline, and albuterol [63]. However, all of these agents have approximately equal efficacy in the treatment of asthma. Another class of drugs, the long-acting β_2-adrenergic agonists (LABA), have bronchodilatory effects for at least 12 hours, but these agents are not currently recommended in the treatment of acute exacerbations [1,2,44]. There has been significant controversy on whether chronic use of these long-acting agents predisposes patients to increased severe, life-threatening, or fatal asthma exacerbations [64].

Among the short-acting β_2-adrenergic agonists, a single-isomer preparation (i.e., R-albuterol or levalbuterol) is available. The potential advantage of this preparation is that the S-enantiomer present in racemic albuterol, does not contribute to bronchodilation and might have deleterious effects in the airways. However, although some studies of levalbuterol (R-albuterol) in the emergency department setting have suggested that levalbuterol is a more efficacious bronchodilator than racemic preparations, there have been no large, randomized, double-blind and controlled trials in adults to confirm these findings [65–67].

The major side effects of β_2-adrenergic agonists during the treatment of severe asthma exacerbations are tremor, cardiac stimulation, and hypokalemia [68]. Case reports have associated lactic acidosis with the use of β_2-adrenergic agonists as well [69]. These side effects are potentially serious, especially in the elderly, who frequently have underlying cardiac disease. Cardiac toxicity can be minimized by using agonists with high β_2-adrenergic receptor selectivity, by avoiding systemic administration of β_2-adrenergic agonists, and by maintaining adequate oxygenation [50,70].

β_2-Adrenergic agonists can be administered to patients by inhaled, subcutaneous, or intravenous routes. Numerous studies have shown that the bronchodilator effects of inhaled β_2-adrenergic agonists are rapid in onset and equal to the effect achieved by systemic delivery [71]. Because the inhaled route allows administration of comparatively small doses directly to the airways with minimal systemic toxicity, this route is almost always preferable to systemic delivery [1,2].

Several options exist for the delivery of inhaled β_2-adrenergic agonists (see Chapter 62). A small-volume nebulizer is widely used. However, studies have shown that metered-dose inhalers (MDIs) equipped with spacer devices are as effective as small-volume nebulizers in the treatment of acute asthma, although some patients may have difficulty coordinating MDI use, especially during an acute exacerbation with severe respiratory distress [1,72,73]. Frequent, multiple inhalations of the medication may allow for progressively deeper penetration of the drug into peripheral airways [74]. In fact, continuous administration by nebulizer may be more effective in severely obstructed patients [75,76]. For administration of inhaled albuterol in the treatment of severe exacerbations of asthma, National Institutes of Health guidelines recommend treatment with MDI (90 μg per puff; four to eight puffs every 20 minutes up to 4 hours, then every 1 to 4 hours as needed) or nebulizer treatments, either intermittent (2.5 to 5.0 mg every 20 minutes for 3 doses, then every 1 to 4 hours as needed) or continuous (10 to 15 mg per hour) [1] (see Management section).

Intermittent positive-pressure breathing devices to deliver aerosols were once popular but are not used today because many patients with severe asthma cannot tolerate the device and because the devices are no more effective than small-volume nebulizers [77]. Furthermore, the risk of barotrauma is significantly increased with intermittent positive-pressure breathing devices, and pneumothorax resulting in death has been reported [78].

Because of its lower density than oxygen, heliox-powered nebulizer treatments have the potential to improve penetration of aerosols into the lungs. Adult patients with severe asthma exacerbations had greater improvements in peak expiratory flow rates and dyspnea scores when albuterol was delivered using heliox, rather than oxygen, driven nebulization [79,80]. Current National Institute of Health Guidelines suggest that heliox-driven albuterol nebulization be considered for patients with life-threatening exacerbations or for those with severe exacerbations even after 1 hour of intensive conventional therapy [1].

Theoretically, systemic administration of beta-adrenergic agonists could deliver drugs via the bloodstream to obstructed airways that are poorly accessible to inhaled aerosols. However, this theoretical advantage has not been supported by most studies [71]. Subcutaneous epinephrine (adults, 0.3 mL of a 1 to 1,000 solution every 20 minutes for three doses) was a traditional therapy for acute asthma in emergency departments, but it is not more effective than aerosol delivery of β_2-adrenergic agonists [81]. A major concern with the use of subcutaneous epinephrine in adults has been cardiac toxicity [82]. More selective β_2-adrenergic agonists, such as terbutaline, are available for subcutaneous use, but cardiac toxicity in elderly individuals is still a significant concern even with these more selective agents. Formerly, intravenous isoproterenol (0.05 to 1.50 μg per kg per minute) was often used to treat severe exacerbations of asthma [83]. However, intravenous delivery of β_2-adrenergic agonists is no longer recommended for the routine treatment of even severe exacerbations of asthma [1,2]. No convincing evidence has shown intravenous administration to be superior to inhaled delivery of β_2-adrenergic agonists. The lack of enhanced efficacy and the potential cardiac toxicity of intravenous β_2-adrenergic agonists have led most authorities to reserve intravenous delivery for those rare patients who continue to deteriorate on mechanical ventilation despite maximal routine therapy with inhaled β_2-adrenergic agonists [83]. Intravenous β_2-adrenergic agonists should be used only in closely monitored adults because myocardial ischemia can occur [84]. It is important to emphasize again that intravenous β_2-adrenergic agonists are not recommended in current NIH guidelines and are unlikely to be any more effective than inhaled β_2-adrenergic agonists such as albuterol [1].

Cholinergic Antagonists

The muscarinic cholinergic antagonists (e.g., atropine, ipratropium and tiotropium) are less effective and more slowly acting bronchodilators than β_2-adrenergic agonists [85–87]. In general, these agents should not be used as the sole bronchodilator therapy for acute asthma. Exceptions may be bronchospasm induced by acetylcholinesterase inhibitors or β_2-adrenergic antagonists and patients with severe cardiac disease who are unable to tolerate β_2-adrenergic agonists.

However, inhaled cholinergic antagonists have a low incidence of side effects and are a recommended adjunct to β_2-adrenergic agonists in the initial emergency department treatment of severe exacerbations of asthma [1,88]. Because even small improvements in airflow could prove clinically significant in the severely obstructed and deteriorating patient, it is recommended that ipratropium be routinely added to β_2-adrenergic agonist therapy during the initial treatment of severe asthma exacerbations in the emergency department [1] (see Management section). However, although comparable trials for adults do not exist, controlled trials in children have not shown a benefit of continuing ipratropium treatment once the patient is hospitalized [89,90]. Therefore, inhaled ipratropium bromide currently is not recommended for hospitalized

patients with severe exacerbations of asthma [1]. The long-acting anticholinergic, tiotropium, has a role in treating outpatients with difficult to control asthma, but whether it has a role in treating hospitalized patients with acute exacerbations of asthma is not yet known [91].

Methylxanthines

Because the literature does not demonstrate a benefit to adding methylxanthines to β_2-adrenergic agonists in the acute setting [92,93] and because they increase toxicity [92], methylxanthines are no longer recommended in the treatment of asthma exacerbations [1]. Whether newer, less toxic, subtype selective phosphodiesterase inhibitors have a role in the management of acute asthma exacerbations remains to be studied.

For rare patients whose condition is deteriorating despite maximal routine recommended therapy with bronchodilators, corticosteroids and other adjuncts [1], the use of methylxanthines might be considered by some physicians. For patients not already taking methylxanthines, a loading dose of aminophylline (6 mg per kg lean body weight) can be administered during 20 to 30 minutes, followed by an intravenous infusion at the rate of 0.6 mg per kg per hour. This infusion rate should be decreased if conditions are present that decrease methylxanthine clearance, especially congestive heart failure, cirrhosis, and the use of cimetidine, ranitidine, allopurinol, oral contraceptives, erythromycin, ciprofloxacin, or norfloxacin. Six hours after initiation of the infusion, the serum theophylline level should be checked and the infusion rate adjusted accordingly, with 10 to 15 μg per mL being therapeutic. Serum concentrations greater than 20 μg per mL are toxic.

Corticosteroids

Numerous studies have documented the safety and effectiveness of short courses of corticosteroids in the treatment of acute exacerbations of asthma [1,2,61,94–96]. Their beneficial effects are attributed to their many potent anti-inflammatory effects on multiple cell types [97]. Corticosteroids inhibit inflammatory cytokine release by macrophages and T cells; decrease expression of endothelial cell adhesion molecules to inhibit migration of inflammatory cells into the airway; increase neutral endopeptidase expression to enhance degradation of neuropeptides that regulate inflammation; decrease mast cells, eosinophils, and CD4+ T lymphocytes in the airway submucosa; and decrease secretions from gland cells [97].

Systemic corticosteroids are the principal therapy for acute exacerbations of asthma [1,2,61]. Prednisone, prednisolone, and methylprednisolone are the preferred agents. Compared with betamethasone and dexamethasone, neither prednisone nor methylprednisolone contain metabisulfites and both have shorter half-lives. Although hydrocortisone has the shortest half-life, it has greater mineralocorticoid effect and may cause idiosyncratic bronchospasm in some aspirin-sensitive individuals [98].

The optimal route of corticosteroid administration in the treatment of acute asthma is not well established by double-blind, placebo-controlled clinical studies. For initial treatment of an acute exacerbation of asthma, several studies suggest that oral administration of corticosteroids is as effective as intravenous therapy [1,2,61,99,100]. The oral route is preferred unless there is the possibility of impaired gastrointestinal tract transit time or absorption [1,2].

Currently, inhaled corticosteroids do not have a well-established role in the treatment of acute exacerbations of asthma in hospitalized patients [1,2,61,101]. However, mounting evidence suggests that inhaled corticosteroids are an effective addition to albuterol in the acute setting and they effectively prevent relapses of asthma after discharge from the emergency room [1,2,102,103]. Inhaled corticosteroids may have topical effects that rapidly (less than 3 hours) vasoconstrict bronchial mucosal blood vessels and this could be one rapid mechanism of relieving airway obstruction, at least partially [104].

The optimum dosages of corticosteroids for the treatment of acute asthma are not well established by randomized controlled clinical trials either [1,2,61,105]. One study compared 15, 40, and 125 mg methylprednisolone every 6 hours and suggested that patients improved most rapidly with the 125-mg dose [106]. However, most studies have failed to show a dose-response relationship for doses this high [105]. For example, one study showed no difference between 100 and 500 mg methylprednisolone in the emergency department treatment of asthma [107].

For adults, NIH guidelines recommend that prednisone, methylprednisolone or prednisolone all be given at 40 to 80 mg per day in one or two divided doses until PEFR is 70% of predicted or personal best [1]. GINA guidelines describe appropriate dosing as the equivalent of 60–80 mg of methylprednisolone as a single daily dose, with 40 mg of methylprednisolone being adequate in most cases [2]. According to NIH guidelines the duration of systemic corticosteroid treatment for a patient requiring an emergency department visit or a hospitalization is usually 3 to 10 days [1]. GINA guidelines recommend a 7-day course for adults [2]. For courses lasting less than 1 week and for treatment courses lasting up to 10 days, there is no established benefit to slowly tapering the daily oral corticosteroid dose, especially if the patient is also using inhaled corticosteroids [1,2,61].

Oxygen

Supplemental oxygen therapy should be the initial intervention in the emergency department [1,2]. Because $\dot{V}/\dot{Q}$ mismatch is the dominant cause of hypoxemia in asthma, the PaO_2 usually increases readily in response to low levels (2 to 4 L per minute oxygen by nasal prongs) of supplemental oxygen therapy. In addition to mitigating the cardiac and neurologic complications of severe hypoxemia, low-flow supplemental oxygen minimizes potential episodes of hypoxemia due to the acute administration of β_2-adrenergic agonists, decreases elevated pulmonary vascular pressures due to hypoxic vasoconstriction, decreases bronchospasm due to hypoxia, and improves oxygen delivery to respiratory muscles. Although low-flow oxygen is beneficial, the routine use of 100% oxygen to treat acute asthma should be avoided because this is usually not necessary and some evidence suggests that it may cause carbon dioxide retention [108].

Fluids

No convincing evidence has shown that fluid administration in excess of euvolemia hastens mobilization of inspissated secretions in the airways [1]. Fluid therapy should be used conservatively unless significant dehydration is present.

Other Agents

Intravenous magnesium sulfate (for adults, 2 g $MgSO_4$ in 50 mL saline during 20 minutes) has bronchodilator properties and it has been recommended that emergency department physicians consider its use in the treatment of severe asthma exacerbations [1,2]. The NIH guidelines recommend that it be used as adjunct treatment only in life-threatening exacerbations and in cases refractory to initial intensive conventional therapy

because it may sometimes help to avoid intubation. Although no major adverse events have been associated with $MgSO_4$ in this setting, guidelines do not recommend its routine use in the treatment of severe acute asthma exacerbations in general because results of meta-analyses remain mixed [1,2,109–111]. Additional study is needed, but some evidence suggests that its use may reduce hospitalization rates in the most severely obstructed patients who have an FEV_1 less than 25% of predicted [112]. Inhaled, rather than intravenous, magnesium sulfate may also have a role in the treatment of acute asthma. That is, there is some evidence to suggest that albuterol nebulized in magnesium sulfate solution may be a more effective bronchodilator than albuterol nebulized in normal saline [113].

Neither GINA nor NIH asthma guidelines recommend helium–oxygen therapy for routine treatment of acute asthma exacerbations [1,2]. Some improvement in airway resistance may be achieved by delivering a mixture of helium and oxygen gases (heliox) to patients, but its role in the routine treatment of acute asthma remains unestablished [114,115]. However, other evidence does support a different role for heliox in the treatment of acute asthma and that is to improve the delivery of inhaled beta-adrenergic agonists, such as albuterol [79,80]. Current NIH guidelines suggest that heliox-driven albuterol nebulization be considered for life-threatening exacerbations or those exacerbations refractory to intensive conventional therapy [1].

Some therapeutic agents that are used in the treatment of stable asthma have no established role in the treatment of severe exacerbations of asthma in hospitalized patients. These include aerosolized corticosteroids and sodium cromolyn as well as oral β_2-adrenergic agonists, which may cause significant systemic toxicities. Although there is as yet no established role for the use of leukotriene antagonists in the treatment of acute asthma exacerbations, some evidence suggests a possible role and need for further study [116]. Mucus is an important cause of airway obstruction in acute exacerbations of asthma, but the routine use of mucolytics, such as acetylcysteine, potassium iodide, or human recombinant deoxyribonuclease (DNase), has not been shown to be effective in treating severe exacerbations of asthma, and at least one of these agents, acetylcysteine, may worsen cough and bronchospasm [117]. However, it is notable that acetylcysteine and DNase may be helpful during therapeutic bronchoscopy (see Additional and Unconventional Management Measures section).

Bacterial infections appear to play, at most, a minor role in the precipitation of severe asthma exacerbations [1,2,118]; for this reason, antibiotics are not routinely administered unless an active bacterial infectious process, particularly pneumonia and bacterial sinusitis, is suspected. However, intriguing evidence suggests that infections due to *Mycoplasma pneumoniae* [119] or *Chlamydia pneumoniae* [120] might play an important role in the pathogenesis of asthma and could be a precipitant of asthma exacerbations. Further work is needed to resolve this important issue.

Unless a patient is mechanically ventilated, sedatives and narcotics have no role in the treatment of severe exacerbations of asthma [1,2]. These agents depress the respiratory central drive to breathe that is critical for adequate minute ventilation. Theoretically, narcotics also may cause mast cell degranulation and worsen bronchospasm.

MANAGEMENT

Emergency Department

The National Asthma Education and Prevention Program, conducted under the auspices of the National Institutes of Health, published guidelines for the assessment and management of patients with acute exacerbations of asthma [1]. These guidelines have been widely accepted and we recommend them. Initial management of a patient with an acute exacerbation of asthma is based on the physician's assessment of the degree of airway obstruction and the patient's response to initial bronchodilator therapy using β_2-adrenergic agonists. If, in the initial assessment, the patient is in extreme distress and has evidence of fatigue, impaired consciousness, or hypercapnia such that respiratory arrest is judged imminent, endotracheal intubation and mechanical ventilation should be the first priorities and then systemic corticosteroids and nebulized β_2-adrenergic agonists and ipratropium should be started immediately. On the other hand, if respiratory arrest is not impending within minutes, 2 to 4 L per minute of supplemental oxygen should be initiated to keep oxygen saturation greater than 90%; β_2-adrenergic agonists should be delivered by aerosol for three doses over 60 to 90 minutes (e.g., albuterol, 2.5 to 5.0 mg, every 20 minutes by small-volume nebulizer for 3 doses, then 2.5 to 10 mg every 1 to 4 hours as needed, or 10 to 15 mg per hour continuously or, alternatively, albuterol, 90 μg per puff, four to eight puffs by MDI with spacer every 20 minutes up to 4 hours, then every 1 to 4 hours as needed). If the PEFR is less than 50% of the predicted value, an oral systemic corticosteroid should be started immediately and an inhaled anticholinergic as well (e.g., ipratropium bromide, 0.5 mg by nebulizer every 20 minutes for three doses and then every 2 to 4 hours as needed). After these treatments are initiated, a more detailed history and physical and laboratory examination can be completed. Close monitoring and repeated airflow measurements are critical for detecting further deterioration during this initial period of treatment.

After the initial treatment with a bronchodilator, patients are reassessed. Those who do not respond substantially (FEV_1 or PEFR greater than 70% of predicted) within 1 hour to initial treatment with β_2-adrenergic agonists should be given systemic corticosteroids (if not already given). Oral prednisone is generally recommended unless there is concern that gastrointestinal tract absorption will be less than optimal [1,2].

In addition to corticosteroids, treatment with β_2-adrenergic agonists and inhaled anticholinergics is continued for 1 to 3 hours with frequent reassessment. Patients who achieve an FEV_1 or PEFR of greater than 70% during this 1- to 3-hour period should be observed for at least 1 additional hour to ensure stability of the improvement. In one study, two thirds of patients who presented to the emergency department responded to albuterol, with the FEV_1 increasing to at least 60% of predicted [121]. Most patients with such a good response do not require hospitalization. Exceptions are patients with a history that is suggestive of high risk for mortality from asthma (e.g., history of intubation and mechanical ventilation; Table 48.4). Patients discharged from the emergency department should be continued on systemic corticosteroids and β_2-adrenergic agonists, considered for initiation of inhaled corticosteroids, given instructions on medication use, given an action plan in case symptoms worsen, and given specific instructions on medical follow-up [1,2,44,122].

Patients who have an FEV_1 or PEFR that is greater than 40% but less than 70% after 4 hours of treatment have an incomplete response and require a careful triage decision. Some patients do well if discharged with detailed instructions, close medical follow-up, and continued systemic corticosteroids. However, other patients do poorly if discharged. It has been recommended that patients with incomplete responses be hospitalized when there is any clinical feature to suggest high risk for asthma mortality (Table 48.4). Patients with an FEV_1 or PEFR of less than 40% of predicted after 4 hours of intensive bronchodilator therapy (poor response) should be hospitalized, often in an intensive care unit (ICU) setting.

TABLE 48.4

FACTORS FAVORING HOSPITALIZATION AFTER INITIAL BRONCHODILATOR THERAPY

Poor response to initial therapy
OR
Incomplete response to initial therapy and one or more of the following:
History of endotracheal intubation or ICU admission for asthma
Recent emergency department visit for asthma
Recent hospitalization for asthma
Multiple emergency department visits for asthma in last year
Duration of current exacerbation >1 wk
Current use of oral corticosteroids
Home situation inadequate for follow-up
Psychiatric conditions that may interfere with medical compliance
History of syncope or seizures during prior exacerbations

Treatment During Pregnancy

Pregnancy should not alter treatment of an uncomplicated acute exacerbation of asthma. Because severe asthma exacerbations have been associated with increased perinatal mortality, probably due to maternal hypoxia and respiratory alkalosis [123,124], the excellent control of asthma should be a main priority [125–127] (see Chapter 51). However, unfortunately, many pregnant women are suboptimally treated for asthma in the acute setting [128]. This is unfortunate because, in both the chronic and the acute setting, abundant evidence supports the safety of β_2-adrenergic agonist use during pregnancy [125]. Also, although chronic administration of systemic corticosteroids throughout pregnancy appears to carry some risk to the fetus [129], short courses of corticosteroids are considered safe for the fetus compared with the serious risks associated with poorly controlled asthma. Therefore, corticosteroids should not be withheld from pregnant women who present with an acute asthma exacerbation. Treatment of chronic asthma during pregnancy should include inhaled corticosteroids [130,131], which is important for preventing development of acute asthma exacerbations [132].

Routine Inpatient Management

Most patients with severe exacerbations of asthma who are admitted to the hospital can be monitored and managed safely on a hospital ward that is well staffed by physicians, experienced nursing personnel, and respiratory therapists. However, patients with severe airway obstruction who are at high risk for mortality from asthma, especially those with an elevated $PaCO_2$ (greater than 42 mm Hg) or changes in mental status despite initial intensive bronchodilator therapy, need the close monitoring of an ICU setting for possible intubation and mechanical ventilation.

Pharmacotherapy for hospitalized patients includes a continuation of the inhaled β_2-adrenergic agonists and systemic corticosteroids begun in the emergency department [1,2]. Specifically, it is not recommended that ipratropium bromide be routinely continued once a patient is hospitalized [1]. For patients with severe airway obstruction and only transient relief from treatment, inhaled β_2-adrenergic agonists can be administered frequently as needed (e.g., every 20 minutes). For patients with less severe obstruction or those with intolerable side effects, frequency can be reduced accordingly. Most patients require β_2-adrenergic agonists a minimum of every 4 hours; however, a recent study has shown that ad libitum administration of albuterol every 4 hours is as effective as regularly timed administration of albuterol [133]. Evidence indicates that delivery of β_2-adrenergic agonists by small-volume nebulizer and delivery by MDI with spacer give equivalent results [1,2,72].

Most hospitalized patients begin to show improvement in expiratory airflow after 6 to 12 hours of systemic corticosteroid therapy, but improvement sufficient for hospital discharge frequently takes 2 to 7 days [134]. In one series, mean length of hospital stay was 4 days, with a range of 0.5 to 17.0 days [135]. Expiratory airflow should be measured at least twice a day to assess the patient's progress. Patient exercise tolerance and PEFR usually improve incrementally during hospitalization, but it is common for patients recovering from exacerbations to have a hospital course punctuated by periods of worsening dyspnea, especially at night. These episodes of nocturnal worsening require patient assessment but generally respond well to inhaled β_2-adrenergic agonists. When the expiratory flow rate does not improve during the initial days of hospitalization, additional or alternative diagnoses, especially laryngeal dysfunction, congestive heart failure, and pulmonary thromboembolism, as well as gastroesophageal reflux disease and sinusitis, should be considered.

As the hospitalized patient recovers, the intensity of therapy is decreased gradually. When the patient has minimal or no wheezing, is no longer awakened by dyspnea at night, can tolerate activity without oxygen desaturation of hemoglobin, and has expiratory flow rates that have substantially improved, he or she is ready for hospital discharge. Patients generally should have a PEFR at least 70% of baseline at the time of discharge. Other patients with an incomplete response to therapy (50% to 70% of baseline) should be assessed individually.

Discharge planning is important for preventing future exacerbations (Table 48.5) [1,2,122]. Patients must be educated about asthma and the importance of seeking medical advice early in the course of exacerbations. Particularly important are detailed instructions on MDI use, routine measurement of PEFR, and keeping a symptom diary at home [136]. On discharge, the patient is given medication instructions with particular attention to oral and inhaled corticosteroids (see Corticosteroids section) [61,105]. This is important, because bronchial hyperresponsiveness remains high for at least 10 days after discharge from an ICU for severe asthma [137]. Patients who have recovered from an exacerbation of asthma should be instructed to use short-acting inhaled β_2-adrenergic agonists on an as-needed basis only.

MANAGEMENT OF RESPIRATORY FAILURE

Assessment

When severe hypoxemic or hypercapnic respiratory failure is present, mechanical ventilation is potentially life-saving. Even patients with severe obstruction can be supported with mechanical ventilation for the vital hours needed for corticosteroid action. However, mechanical ventilation for a severe asthma exacerbation can be complicated by morbidity and mortality, with mortality ranging from 0% to 38% in the literature [138–140].

The decision to initiate mechanical ventilation for a severe asthma exacerbation should be based on a number of considerations individualized for each patient [140]. For patients in severe distress in whom respiratory arrest has already occurred or is imminent, the need for intubation and mechanical ventilation is obvious. The possibility of pneumothorax should be promptly addressed in these patients. Patients who are not *in extremis* should be monitored closely during initial bronchodilator therapy, and the physician should be prepared to perform intubation in case of substantial deterioration. The decision to intubate during a severe asthma exacerbation is a clinical judgment. In severely obstructed patients with decreasing objective measures of airflow, worsening mental status, or signs of respiratory muscle fatigue despite bronchodilator therapy, urgent intubation and mechanical ventilation should be strongly considered. In general, any patient who responds poorly to initial bronchodilator therapy and has an initial $PaCO_2$ of 40 mm Hg or more in association with moderately severe hypoxemia should have close serial ABG monitoring. In patients with a $PaCO_2$ of greater than 55 to 70 mm Hg, increasing $PaCO_2$ (greater than 5 mm Hg per hour) in association with a PaO_2 of less than 60 mm Hg or the presence of metabolic acidosis, intubation and mechanical ventilation should be very strongly considered [52,138]. However, it is emphasized that when clinical signs indicate a need for intubation, the decision to intubate should be made immediately and never delayed, waiting for an ABG result. The role of noninvasive positive-pressure ventilation in managing patients with acute asthma is not established and NIH asthma guidelines do not make recommendations on its application, considering it experimental at this time [1,141–143] (see Chapter 59).

Endotracheal Intubation

Airway control should be established by the most experienced personnel available because even minor manipulation of the larynx and trachea can precipitate vagal reflexes that elicit laryngospasm and bronchospasm [140]. Atropine can be given before intubation to attenuate these vagally mediated reflexes. Lidocaine can be used to achieve topical anesthesia of the hypopharynx and larynx, but even lidocaine has been associated with bronchospasm [144]. Administration of a short- and rapid-acting intravenous benzodiazepine often can facilitate patient relaxation and preoxygenation, allowing time for a controlled intubation that minimally irritates the larynx and trachea. Opiates are not used for intubation or sedation in asthmatic patients because narcotics can provoke nausea and vomiting and theoretically can provoke histamine release that worsens bronchospasm.

Oral, rather than nasal, intubation is preferred in patients with a severe asthma exacerbation because nasal polyps and sinusitis are common in asthma and because the oral route allows placement of a larger endotracheal tube (internal diameter, 8 mm). A large endotracheal tube facilitates the option of therapeutic bronchoscopy at a later time.

TABLE 48.6

GOALS OF MECHANICAL VENTILATION

Maintain oxygen saturation of hemoglobin (>90%; 95% during pregnancy)
Minimize dynamic hyperinflation Decrease minute ventilation Increase expiratory time Accept hypercarbia
Monitor closely for complications of mechanical ventilation

Invasive Mechanical Ventilation

The guiding principle for mechanical ventilation during a severe exacerbation of asthma is to provide adequate oxygenation while minimizing the risk of barotrauma (Table 48.6). Because the risk of barotrauma is related to dynamic hyperinflation of the lungs and high plateau airway pressures, a ventilatory strategy that minimizes lung volumes and airway pressures should be used [1,2,6,7,140]. (See Chapter 58 for a discussion of initiating mechanical ventilation.)

With outmoded mechanical ventilation strategies that aimed to normalize the $PaCO_2$, high tidal volumes and rapid frequencies of ventilation were required, and this promoted increased air trapping and high airway pressures. Most authorities now believe that high airway pressures are to be avoided because they are a major cause of serious morbidity and mortality during mechanical ventilation of asthmatic patients [140,145–147].

The modern strategy for mechanical ventilation for a severe exacerbation of asthma is controlled hypoventilation with permissive hypercapnia [6,7,140,145–148] (see Chapter 58). This strategy does not attempt to establish a normal $PaCO_2$ as long as the minute ventilation and fraction of inspired oxygen maintain adequate tissue oxygenation. Physician acceptance of hypercapnia in this setting is termed *permissive hypercapnia* [145–147]. When possible, measurement of volume at end inspiration should be part of the management plan to monitor for the development of dynamic hyperinflation [149] (see Chapter 58).

Although the use of sodium bicarbonate to treat acidosis is controversial, advocates for its use in severe acute respiratory acidosis have regarded a pH of 7.20 to be the minimum safe level [150]. This impression and the practice of infusing sodium bicarbonate to maintain a pH of more than 7.2 is based on two uncontrolled studies in which stuporous and comatose patients with acute respiratory acidosis markedly and quickly improved when infusion of sodium bicarbonate increased the pH to greater than 7.2 [151,152]. However, no controlled studies of respiratory acidosis support the use of sodium bicarbonate to maintain a specific pH value.

The physiologic responses to metabolic and respiratory acidosis include increases in cardiac output, pulmonary arterial pressure, and heart rate, whereas systemic vascular resistance decreases and mean systemic arterial pressure remains unchanged [153–155]. In diseased lungs, PaO_2 improves [153]. The hemodynamic changes are mediated directly by endogenous secretion of catecholamines, primarily norepinephrine, stimulated by decreases in pH. The effects of sodium bicarbonate infusions on these hemodynamic responses and gas exchange have been studied. As the acidosis lessens, cardiac output and PaO_2 worsen [154,155]. Moreover, sodium

bicarbonate infusions have been shown neither to improve survival nor to enhance bronchodilation. Although studies from the 1950s and 1960s suggested that endogenous epinephrine release was depressed in acidosis, more recent studies have conclusively shown that it is either unchanged or augmented [155]. Because carbon dioxide is generated when infused sodium bicarbonate buffers hydrogen ions, infusion of sodium bicarbonate predictably raises carbon dioxide tensions in blood [156]. Because carbon dioxide readily diffuses across cell membranes, sodium bicarbonate therapy may cause paradoxic intracellular acidosis [157], and this may adversely affect survival. For these reasons, we suggest use of sodium bicarbonate only when the acidosis appears to be adversely affecting the patient's hemodynamic status.

In managing patients during mechanical controlled hypoventilation with permissive hypercapnia, the minimum safe pH is not known. In three uncontrolled studies, pH values were not maintained at greater than 7.2, and outcomes did not appear to be adversely affected. Sodium bicarbonate was not given in one study unless pH was less than 7.15 [149]; in the other two studies, it was not given to any patient even when pH was 7.02 and less than 7.00 [145,158].

Neuromuscular blocking agents, such as pancuronium, vecuronium, and atracurium, can be used to help maintain low airway pressures during delivery of mechanical ventilation (see Chapter 25). Paralyzing skeletal muscles prevents the development of high airway pressures due to the patient bucking or fighting the ventilator. Notably, a side effect of neuromuscular blocking agents can be severe bronchospasm. Vecuronium is often reported to be unlikely to cause bronchospasm, but case reports suggest that vecuronium too can rarely cause bronchospasm [159]. Another adverse effect of these agents is that patients who undergo even brief neuromuscular blockade in conjunction with corticosteroid administration have a risk of developing a prolonged and sometimes severe myopathy [160]. Because all patients with severe exacerbations of asthma are treated with corticosteroids, paralyzing agents should be avoided whenever possible. For patients who cannot be managed without neuromuscular blockade, continuous infusions of neuromuscular blocking agents should be avoided and muscle function should be allowed to recover partially between repetitive boluses.

Mechanical ventilation accomplishes the work of breathing while the severely obstructed patient is treated intensively with inhaled bronchodilators and glucocorticoids. With this intensive pharmacologic therapy, mechanical ventilation usually can be discontinued in 1 to 3 days once discontinuation guidelines are met [140,161–163] (see Chapter 60). Some patients may require 2 to 4 weeks of mechanical ventilation, especially when pneumonia complicates an acute exacerbation of asthma.

Complications of Mechanical Ventilation

Serious complications have been reported as a result of mechanical ventilation for severe exacerbations of asthma [138,139,140,148]. Most of these are preventable or treatable if detected early. Problems with airway control, including traumatic and esophageal intubation, should always be anticipated. Intubation of the right mainstem bronchus is a serious problem of airway control because delivery of tidal volumes to one lung increases the risk of barotrauma. Once an airway is established and mechanical ventilation initiated, hypotension may occur because high intrathoracic pressures that occur during mechanical ventilation in severe asthma exacerbations impede venous return to the right ventricle of the heart. This is treated by administering intravenous fluids and adjusting tidal volumes, respiratory frequency, and inspiratory flow to decrease hyperinflation and intrinsic positive end-expiratory pressure [164].

Barotrauma is a major cause of morbidity and mortality among patients receiving mechanical ventilation for severe exacerbations of asthma [140,148,164]. High plateau airway pressures are associated with overdistended alveoli that rupture. Air may dissect along the bronchovascular interstitium and sometimes is evident on chest radiograph as parenchymal air cysts, linear air streaks emanating from the hila, and perivascular air halos [165,166]. As the air dissects centrally, mediastinal and subcutaneous emphysema develop. As an alternative, air from ruptured alveoli may dissect through the pleural surfaces into the pleural space to create a pneumothorax [167]. For patients on mechanical ventilation, pneumothorax progresses to tension pneumothorax rapidly and always should be treated immediately with tube thoracostomy. It must be presumed, emergently, that any pneumothorax during mechanical ventilation is under tension [168]. (See Chapter 58 for the discussion of minimizing barotrauma during mechanical ventilation.)

Mucous plugging commonly occurs during acute exacerbations of asthma. Large mucous plugs occluding the endotracheal tube should be considered when there is insurmountable difficulty in ventilating a patient. Large mucous plugs also may cause lobar or lung atelectasis that impairs gas exchange and increases airway pressures. Therapeutic bronchoscopy may be considered to relieve large mucous plugs if conservative measures, corticosteroids, and bronchodilators are not effective. Retained secretions and atelectasis also contribute to the significant risk of nosocomial pneumonia during mechanical ventilation [169].

Other complications are indirectly related to mechanical ventilation. Thromboembolism and gastric stress ulcers may occur with greater frequency in patients with severe exacerbations of asthma [170]. Arrhythmias and hypokalemia may occur during treatment for acute asthma because of therapy with sympathomimetic drugs. Hypophosphatemia may develop secondary to alkalosis [171].

Additional and Unconventional Management Measures

Even after using bronchodilators, corticosteroids, sodium bicarbonate, and mechanical ventilation, airway obstruction sometimes is sufficiently severe to prevent maintenance of an acceptable arterial pH or adequate tissue oxygenation. In these rare cases, additional, sometimes unconventional, measures can be used to support the patient until corticosteroids have had time to suppress the underlying inflammatory process. Some of these measures are based on anecdotal experience (Table 48.7).

If airway pressures remain high on mechanical ventilation despite the proper application of controlled hypoventilation with permissive hypercapnia, delivering heliox by mechanical ventilation has been suggested to allow adequate ventilation

TABLE 48.7

SPECIAL OR UNCONVENTIONAL THERAPEUTIC MEASURES

Intravenous β_2-adrenergic agonists
Methylxanthines
Helium–oxygen mixtures delivered through the ventilator
General anesthetics
Bronchoscopy with therapeutic lavage (intubated patients only)
Hypothermia
Extracorporeal life support

of the patient at reduced airway pressures [172]. Caution is necessary when using heliox in this setting because the low density of the gas mixture makes ventilator settings inaccurate (e.g., tidal volume) [173].

Bronchospasm usually is not the major factor limiting airflow in patients who are already being maximally treated for an acute exacerbation of asthma. However, for those who fail to respond to maximal conventional therapy, a variety of strategies have been advocated to maximize bronchodilation. Some reports suggest that intravenous β_2-adrenergic agonists may significantly improve airway obstruction in select patients but this treatment is not established and not recommended in current NIH asthma guidelines because of danger of cardiac toxicity [1,83,84]. General anesthetics are excellent bronchodilators and an important option for patients whose conditions are refractory to maximal routine therapy. Anecdotally, halothane [174,175], thiopental [176], ketamine [177,178], and isoflurane [179] all have been used successfully to treat patients with severe asthma exacerbations. If general anesthetics are used, an anesthesiologist should be consulted.

Because a major cause of airway obstruction during an acute exacerbation of asthma is mucous plugging, therapeutic bronchoscopy with lavage has been used as an additional supportive measure in patients who are extremely difficult to ventilate adequately [180–182]. While therapeutic bronchoscopy is not performed routinely in asthma because worsening bronchospasm is a recognized complication of bronchoscopy in asthmatics, should the need arise, a flexible bronchoscope with a large suction channel should be used, and the mechanically ventilated patient should be sedated. *N*-acetylcysteine, a mucolytic agent, is associated with bronchospasm in asthmatic patients but, anecdotally, has been used successfully during therapeutic bronchoscopy by delivering a dilute solution (less than 1%) through the bronchoscope to dissolve mucous plugs [180]. DNase (2.5 mg in 10 mL of sterile normal saline) has been administered through a bronchoscope to relieve mucous plugging causing atelectasis in a child with asthma [183].

Case reports describe unconventional measures that might be considered for the management of rare, exceedingly difficult cases. For example, hypothermia and extracorporeal life support have been methods used to support critically ill patients whose conditions are refractory to conventional therapy [184,185].

Advances in asthma, based on randomized, controlled trials or meta-analyses of such trials, are summarized in Table 48.8 [186].

TABLE 48.8

TREATMENT OF ACUTE ASTHMA: RANDOMIZED CONTROLLED TRIALS AND META-ANALYSES

- β-Adrenergic agonists are first-line therapy for acute asthma because they are rapidly acting and provide more bronchodilation than methylxanthines and cholinergic antagonists [62].
- Metered-dose inhalers with a holding chamber are at least as effective as wet nebulization for the delivery of β-adrenergic agonists in the treatment of acute asthma [72,73].
- Adding inhaled ipratropium bromide to treatment with β-adrenergic agonists provides benefit to adults with acute asthma in the emergency department [88].
- In hospitalized adult patients with acute asthma, systemic glucocorticoids speed improvement of symptoms and lung function [96].
- In addition to a short course of oral corticosteroids, initiate or continue daily inhaled corticosteroids on emergency room discharge of patients with persistent asthma [186].

CHAPTER 49 ■ RESPIRATORY FAILURE PART IV: CHRONIC OBSTRUCTIVE PULMONARY DISEASE

MEYER S. BALTER AND RONALD F. GROSSMAN

Chronic obstructive pulmonary disease (COPD) is defined in the National Heart, Lung, and Blood Institute/World Health Organization Global Initiative for Chronic Obstructive Lung Disease as a disease state characterized by airflow limitation that is not fully reversible [1]. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases. Any patient presenting with symptoms of cough, sputum production, or dyspnea, and/or a history of exposure to risk factors should be considered as having the diagnosis of COPD. The diagnosis can be confirmed by spirometry especially if the forced expired volume of air in 1 second (FEV_1) measured after inhaled bronchodilator (postbronchodilator FEV_1) is less than 80% of the predicted value in combination with an FEV_1 to forced vital capacity ratio less than 70%.

Although a variety of conditions characterized by chronic airflow obstruction have been termed "COPD," the presence of largely irreversible chronic airflow obstruction predominantly in current or former cigarette smokers is the meaning commonly used in the subsequent discussion. Emphysema is the underlying disease process that is mainly responsible for severe airflow obstruction. The distinction between chronic obstructive bronchitis, bronchiolitis, and emphysema is difficult to make with precision and is usually clinically unimportant.

COPD affects more than 5% of the adult population and is associated with increasing morbidity and mortality in the United States and other countries [2]. Mortality rates in the United States have increased from 25.6 per 100,000 population in 1979 to 40.5 per 100,000 population in 2006 [3]. Approximately 750,000 admissions to hospital annually in the United States can be directly attributed to COPD, and the costs associated with the care of all COPD patients has been estimated to be around $24 billion [4]. The World Health Organization has predicted that COPD will be the third leading cause of death and fifth leading cause of disability worldwide by 2020 [5].

ETIOLOGY

The major risk factor associated with the development of COPD is cigarette smoking [6]. The total number of pack-years of smoking correlates best with development of COPD [7,8], although the total length of time spent smoking probably contributes as well [8]. Significant COPD develops in only a minority of even heavy cigarette smokers [9], suggesting that some cofactor(s) (e.g., host susceptibility) must be important. Homozygous α_1-antitrypsin deficiency (a relatively rare condition) is a risk factor for the development of COPD [10] even in the absence of cigarette smoking. It has been estimated that approximately 60,000 patients in the United States have this condition but only a minority are treated [10]. COPD does not necessarily develop in nonsmoking patients with α_1-antitrypsin deficiency, which may explain why only a minority of patients with this condition are treated. Various other factors may increase the risk of COPD, including childhood respiratory illnesses, adenovirus infection, air pollution, the presence of increased airway reactivity, and occupational exposures [11].

PATHOPHYSIOLOGY

Pathogenesis

Respiratory bronchiolitis is the initial lesion seen in smokers [12]. The inflammatory process may progress in susceptible people to glandular enlargement in bronchi, goblet cell metaplasia, smooth muscle hypertrophy, inflammation in membranous bronchioles, worsening respiratory bronchiolitis, and parenchymal involvement with emphysema [13]. The progression of COPD is strongly associated with an increase in the volume of tissue in the wall and the accumulation of inflammatory

mucous exudates in the lumen of small airways [14]. Normally, a relative balance exists between destructive proteolytic enzymes, which are released in the lung as a result of inflammation, and various inhibitory, antiproteolytic substances, which act to dampen the response and limit the damage [15]. In some cigarette smokers, there may be a genetic tendency favoring a greater inflammatory and destructive response to certain elements of cigarette smoke. Population studies show a definite familial tendency toward COPD [16], and pulmonary function comparison studies of identical twins suggest a genetic susceptibility [17].

COPD is characterized by chronic inflammation throughout the airways, parenchyma, and pulmonary vasculature. Macrophages, T lymphocytes (predominately CD8+), and neutrophils are increased in various parts of the lung [18]. Activated inflammatory cells release a variety of mediators—including leukotriene B4, interleukin-8, tumor necrosis factor-α, and others—capable of damaging lung structures and/or sustaining neutrophilic inflammation [5]. There is a relationship between the extent of airway occlusion by inflammatory mucus exudates and the severity of COPD [14].

Physiologic Derangements

Expiratory airflow obstruction results from structural airway narrowing as well as functional narrowing due to loss of radial distending forces on the airways. Inflammatory edema, excessive mucus, and glandular hypertrophy are responsible for intrinsic obstruction of airways. Destruction of alveolar walls causes loss of elastic recoil and airflow obstruction, which increases in a dynamic fashion with expiratory effort.

The pathophysiologic consequences of severe, chronic airflow obstruction in the lung include (a) reduced flow rates that limit minute ventilation; (b) maldistributed ventilation, resulting in wasted ventilation (high ventilation-perfusion [$\dot{V}/\dot{Q}$] mismatch) and impaired gas exchange (low $\dot{V}/\dot{Q}$ mismatch) [19]; (c) increased airway resistance, which causes increased work of breathing [19]; and (d) air trapping and hyperinflation, which alter the geometry of the respiratory muscles and place them at a mechanical disadvantage. The maximum force that they are capable of generating is decreased, which may predispose them to fatigue [20]. In addition to these factors, some patients with COPD may have a blunted respiratory center drive, which further predisposes them to carbon dioxide retention [21].

DIAGNOSIS

The diagnosis of COPD is based on clinical grounds but confirmed by pulmonary function tests (PFTs). Arterial blood gas (ABG) values determine the diagnosis of respiratory failure. Clinical findings are used primarily to suggest the diagnosis, which then must be confirmed on the basis of laboratory findings.

History and Physical Examination

A chronic productive cough and dyspnea on exertion are the two symptoms most commonly associated with COPD. However, a history of a chronic productive cough is nonspecific and may result from a variety of other conditions. Previous studies indicated that there was little correlation found between a chronic productive cough (reflecting large-airway mucus hypersecretion) and the development of significant airflow limitation (predominantly a manifestation of disease of small airways less than 2 mm in diameter) [22]. However, recent studies have shown a consistent association between chronic mucus hypersecretion and both an accelerated decline in FEV_1 and an increased risk of subsequent hospitalization [23]. A history of dyspnea on exertion in a heavy cigarette smoker should always raise the possibility of COPD, which can then be confirmed by objective investigations.

The physical examination can distinguish patients who should undergo objective laboratory testing, but it is less accurate than PFTs in detecting and quantifying the severity of COPD [24]. The most useful physical finding is a definite decrease in breath sound intensity [25,26]. Other suggestive clinical signs include hyperinflation, prolonged forced expiratory time, and wheezing.

A combative, confused, or obtunded patient should alert the physician to the possibility of hypercapnia or hypoxia. Respiratory muscle fatigue is heralded by new onset of paradoxical respiratory motion or respiratory alternans [27]. During normal inspiration, the rib cage moves upward and outward, and the anterior abdominal wall moves outward. With diaphragmatic fatigue, the anterior abdominal wall may move inward during inspiration and outward during expiration. *Respiratory alternans* describes alternate abdominal (diaphragmatic) breathing and rib cage (intercostal) breathing. When overt, this condition can be detected clinically by observing dramatic shifts in relative movement of the abdomen and rib cage every few breaths.

Radiology

Radiographic findings may include (a) hyperinflation with flattened diaphragmatic domes and increased retrosternal and retrocardiac air space; (b) one of two distinctly different bronchovascular patterns, vascular attenuation or prominence of lung markings; (c) enlarged hilar pulmonary arteries and right ventricular enlargement; and (d) regional hyperlucency and bullae [28]. Radiographic studies have low sensitivity for the diagnosis of mild COPD [29].

Computed tomography scanning of the chest is superior to the chest radiograph in diagnosing emphysema and determining the nature and the extent of the disease [29]. Centrilobular emphysema is characterized by the upper lobe distribution of focal areas of low attenuation usually less than 1 cm in diameter. Panlobular emphysema is frequently more recognized in the lower lobes and there is a generalized decrease in lung markings with few blood vessels.

In patients presenting with acute deterioration in respiratory status, a chest radiograph may exclude reversible conditions such as pneumonia, pleural effusion, pneumothorax, atelectasis, and pulmonary edema. However, the diagnostic yield of routine radiographs is low [30]. In the intensive care unit (ICU), technical factors limit the quality of the chest films, making interpretation of a portable anteroposterior film even more difficult. Nevertheless, these studies provide valuable information, particularly in patients receiving mechanical ventilation.

Pulmonary Function Tests

A decrease in the ratio of FEV_1 to forced vital capacity is the hallmark of obstructive airways disease and is useful in the diagnosis of mild disease. However, it is the FEV_1 that is correlated with clinical outcome and mortality [23]. Hypercapnic respiratory failure from COPD is extremely unlikely unless FEV_1 is less than 1.3 L [31] and is usually not observed unless FEV_1 is less than 1 L. COPD is also associated with an increase in total lung capacity and residual volume and a reduction in carbon monoxide diffusing capacity [32].

PFTs are essential for the diagnosis and estimating the severity of COPD; on the other hand, ABG values provide the data

necessary to diagnose and quantitate the severity of respiratory failure. The patient with severe COPD typically presents with an elevated arterial carbon dioxide tension ($PaCO_2$), substantially decreased arterial oxygen tension (PaO_2), and an alveolar–arterial oxygen tension gradient that is significantly increased [33].

DIFFERENTIAL DIAGNOSIS

Asthma, cystic fibrosis, bronchiectasis, and bronchiolitis obliterans all can cause expiratory airflow obstruction. A previous PFT demonstrating reversibility of the airflow obstruction, younger age, presence of blood or sputum eosinophilia, absence of cigarette smoking, and presence of expiratory and inspiratory monophonic wheezing are all suggestive of asthma. Cystic fibrosis is diagnosed on the basis of a positive sweat chloride test in a patient with obstructive lung disease, positive family history for cystic fibrosis, or pancreatic insufficiency. Bronchiectasis may be suggested by a history of copious sputum production, by recurrent chest infections or hemoptysis, or from the chest radiograph.

FACTORS CAUSING AN EXACERBATION OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

According to WHO/NHLBI Global Initiative for Chronic Obstructive Lung Disease (GOLD) document an acute exacerbation is defined as "an event in the natural course of the disease characterized by a change in the patient's baseline dyspnea, cough, and/or sputum that is beyond normal day-to-day variations, is acute in onset, and may warrant a change in regular medications in a patient with underlying COPD" [34]. This can be accompanied by a change in the color and consistency of the expectorated sputum, a feature that is predictive of bacterial infection [35]. Expiratory airflow obstruction is worsened, the work of breathing increases, and mucus production or mucociliary clearance, or both, are altered. Although many factors may be associated with an acute exacerbation (Table 49.1), the most commonly identified cause is an acute upper or lower respiratory tract infection that may be viral or bacterial in etiology [36]. Spirometry shows worsened expiratory airflow obstruction, whereas ABGs usually demonstrate an additional decrease in the PaO_2 and, in patients with severe COPD, development or worsening of arterial hypercapnia. Systemic effects such as fever and neutrophilia are uncommon, and the chest radiograph typically shows no new abnormality.

Some of the other factors listed in Table 49.1 may be easily recognizable, such as a large pneumothorax or pneumonia, but others may be subtle, such as an electrolyte abnormality or unrecognized use of drugs that can cause respiratory center depression. Furthermore, events such as pulmonary embolism may go totally unrecognized because clinical findings such as dyspnea or tachypnea may be attributed to the underlying COPD itself [37] and may be more common than previously thought [38].

TREATMENT

Treatment of the patient with COPD involves chronic management of the stable patient, treatment of acute exacerbations (Table 49.1), and treatment of respiratory failure.

TABLE 49.1

DIFFERENTIAL DIAGNOSIS OF ACUTE DECOMPENSATION IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Air pollution
Aspiration
Bronchiolitis
Carcinoid syndrome
Cardiac arrhythmia
Chest wall injury (e.g., rib fracture)
Cigarette smoking
Cystic fibrosis
Lymphangitic carcinomatosis
Metabolic derangements (e.g., hypophosphatemia)
Parasitic infections
Pleural effusion
Pneumonia
Pneumothorax
Pulmonary edema
Pulmonary embolism
Sedation
Surgery
Systemic illness
Tracheobronchial infection
Upper respiratory tract infection

Chronic Management

Once COPD is diagnosed, smoking cessation is the most important and obvious first step in management. The annual decline in FEV_1 has been demonstrated to be less in ex-smokers than in current smokers [6]. The success of smoking cessation programs is limited, with a 70% to 80% relapse rate in the first year. However, nicotine replacement therapy, the antidepressant bupropion, and repeated counseling are effective in increasing quit rates [39]. The addition of varenicline, an $\alpha_4\beta_2$ nicotinic receptor partial agonist, has improved cigarette-smoking quit rates [40]. Annual influenza vaccination is a useful, cost-effective preventive measure and has been shown to decrease morbidity and mortality related to influenza even among patients with chronic respiratory disease [41,42]. Data regarding the benefit of pneumococcal vaccination are limited to bacteremic pneumococcal infection, but a decrease in hospitalizations and deaths among vaccinated patients with COPD has been observed in observational studies [43].

Inhaled bronchodilators improve airflow obstruction, although to a less marked degree than in asthmatic patients, and improve exercise capacity and quality of life [44]. Although β-agonists and the anticholinergic agent ipratropium bromide are efficacious, the combination is more effective than either of the two agents alone [45]. Long-acting β_2-adrenergic agonists in combination with ipratropium or theophylline are superior to either agent alone, and a long-acting β_2-adrenergic agonist combined with ipratropium is more effective than the short-acting β_2-adrenergic agonist plus ipratropium [46,47]. A long-acting β_2-adrenergic agonist appears to offer the additional benefit of extending the time to an exacerbation [47]. Long-acting anticholinergics have been demonstrated to improve lung function, reduce exacerbations, and improve health-related quality of life [48,49]. In addition to some bronchodilator effects, theophylline may have beneficial effects on diaphragmatic strength, resistance to fatigue, and central nervous system (CNS) respiratory drive [50,51]. This agent produces a clinical benefit in some patients with COPD [52] but, with its narrow therapeutic window, the potential for toxicity

must be recognized. All categories of bronchodilators have been shown to increase exercise capacity in COPD without necessarily producing significant changes in FEV_1 probably by decreasing dynamic hyperinflation. Regular treatment with long-acting bronchodilators is more effective and convenient than treatment with short-acting bronchodilators, but more expensive. They safely attenuate airflow obstruction, decrease the frequency and severity of symptoms by reducing the amount of dynamic hyperinflation, and improve quality of life [53].

Although oral corticosteroids are not routinely recommended in the chronic management of patients with COPD, a small subgroup of patients does benefit [54]. A corticosteroid trial, with PFTs before and after a 2-week course of 20 to 40 mg prednisone daily, has been recommended in the past to identify these patients. More recent studies suggest, however, that this is a poor predictor of long-term response to inhaled corticosteroids [55]. Several studies have documented little effect on the rate of lung function decline with inhaled corticosteroid therapy, but the severity and number of exacerbations may be reduced, especially among patients with frequent exacerbations [56,57]. Short-term treatment with a combined inhaled glucocorticosteroid and long-acting β-agonist resulted in greater control of lung function and symptoms than combined anticholinergic and short-acting β-agonist [58]. Analysis of a number of placebo-controlled trials of inhaled corticosteroids has demonstrated a reduction in all-cause mortality by about 25% relative to placebo [59]. Stratification by individual trials and adjustments for age, sex, baseline postbronchodilator percentage predicted FEV_1, smoking status, and body mass index do not materially change the results. Former smokers and women seem to benefit the most.

There is a growing body of evidence to suggest that the use of a combination of inhaled corticosteroids and long-acting β_2-agonists improves lung function, symptoms, and health status and reduces exacerbations in patients with moderate-to-severe COPD [60]. There may also be a survival benefit. A subsequent post hoc analysis of the Toward a Revolution in COPD Health (TORCH) study indicated that pharmacotherapy with salmeterol plus fluticasone propionate, or the components, reduced the rate of decline of FEV_1 in patients with moderate-to-severe COPD, thus slowing disease progression [61].

The addition of a combination of inhaled corticosteroid and long-acting β_2-agonist (salmeterol plus fluticasone) to a long-acting anticholinergic (tiotropium) improved lung function, health status and reduced hospitalizations compared with the use of a long-acting anticholinergics alone [62]. Therapy with tiotropium added to other respiratory medication (mainly a combination of inhaled corticosteroid and long-acting β_2-agonist) was associated with improvements in lung function, quality of life, and exacerbations during a 4-year period but did not significantly reduce the rate of decline in FEV_1 [63].

Long-term oxygen therapy used for at least 15 hours per day in patients with severe COPD and hypoxia when breathing room air is associated with prolonged survival and improved quality of life, increasing life span by 6 to 7 years [64,65]. Oxygen therapy is recommended for patients with a PaO_2 of less than 55 mm Hg and those with a PaO_2 of 55 to 59 mm Hg who have polycythemia or right-sided heart failure. Significant increases in $PaCO_2$ usually do not occur as a result of this therapy [66].

Pulmonary rehabilitation programs have been demonstrated to improve exercise tolerance and reduce dyspnea and should be part of routine management for patients with significant COPD [67–69]. Nocturnal negative-pressure ventilatory assistance has been used to rest respiratory muscles [70]. Whether this intervention is beneficial is unclear, as a large controlled trial failed to demonstrate improvement in exercise tolerance, ABG values, or quality of life [71]. Successful therapeutic results with nocturnal noninvasive positive-pressure assistance in COPD patients have not been uniformly reported, but there may be a role for selected patients [72].

Acute Exacerbation

Treatment of acute exacerbation can be divided into two primary methods: supportive and specific.

Supportive Therapy

Oxygen Therapy. Supplemental oxygen therapy should be administered to all hypoxemic patients who present with an acute exacerbation. The $PaCO_2$ commonly rises somewhat when a patient with COPD receives supplemental oxygen, but carbon dioxide narcosis due to oxygen therapy is uncommon [73]. Patients should not be kept hypoxemic for fear that oxygen therapy will aggravate carbon dioxide retention, but ABG values should be closely monitored. Supplemental oxygen therapy is discussed later in this chapter (see Respiratory Failure section) and in Chapter 62.

Bronchodilators. Although COPD is characterized by poorly reversible airflow obstruction, there is frequently a significant reversible component, particularly in the setting of an acute exacerbation. Many patients with acute exacerbations of COPD respond to these agents with some improvement in airflow obstruction [74]. Inhaled β-agonists and ipratropium appear to be equally effective bronchodilators in patients with acute exacerbations [75]. These agents can be administered by nebulizer or, with equal efficacy, by metered-dose inhaler using a spacer device [76]. A metered-dose inhaler with an aerosol holding chamber also can be used effectively for patients on mechanical ventilation and is as effective as a nebulizer [77]. For specific details on the use of these agents, see Chapter 62.

The role of theophylline in acute exacerbations is less well accepted than in chronic management. A double-blind, placebo-controlled trial demonstrated no additional benefit of aminophylline over standard therapy, but increased adverse effects were noted [78].

Antibiotics. Although there is no evidence that antibiotics given routinely are beneficial in all exacerbations of COPD, antibiotic therapy is appropriate, particularly in more severe exacerbations (i.e., patients experiencing increased dyspnea and cough with increased sputum volume or purulence) [79]. Frequently, bacteria can be isolated from lower airway samples of patients who have COPD in the stable state. This is known as lower airway bacterial colonization and the presence of these organisms is associated with increased frequency and severity of exacerbations and a more rapid decline in FEV1 [80]. Microbiologic surveys in patients with severe exacerbations requiring mechanical ventilation reveal that potentially pathogenic organisms can be found in 72% [81]. The rate of Gram-negative enteric bacilli and Pseudomonas was high (30%) and could not be predicted clinically. Although the results of a number of earlier, poorly designed studies are inconclusive (Table 49.2), a double-blind, placebo-controlled study on the effects of broad-spectrum antibiotics on exacerbations of COPD demonstrated significant benefit [35]. Antibiotic treatment produced significantly earlier resolution of symptoms and prevented clinical deterioration [35]. A meta-analysis confirmed these observations, suggesting that antibiotics are useful, particularly in patients with significant impairment of lung function [82]. Another meta-analysis suggested antibiotics reduced the risk of short-term mortality by 77%, decreased the risk of treatment failure by 53% and the risk of sputum purulence by 44%; with a small increase in the risk of diarrhea [83]. Clinical benefits from antibiotic therapy are most likely to occur in patients

TABLE 49.2

SUMMARY OF PLACEBO-CONTROLLED TRIALS OF ANTIBIOTIC USE IN EXACERBATIONS OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

No. of patients	Antibiotic	Regimen	Outcome	Reference
71	TMP-SMX or amoxicillin	14-d course	No accelerated recovery	[132]
173	TMP-SMX, amoxicillin, or doxycycline	Ambulatory, 10-d course	Earlier resolution of symptoms; prevented deterioration	[35]
40	Tetracycline	Hospitalized, 7-d course	No benefit over placebo	[133]
259	Tetracycline or chloramphenicol	Ambulatory, 12-d course	Earlier recovery; no difference at 1 mo	[134]
30	Penicillin + streptomycin	Hospitalized, parenteral therapy	Prevented deterioration	[135]
56	Ampicillin	Hospitalized, 7-d course	No benefit over placebo	[136]

TMP-SMX, trimethoprim-sulfamethoxazole.

with more serious exacerbations, particularly those with fever and grossly purulent sputum [84]. The organisms that are usually responsible for bacterial infection in acute exacerbations include *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis*. Between 20% and 40% of strains of *H. influenzae* and 80% to 90% of strains of *M. catarrhalis* are β-lactamase-producing and are resistant to β-lactam antibiotics such as amoxicillin, although the rate of resistance of *H. influenzae* seems to be declining [85]. There is evidence to suggest that more potent, broad-spectrum antibiotics such as amoxicillin-clavulanate or respiratory fluoroquinolones may be associated with better outcomes [86].

Corticosteroids. Short-term use of corticosteroids has been generally advocated in acute exacerbations, although it is only recently that this has been supported by randomized clinical trials (Table 49.3). A short course (2 weeks) of prednisone results in a more rapid improvement in FEV_1, reduced rate of deterioration, and shortened hospital stay and prevents relapses [87–90]. The optimal dose and duration are unclear, but no benefit was noted with an 8-week course compared with 2 weeks [89]. The major adverse effect is hyperglycemia.

Other Interventions. In stable patients with COPD, chest percussion and postural drainage produce no significant improvement in airflow or gas exchange [91]. Moreover, there is no evidence to suggest that these modalities are effective in the COPD patient in exacerbation in the absence of bronchiectasis or bronchorrhea, or both (expectoration of sputum greater than 30 mL per 24 hours).

Patients with severe COPD are frequently nutritionally depleted, contributing to their overall poor status and decreased respiratory muscle strength [92,93]. Nutritional support should be instituted early in the course of hospitalization [94]. A high carbohydrate load via parenteral alimentation may, however, result in increased carbon dioxide production [95]. In a patient with a limited ability to increase ventilation, significant worsening of arterial hypercapnia can result, even requiring the institution of mechanical ventilatory support. Nonprotein calories in the form of fat cause a lower production of carbon dioxide compared with isocaloric amounts of carbohydrate, and a higher fat and reduced carbohydrate supplement may lessen the degree of hypercapnia in selected patients [96]. Such a modification in nutritional support is only necessary when excessive calories are given [97]. A recent systematic overview in patients with COPD suggested that patients with marginal ventilatory reserve might benefit from a dietary regimen in which a high percentage of calories are supplied by fat [98]. Although there are reports of the benefits of nutritional repletion, trials of more than 2 weeks failed to show consistent benefit on body weight.

TABLE 49.3

SUMMARY OF CLINICAL TRIALS OF CORTICOSTEROID USE IN EXACERBATIONS OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Patients	Study design	Therapeutic regimen	Outcome	Reference
271	Randomized controlled	Methylprednisolone 125 mg every 6 h for 72 h IV followed by a tapering oral course of prednisone (2 or 8 wk)	Improved FEV_1, shorter hospital stay	[89]
56	Randomized controlled	30 mg prednisolone orally for 14 d	Improved FEV_1, shorter hospital stay	[88]
30[a]	Retrospective	IV in ED (mean dose 365 mg hydrocortisone) followed by oral (mean dose 42 mg)	Decreased relapse rate at 48 h	[90]
96	Randomized controlled	100 mg methylprednisolone as a single dose IV in ED	No difference in FEV_1 at 5 h or relapse at 48 h	[137]

[a]Thirty patients with 90 acute exacerbations treated with or without steroids.
ED, emergency department; FEV_1, forced expiratory volume in 1 second; IV, intravenously.

Patients with acute respiratory failure may have elevated levels of antidiuretic hormone, decreased renal blood flow, and right heart failure [99]. Diuretics are helpful in correcting these problems [99], but a complicating metabolic alkalosis may follow. In patients with COPD, digitalis preparations are of little benefit in the routine treatment of cor pulmonale unless concomitant left ventricular dysfunction is found [100]. Furthermore, because patients with acute decompensation of COPD tend to be at increased risk of digitalis toxicity [101], digitalis should be avoided in this setting.

Respiratory stimulants such as doxapram and nikethamide have not been shown to be beneficial, using clinically relevant end points [73,102], and are associated with substantial toxicity [73]. Almitrine may increase ventilation and improve $\dot{V}/\dot{Q}$ relationships in patients with COPD [103], but there is a high incidence of significant side effects [104].

Specific Therapy

Exacerbations of COPD are usually due to upper or lower airway infections (e.g., viral or bacterial, or both). However, should a specific condition among those listed in Table 49.1 be determined to be the cause of deterioration in respiratory status and specific treatment exists (e.g., anticoagulation for pulmonary embolism), it should be instituted.

Respiratory Failure

Administration of controlled oxygen therapy is probably the single most useful treatment in COPD-induced hypercapnic respiratory failure. The increasing availability and evidence for the benefits of noninvasive ventilation has decreased the need for invasive ventilation and led to improved outcomes. The decision to intubate the trachea and mechanically ventilate the lungs is often complicated by concerns that it may not be easy to wean the patient from the ventilator but most individuals with an acute reversible process are successfully liberated from the ventilator [105–107]. Those with significant comorbidity and high severity of illness scores are more likely not to survive an episode of acute respiratory failure [108,109]. Patients with progressive end-stage lung disease should be identified and carefully assessed to determine whether a reversible component exists.

Supplemental Oxygen

Patients with exacerbations of COPD may present with profound hypoxemia. A PaO_2 below 34 mm Hg in otherwise normal animals is associated with the development of lactic acidosis [110]. Any concomitant decrease in cardiac output leads to the development of lactic acidosis at even higher levels of PaO_2 [110]. A low PaO_2 leads to pulmonary arterial vasoconstriction and pulmonary hypertension [111]. Renal function, particularly the excretion of a free water load, may be significantly impaired when PaO_2 falls below 40 mm Hg [112]. The mechanism appears to be CNS release of antidiuretic hormone in response to severe hypoxemia [113]. Other consequences include CNS dysfunction [114] and cardiac arrhythmias or ischemia [115].

The use of supplemental oxygen leads to (a) a decrease in anaerobic metabolism and lactic acid production; (b) an improvement in brain function; (c) a decrease in cardiac arrhythmias and ischemia; (d) a decrease in pulmonary hypertension; (e) an improvement in right-sided heart function with improvement in right-sided heart failure; (f) a decrease in the release of antidiuretic hormone and an increase in the kidneys' ability to clear free water; (g) a decrease in the formation of extravascular lung water (i.e., pulmonary edema); (h) an improvement in survival; and (i) a decrease in red blood cell mass and hematocrit [116].

A simple relation between PaO_2 and oxygen delivery often does not exist in these patients. In individuals with an acute exacerbation of COPD with severe arterial hypoxemia, the administration of supplemental oxygen results in a direct increase in oxygen delivery with no change in cardiac output [117]. On the other hand, in patients with acute exacerbations of COPD and moderate degrees of arterial hypoxemia, the result of supplemental oxygen is no change in oxygen delivery but a decrease in previously elevated cardiac output [117].

Administration of supplemental oxygen is often associated with an additional rise in the $PaCO_2$. This is probably due to a change in dead space or shift of the hemoglobin–oxygen binding curve rather than decreased respiratory drive [118]. This rise is expected and should not be specifically treated unless it is excessive, resulting in a trend toward acute respiratory acidosis on serial ABG determinations, with CNS or cardiovascular side effects. Should this occur, the supplemental oxygen should not be discontinued abruptly but rather decreased slowly until the $PaCO_2$ returns to a more acceptable level [73] and the situation is stabilized. Because abrupt discontinuation of supplemental oxygen may not be associated with a prompt increase in ventilation, the $PaCO_2$ may not fall. Therefore, abrupt withdrawal of supplemental oxygen may additionally depress the already low PaO_2, causing more profound arterial hypoxemia [73]. Carbon dioxide narcosis may occur with excessive oxygen therapy but is much less likely with low-flow–controlled oxygen therapy [73]. It occurs more commonly in patients with more marked hypoxemia [79]. Clinically significant hypercapnia is less likely to occur with oxygen therapy administered to maintain oxygen saturation at 91% to 92% [119]. Oxygen therapy is more effective with a prescription chart [120]

Mechanical Ventilation

Whether to institute mechanical ventilatory support is often a difficult decision in hypercapnic respiratory failure associated with COPD. This decision reflects a continuous reassessment of the patient's status, including the trend of ABG values and determining whether the patient is strong and alert enough to clear his or her secretions and protect the airway. The presence of worsening acute respiratory acidosis with a low arterial pH (e.g., less than 7.2) and inadequate PaO_2 (e.g., less than 55 mm Hg) or CNS and cardiovascular dysfunction dictates the need for assisted ventilation. Difficulty arises when the data are not as definitive. An alternative to endotracheal intubation is noninvasive mask ventilation, and early institution of this mode of ventilatory support is associated with a significant outcome benefit.

Noninvasive Ventilation. Numerous randomized trials and recent systematic reviews have clearly shown that the use of noninvasive ventilation (NIV) markedly improves in-hospital outcomes in acute exacerbations of COPD [121–123] (Table 49.4). See Chapter 59 for a comprehensive discussion of this topic in general and in COPD patients.

Invasive Mechanical Ventilation. Although it is prudent to avoid intubating the trachea in a patient with COPD whenever possible, the development of stupor or coma may necessitate emergency intubation, a potentially disastrous complication. The decision to institute mechanical ventilatory support is a clinical one and supported by lack of response or intolerance to NIV or progressive acidosis or respiratory rate. See Chapter 58 for a comprehensive discussion of this topic in general and in patients with COPD.

TABLE 49.4

RECOMMENDATIONS BASED ON RANDOMIZED CONTROLLED CLINICAL TRIALS

Recommendation	References
1. Give bronchodilators	[44–49]
2. Give inhaled corticosteroids for people with an FEV1 less then 50%–60% predicted	[55–60]
3. Give antibiotics for purulent exacerbations of COPD	[35,82–84]
4. Use oxygen	[64,65]
5. Use noninvasive ventilation for patients with severe exacerbations and respiratory failure	[121–123]

PROGNOSIS

The prognosis for patients admitted to hospital for an acute exacerbation of COPD is variable and is related to the severity of the underlying disease and whether an ICU admission or ventilation was required. In-hospital mortality rates of 8% to 25% [124] are generally quoted with 1-year mortality ranging from 21% to 43% [125,126]. The prognosis for patients treated in the ICU is significantly worse with in-hospital mortality as high as 25% and 1-year mortality approaching 39% [127,128]. Although a dismal outcome is often quoted for patients with COPD who require prolonged ventilation (more than 21 days), half of these patients can ultimately be weaned [107]. Systemic markers of health such as APACHE II scores and serum albumin are the best predictors of ICU survival.

Readmission rates following hospitalization range from 61% to 80% in the year following discharge. Risk factors for readmission include a low FEV_1, number of days in hospital in the previous year, low physical activity scale, and poor overall quality of life scores [129].

The major predictors of hospital mortality in patients with acute exacerbations of COPD appear to be indices of nonrespiratory organ dysfunction (e.g., serum albumin, body mass index) and severity of illness [108], whereas the severity of respiratory disease predicts 1-year mortality [130]. Age older than 65 years is an important prognostic indicator [130,131]. Of note, parameters of cardiac dysfunction (cor pulmonale, arrhythmias) are important determinants of poor outcome [106,130].

CHAPTER 50 ■ RESPIRATORY FAILURE PART V: EXTRAPULMONARY CAUSES OF RESPIRATORY FAILURE

HELEN M. HOLLINGSWORTH, MELVIN R. PRATTER AND RICHARD S. IRWIN

The conditions that cause respiratory failure primarily by their effect on structures other than the lungs are discussed in this chapter. Severe impairment of the extrapulmonary compartment produces respiratory failure through the mechanism of hypoventilation (see Chapter 46), so the resultant respiratory failure is always hypercapnic. Extrapulmonary causes account for up to 17% of all cases of hypercapnic respiratory failure [1]. This chapter is organized to follow sequential sections of pathophysiology, diagnosis, differential diagnosis, and treatment.

PATHOPHYSIOLOGY

The extrapulmonary compartment includes the (a) central nervous system (CNS), (b) peripheral nervous system, (c) respiratory muscles, (d) chest wall, (e) pleura, and (f) upper airway [2]. Because many conditions can cause extrapulmonary respiratory failure, it is helpful to categorize them according to the specific component affected by the disease process (Fig. 50.1). We have limited the discussion that follows to descriptions of the individual diseases and conditions that are most important to the topic of respiratory failure. They are summarized in Tables 50.1 through 50.4.

The pathophysiology of extrapulmonary respiratory failure is described in Chapter 45. Functionally, extrapulmonary disorders can lead to hypercapnic respiratory failure due to a decrease in normal force generation (e.g., CNS dysfunction, peripheral nervous system abnormalities, or respiratory muscle dysfunction) or an increase in impedance to bulk flow ventilation (e.g., chest wall and pleural disorders or upper airway obstruction) [3].

DIAGNOSIS

General Considerations

Arterial hypercapnia in the presence of a normal alveolar–arterial oxygen tension [$P(A–a)O_2$] gradient on room air is the sine qua non of extrapulmonary respiratory failure [4]. The normal gradient reflects the fact that in pure extrapulmonary failure distal gas exchange is normal, and the decrease in the partial pressure of arterial oxygen (PaO_2) directly reflects the decrease in the partial pressure of alveolar oxygen (PAO_2). A $P(A–a)O_2$ gradient of less than 20 mm Hg in the presence of an elevated partial pressure of carbon dioxide ($PaCO_2$) is, with few exceptions, diagnostic of extrapulmonary respiratory failure [5–11]. The main exception occurs in patients with chronic obstructive pulmonary disease (COPD) who have increasing hypercapnia [12]. Their $P(A–a)O_2$ gradient can occasionally narrow to normal, probably related to substantial changes in the position of the alveolar and arterial points on the oxyhemoglobin dissociation curve related to ventilation–perfusion inequalities [12]. Thus, arterial hypercapnia with a normal $P(A–a)O_2$ gradient is consistent with pure extrapulmonary respiratory failure, but a normal $P(A–a)O_2$ cannot, by itself, rule out severe COPD.

Pulmonary parenchymal disease can also exist concomitantly with extrapulmonary dysfunction. For example, a patient with polymyositis can have respiratory muscle weakness in addition to interstitial pulmonary fibrosis. This may be suggested by the combination of hypercapnia and only mild-to-moderate widening of the $P(A–a)O_2$ gradient. A gradient between 20 and 30 mm Hg in the presence of arterial hypercapnia should raise the suspicion that a significant element of extrapulmonary dysfunction may be present. It is also important to realize that even when the $P(A–a)O_2$ gradient exceeds 30 mm Hg, some degree of extrapulmonary dysfunction can also be present in association with significant pulmonary impairment. For example, when hypercapnic respiratory failure results from an acute exacerbation of COPD, respiratory muscle fatigue often contributes to the development of carbon dioxide retention [13]. A less common example is the presence of a large abdominal ventral hernia in a patient with COPD. The resultant paradoxic breathing pattern can contribute significantly to abnormal gas exchange and increased dyspnea [14].

Decrease in Normal Force Generation

Because the inspiratory muscles generate the force that results in ventilation, any condition that directly or indirectly impairs respiratory muscle function can result in decreased force generation [3]. Dysfunction of the respiratory center, peripheral nervous system pathways, or the respiratory muscles themselves decreases the force available to produce ventilation. If this impairment is severe enough, the level of minute ventilation will be insufficient to clear the amount of carbon dioxide produced by ongoing metabolic processes, and hypercapnic respiratory failure results.

An acute decrease in CNS output sufficient to result in hypercapnic respiratory failure (e.g., acute narcotic overdose) is usually accompanied by obvious evidence of generalized CNS depression. In contrast, a chronic (e.g., primary alveolar hypoventilation) or episodic (e.g., central sleep apnea) cause of decreased impulse formation may present a much more difficult diagnostic dilemma. Tests to evaluate respiratory center drive, such as voluntary hyperventilation, carbon dioxide stimulation, or polysomnography, may be necessary to define the problem.

Peripheral nervous system dysfunction or primary weakness of the respiratory muscles is often indicated by the presence of certain suggestive clinical findings that vary depending on the

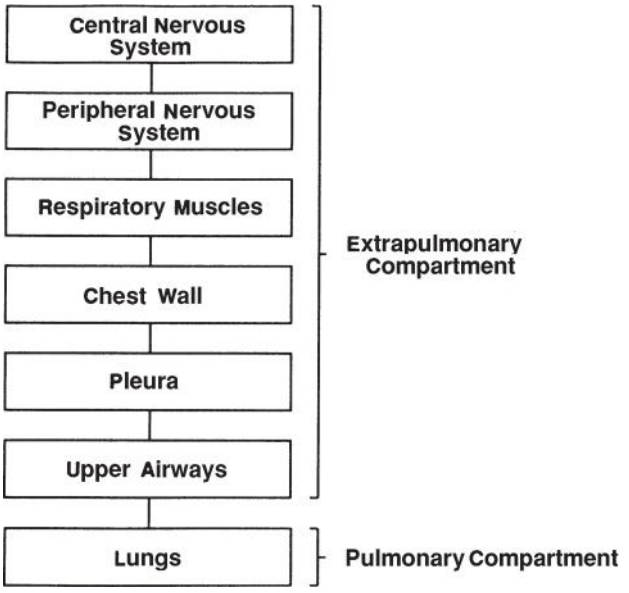

FIGURE 50.1. Schematic representation of the anatomy of the respiratory system.

specific entity present (see following discussion). Respiratory muscle fatigue or weakness may be suspected clinically and documented using a number of tests designed to evaluate respiratory muscle function.

Symptoms are usually nonspecific; patients may report dyspnea on exertion, either when supine (bilateral diaphragmatic paralysis) or when upright (C5–6 quadriplegia). Reports of weakness in other muscle groups, difficulty swallowing, and change in voice volume or tone may be other clues. Physical findings of changes in the rate, depth, and pattern of breathing suggest stressed, fatigued, or weakened respiratory muscles. For example, an increased respiratory rate, a decreased tidal volume, and paradoxic inward motion of the anterior abdominal wall during inspiration may be observed. The latter finding indicates a failure of the diaphragm to contract sufficiently to descend and move the abdominal contents downward and the abdominal wall outward during inspiration. A breathing pattern that cycles between predominantly chest wall or predominantly abdominal wall motion, called *respiratory alternans*, represents the alternating contraction of intercostal and accessory muscles, on the one hand, and the diaphragm, on the other. The assumption is that these two muscle groups alternate in their contribution to the work of breathing, allowing one another to rest during periods of muscle overload or fatigue.

Two readily available tests can be useful diagnostically to help assess respiratory muscle function. First, measurement of maximal inspiratory and expiratory pressures at the mouth is easy to perform, noninvasive, and can accurately predict the development of hypercapnic respiratory failure due to decreased respiratory muscle force generation [15,16]. Arterial hypercapnia due to respiratory muscle weakness is generally not seen until the maximal inspiratory pressure is reduced to 30% or less of normal [15,16]. Although normal predicted values vary (primarily on the basis of age and gender [17,18]), a maximal inspiratory pressure less negative than −30 cm H_2O is likely to be associated with arterial hypercapnia [16,19]. Maximal expiratory pressures are also reduced when there is respiratory muscle weakness, and in some neuromuscular disorders, the decrease may be even greater than that of the corresponding inspiratory pressure [16]. A maximal expiratory pressure of less than 40 cm H_2O is generally associated with a poor cough and difficulty clearing secretions [19].

A second measurement that is valuable in predicting the development of arterial hypercapnia due to neuromuscular weakness is the vital capacity. It can be performed either in the pulmonary function laboratory or at the bedside. [15,19]. Although a vital capacity of less than 1 L, or less than 15 mL per kg of body weight is commonly associated with arterial hypercapnia [1,19], the vital capacity is a less sensitive predictor of arterial hypercapnia than is the maximal inspiratory pressure, particularly in patients with chest wall disorders such as kyphoscoliosis [16]. Significant arterial hypercapnia is unlikely to occur with an inspiratory pressure more negative than −30 cm H_2O; however, arterial hypercapnia may be present with a vital capacity as high as 55% or as low as 20% of the predicted value [15,16].

The measurement of transdiaphragmatic pressures (P_{di}) and diaphragmatic electromyograms (EMGs), although not commonly used clinically, may be helpful. An inspiratory effort associated with a P_{di} consistently more than 40% of maximum predictably results in diaphragmatic fatigue [20]. Therefore, it follows that patients with diaphragmatic weakness and a reduced maximum P_{di} are at risk for developing diaphragmatic fatigue and respiratory failure, even in the face of normal inspiratory pressure [20]. Similarly, a decrease of more than 20% from baseline in the high- to low-frequency ratio as measured by the diaphragmatic EMG indicates diaphragmatic fatigue and portends the development of hypercapnic failure [21,22].

Central Nervous System Dysfunction

The respiratory center, located in the brainstem, is composed of two main parts, the medullary center and the pneumotaxic center [23,24]: The medullary center is responsible for initiation and maintenance of spontaneous respiration, and the pneumotaxic center in the pons helps coordinate cyclic respiration. A decrease in central drive can occur due to a direct central loss of sensitivity to changes in $PaCO_2$ and pH or a peripheral chemoreceptor loss of sensitivity to hypoxia as a result of CNS depressants, metabolic abnormalities, structural lesions, primary alveolar hypoventilation, and central sleep apnea (Table 50.1) [25–43].

Peripheral Nervous System Dysfunction

Disruption in impulse transmission from the respiratory center to the respiratory muscles can eventuate in respiratory failure. This disruption can be caused by spinal cord disease [44], anterior horn cell disease [45,46], peripheral neuropathy, or neuromuscular junction blockade [19] (Table 50.2) [5,25,44–88]. Denervation of the inspiratory muscles may occur as part of a generalized process (e.g., Guillain–Barré syndrome, myasthenia gravis [19]) or as an isolated abnormality (e.g., phrenic nerve palsy secondary to hypothermic cardioplegia during cardiac surgery [67,89]).

Peripheral nervous system dysfunction severe enough to produce hypercapnic respiratory failure is always associated with pulmonary function test findings of a reduced vital capacity (usually less than 50% of the predicted value [15,19]) and markedly decreased maximal inspiratory and expiratory pressures (usually 30% of the predicted pressures [15,19,55]). This type of respiratory failure is characterized by an ineffective cough and a high incidence of aspiration, atelectasis, and pneumonia [5].

The effect on the respiratory system of interruption of CNS impulse transmission due to spinal cord abnormalities is highly dependent on the level of the injury [44,47]. A lesion at the C3

TABLE 50.1

RESPIRATORY FAILURE CAUSED BY CENTRAL NERVOUS SYSTEM DYSFUNCTION

Causes [Reference]	Salient clinical features	Diagnostic tests	Treatment
Central nervous system depressant drugs [25–27]	Pupillary changes Needle marks	Toxicology screen Electrocardiogram in tricyclic overdose	See Section 10 (Pharmacology, Overdoses, and Poisonings)

Neoplasm	Headache	CT, MRI, cerebrospinal fluid cytology	Radiation, chemotherapy
Infection	Headache, fever	CT, MRI CT, MRI, cardiac echo	Antimicrobial therapy
Primary alveolar hypoventilation (Ondine's curse) [33–41]	Daytime hypersomnolence Headache Rarely dyspneic Polycythemia Cor pulmonale	Blunted or absent ventilatory response to ↑ CO_2, ↓ O_2 in inspired gas Normal pulmonary function tests	Nighttime ventilatory support Electrophrenic pacing Medroxyprogesterone acetate Supplemental oxygen
Central sleep apnea [31,41–43]	Same as primary alveolar hypoventilation	Polysomnography: apnea without respiratory effort Normal CO_2, O_2 response curves while awake	Nighttime ventilatory support Electrophrenic pacing Supplemental oxygen

↓, decreased; ↑ increased; CT, computed tomography; MRI, magnetic resonance imaging.

vertebral level or above abolishes both diaphragmatic and intercostal activity, leaving only some residual accessory muscle function [47]. The result is severe hypercapnic respiratory failure. Acute spinal cord lesions at the C5 and C6 levels produce an immediate fall in the vital capacity to 30% of the predicted value, due to loss of intercostal and abdominal muscle function [44]. This is associated with a limitation of both inspiratory capacity and active expiration. Within approximately 3 months of injury, however, the denervated muscles become stiff, which enables improved diaphragmatic efficiency. This improvement usually leads to an increase in the vital capacity to 50% to 60% of normal. Midthoracic spinal cord lesions have relatively little impact on respiratory muscle function because they principally affect the abdominal muscles, resulting in only a limitation of active expiration and cough [5,47].

Most spinal cord diseases interrupt impulse transmission, resulting in respiratory muscle weakness, but two notable exceptions exist: tetanus and strychnine poisoning. In both conditions, inhibitory influences at the spinal cord and anterior horn cell level decrease [51–52], causing a simultaneous increase in motor activity to groups of muscles that are normally antagonistic to one another. This results in intense muscle spasms, including involvement of the upper airway muscles, diaphragm, and intercostal muscles. The repetitive spasms and episodes of apnea, result in severe arterial hypoxemia, hypercapnia, and metabolic acidosis [51,52].

Diseases that involve the anterior horn cells of the spinal cord interrupt efferent impulse transmission. Amyotrophic lateral sclerosis (ALS) is the most common anterior horn cell disease causing respiratory failure [5,45,47]. In most cases of ALS, the patient develops segmental muscular atrophy, weakness of the distal extremities, hyperreflexia, fasciculations, and bulbar paralysis [45]. Although respiratory failure usually develops late in the course of the disease, it may rarely be the presenting manifestation [45]. Repetitive episodes of aspiration secondary to bulbar dysfunction may contribute to respiratory impairment [5]. It has been speculated that antecedent poliomyelitis may be involved in some cases of amyotrophic lateral sclerosis [53]. A postpolio syndrome, characterized by new, slowly progressive muscle weakness, may develop years after recovery from acute poliomyelitis [57].

Polyneuropathies with prominent motor neuron involvement, (e.g. Guillain–Barré syndrome) can affect the respiratory nerves and lead to respiratory failure (see Chapter 175) [25]. Symmetric, predominantly distal muscle weakness with absent tendon reflexes is the typical presentation [25]. In one series of patients with Guillain–Barré syndrome, 28% required mechanical ventilatory assistance. The average duration of mechanical ventilation was 9 weeks (range, 3 weeks to 7 months). Although the mortality rate is generally low, 21% of hospitalized patients died in one series [90]. Guillain–Barré syndrome may be associated with autonomic dysfunction including new-onset hypertension (57%), sinus tachycardia (50%), postural hypotension (43%), or facial flushing (25%) [90].

Dinoflagellate toxin poisoning, from red tide-contaminated shellfish and ciguatera-contaminated reef and other fish, is a dramatic but uncommon cause of peripheral neuropathy resulting that can produce respiratory failure [61–66]. The responsible agents are heat-stable neurotoxins that interfere with action potential propagation along peripheral nerves. During the warm summer months, the dinoflagellates that produce the toxins proliferate and are ingested by shellfish and fish. The

TABLE 50.2

RESPIRATORY FAILURE CAUSED BY PERIPHERAL NERVOUS SYSTEM DYSFUNCTION

Causes [Reference]	Salient features	Diagnostic tests	Supportive
Spinal cord disease [5,25,44,47–50]	Above C5, diaphragm, intercostal and abdominal activity abolished	Spinal X-ray film, CT, MRI	Supportive, vital capacity tends to improve more than 3 mo in traumatic lesions C5 and below
Traumatic	Below C5, diaphragm preserved, intercostal and abdominal activity abolished		Phrenic nerve pacing for high cervical cord lesions with intact phrenic nerve
Neoplasm Hemorrhage Syrinx Infarct Transverse myelitis	Below T5, abdominal activity diminished, impaired force expiration		
Tetanus [51]	Intense muscle spasms Trismus Apnea Metabolic acidosis History of penetrating wound	Clinical setting Gram's stain, anaerobic culture of wound History of inadequate immunization	Human antitetanus antiglobulin Wound debridement Penicillin, high dose Tetanus toxoid vaccination to prevent recurrence
Strychnine [52]	Intense muscle spasms Apnea Metabolic acidosis	Toxicology screen Clinical picture	Supportive Gastric lavage, charcoal
Anterior horn cell disease Amyotrophic lateral sclerosis [5,45,46,53,54] Poliomyelitis [55,57]	Segmental muscle atrophy Hyperreflexia Fasciculations Distal extremity weakness	EMG	Supportive
Polyneuropathy [25]	Viral illness, symmetric ascending distal muscle weakness	Elevated CSF protein without pleocytosis	Prevention with vaccine
Guillain–Barré syndrome [25,58–60]	Ascending paralysis Areflexia Autonomic dysfunction	Demyelination by electrophysiology tests	See Chapter 175
Dinoflagellate poisoning Shellfish poisoning (red tide) [61–63]	Paresthesias of face, progressive muscle weakness starting 30 min after ingestion of shellfish	History of contaminated shellfish ingestion	Supportive
Ciguatera poisoning [64–66]	Gastrointestinal symptoms Paresthesias, abnormal temperature differentiation	Mouse bioassay, monoclonal antibody to ciguatoxin	Early gastric lavage, mannitol, avoid caffeine
Bilateral phrenic nerve palsy [67,69]	Severe orthopnea Abdominal paradoxic respiration	Fluoroscopy of diaphragm Surface EMG of diaphragm, transdiaphragmatic pressure	Diaphragmatic pacing
Charcot–Marie–Tooth disease [70]	Peripheral muscle weakness and wasting, hereditary pes cavus, hammertoes	EMG	Supportive
Diphtheria [25]	Numbness of lips, paralysis of pharyngeal and laryngeal muscles	Throat culture	Diphtheria antitoxin Penicillin G or Erythromycin
Tick paralysis [25]	Tick exposure Age <10 y	Find tick Normal sensation	Remove tick

CONTINUED

Causes [Reference]	Salient features	Diagnostic tests	Supportive
Acute intermittent porphyria [25]	Acute polyneuropathy-like Guillain–Barré syndrome Mental disturbance Abdominal pain	Urine for porphobilinogen, δ-aminolevulinic acid	Hemin chloride, cimetidine Avoid exacerbating drugs such as phenytoin, barbiturates, ethosuximide
Myasthenia gravis (autoimmune and drug-induced) [25,71–76]	Muscle weakness Rapid fatigability Antecedent surgery, glucocorticoid, or aminoglycoside	EMG Tensilon test Antibodies to acetylcholine receptors	Anticholinesterase/calcium gluconate/thymectomy/ glucocorticoids/ immunosuppressants See Chapter 176 Plasmapheresis
Eaton-Lambert syndrome [56,77]	Muscle wasting, hyporeflexia Associated cancer (e.g., small cell of lung)	Incremental pattern on EMG chest film	Treatment of associated cancer 3, 4-Diaminopyridine Anticholinesterase
Critical illness polyneuropathy [78–81]	Sepsis, multiorgan failure, generalized weakness, areflexia	Normal CSF, axonal degeneration by NCS	Supportive
Persistent drug-induced neuromuscular blockade [78,82,83]	Renal insufficiency Glucocorticoids	Creatinine phosphokinase, EMG, NCS, repetitive nerve stimulation	Limit use of neuromuscular blocking agents
Pseudocholinesterase deficiency [25]	Prolonged paralysis after succinylcholine Family history	Serum pseudocholinesterase EMG	Avoid succinylcholine
Botulism [85,86]	Wound infection, fever Ingestion of contaminated food: nausea and vomiting	Gram's stain and culture of stool, wound, or suspected food Demonstrate toxin in stool, serum, or food by mouse neutralization test	Trivalent antitoxin Wound debridement, penicillin G (or metronidazole if penicillin allergy) Nasogastric lavage
Organophosphates [87,88]	Dysphagia, diplopia, ptosis, dysarthria Use of insecticides Cholinergic toxicity (vomiting, diarrhea, weakness, cramps, sweating, ataxia, mental status changes)	History of exposure RBC Acetyl cholinesterase level Atropine 1 mg challenge	Atropine Pralidoxime Benzodiazepine Cutaneous decontamination
Neuralgic amyotrophy [68]	Shoulder and neck pain, upper extremity weakness, breathlessness, orthopnea	Fluoroscopy of diaphragm, chest film, EMG	Analgesics, possible glucocorticoids

CSF, cerebrospinal fluid; CT, computed tomography; EMG, electromyogram; MRI, magnetic resonance imaging; NCS, nerve conduction study; RBC, red blood cell.

clinical picture is virtually pathognomonic. Within 30 minutes of ingesting contaminated shellfish, tingling and numbness of the face, lips, and tongue develop. Paresthesias and muscle weakness follow, with rapid progression to limb and respiratory muscle paralysis [62,63]. Multiple-case presentations from one source of exposure are common.

Peripheral phrenic nerve palsies can contribute to or cause hypercapnic respiratory failure, particularly if they are bilateral [91]. Bilateral phrenic nerve palsies have been described as an uncommon complication of hypothermia used for cardioplegia during cardiac surgery (particularly when ice slush is used) [67], trauma [67,91], a variety of neurologic diseases (e.g., poliomyelitis and Guillain–Barré syndrome) [67,68,91], Charcot–Marie–Tooth disease [70], intrathoracic malignancies [92], and as a part of a paraneoplastic syndrome [93]. Bilateral diaphragmatic paralysis can also be idiopathic [94]. The characteristic clinical findings of bilateral diaphragmatic paralysis are severe orthopnea and marked abdominal paradoxic in the supine position [69,89,91,95]. Fluoroscopy during a sniff test is more helpful in identifying unilateral than bilateral diaphragm paralysis, as upward motion of the ribs during inspiration can make the diaphragm appear to descend. The diagnosis of diaphragmatic paralysis is usually confirmed by transdiaphragmatic pressure measurements that reveal a minimal or absent P_{di} gradient [91]. Electromyography of the diaphragm and phrenic nerve conduction velocity studies may also be helpful.

Several other causes of peripheral neuropathy can involve the efferent pathways to the respiratory muscles including diphtheria, herpes zoster infection, tick paralysis, acute

intermittent porphyria, beriberi, and a variety of metabolic disorders [25]. Respiratory failure associated with diphtheria is of delayed onset, usually occurring 4 to 6 weeks after the onset of illness [25]. Tick paralysis is seen mainly in children in whom the presence of the tick goes unnoticed for 5 to 6 days [25]. In acute intermittent porphyria, respiratory involvement may be a slowly progressive process or may cause an abrupt deterioration in respiratory function due to bilateral phrenic nerve paralysis [37]. Myasthenia gravis [19], botulism [84–86], organophosphate poisoning [25], and a variety of drugs can produce neuromuscular blockade that results in respiratory failure [76]. Although patients with myasthenia gravis typically show signs of obvious muscle weakness and rapid fatigability, particularly of the cranial muscles, before the development of respiratory failure, acute respiratory failure is occasionally a presenting manifestation [25,72]. More commonly, respiratory failure complicates myasthenia gravis after surgical procedures, following the institution of glucocorticoid therapy, or, as a result of under- or overtreatment with anticholinesterase medications [19].

Although the diagnosis of myasthenia gravis is suspected on clinical grounds and a positive response to edrophonium chloride (Tensilon) is supportive, the diagnosis is confirmed by a typical EMG (decremental responses on repetitive nerve stimulation) and an elevated serum level of antibodies to acetylcholine receptors [71] (see Chapter 176). Part of the management of a patient with myasthenia gravis includes serial measurement of the, maximum inspiratory pressure and vital capacity to assess the risk for respiratory failure [25]. A decrease in maximum inspiratory pressure to a value less negative than -30 cm H_2O or a decrease in vital capacity to a liter or less is a warning sign of impending respiratory failure [19].

Eaton–Lambert syndrome, a form of neuromuscular blockade similar to myasthenia gravis, occurs in association with certain carcinomas, particularly small cell carcinoma of the lung [55,56]. The neuromuscular blockade in most cases precedes other evidence of the carcinoma, and the EMG shows an incremental pattern unlike that in true myasthenia.

Critical illness polyneuropathy occurs in the setting of sepsis and multiorgan failure in up to 30% of patients by clinical examination and up to 70% by electrophysiologic testing [78,81]. Profound generalized muscle weakness due to critical illness polyneuropathy is a major reason why these patients often require prolonged mechanical ventilatory support. Similar to patients with Guillain–Barré Syndrome, patients with critical illness polyneuropathy also have areflexia, but in contrast, they also may have prominent sensory nerve findings and a normal cerebrospinal fluid examination. Electrophysiologic testing helps to distinguish critical illness polyneuropathy from Guillain–Barré syndrome; in critical illness, polyneuropathy nerve conduction studies show axon degeneration rather than demyelination. Although the etiology of critical illness polyneuropathy is not known, it is predominantly a disease of older patients who stay in the intensive care unit for more than 28 days and who have elevated serum glucose and decreased albumin levels at the time of diagnosis. Approximately half of patients with sepsis, multiorgan system failure, and critical illness polyneuropathy survive and the prognosis of survivors for significant improvement from the neuropathy is good [79] (see Chapter 180 for additional details).

Prolonged administration (longer than 2 days) of neuromuscular blocking agents, such as pancuronium and vecuronium, has been associated with two distinct patterns of neuromuscular dysfunction [82]: (a) persistent neuromuscular junction blockade in patients with renal insufficiency who accumulate the parent drug and its active metabolites, and (b) an acute noninflammatory myopathy that becomes apparent as neuromuscular transmission improves. The myopathy appears to be a consequence of an interaction between neuromuscular blocking agents and glucocorticoids and seems to be related to the total dose of the neuromuscular blocking agent [83]. This has been particularly dramatic in previously healthy asthmatic patients who became quadriparetic for days to weeks after concomitant treatment with high-dose glucocorticoids and a neuromuscular-blocking agent [82].

Neuromuscular blockade also may occur as a result of administration of a variety of drugs [76]. Certain cardiovascular drugs (e.g., Xylocaine, quinidine, procainamide, and propranolol), anticonvulsants (e.g., phenytoin and trimethadione), D-penicillamine, and a number of antibiotics (most notably the aminoglycosides) can prolong postoperative respiratory depression, unmask underlying myasthenia gravis, or cause a drug-induced form of myasthenia gravis [76]. The definitive diagnosis of drug-induced neuromuscular blockade is usually made in retrospect if the abnormality reverses after elimination of the offending agent. In some cases, the administration of calcium gluconate has been reported to result in prompt improvement in neuromuscular transmission [76].

Prolonged neuromuscular blockade is occasionally seen after the administration of succinylcholine in individuals with pseudocholinesterase deficiency [25]. In contrast to the usual duration of paralysis of approximately 3 minutes, the effect in these individuals usually lasts 4 to 6 hours, during which time they require mechanical ventilatory support [25].

In botulism, neuromuscular blockade develops as a result of a neurotoxin produced by the bacteria *Clostridium botulinum*. Most cases are caused by neurotoxin-contaminated food [84–86], but occasionally botulism develops as a result of a wound infected with *C. botulinum* [51] (see Chapter 88). Certain findings help to predict whether respiratory failure requiring mechanical ventilation will develop. A vital capacity of 30% or less of the predicted value is generally associated with hypercapnic failure [50]. Other clues are the presence of nausea, vomiting, diarrhea, dyspnea, ptosis, or extremity weakness on initial examination.

Organophosphates, commonly used in insecticides, inhibit the enzyme cholinesterase, resulting in accumulation of acetylcholine at neurosynaptic junctions. The symptoms of organophosphate poisoning are those of cholinergic toxicity, including blurred vision, weakness, vomiting, diarrhea, cramps, sweating, increased secretions, incoordination, twitching, ataxia, mental status changes, and, if severe enough, respiratory failure and death [87,88]. Respiratory muscle paralysis combines with respiratory center depression, excessive secretions, and, possibly, bronchoconstriction to cause respiratory failure [87,88] (see Chapter 128). Neuralgic amyotrophy, a disorder of the peripheral nervous system affecting the brachial plexus, has recently been associated with diaphragmatic dysfunction and dyspnea [68]. It usually presents with acute severe shoulder pain that may extend to the neck, back, and arm. Motor weakness of the ipsilateral shoulder and arm usually develops within 1 month of the onset of pain. A sensory defect may be present in one fourth of patients. In one study [68], 12 of 16 patients had bilateral diaphragm paralysis, and 4 of 16 had unilateral diaphragm paralysis. Mild nocturnal desaturation, hypopneas, and obstructive sleep apneas (OSAs) were found in some patients, but alveolar hypoventilation was not found.

Respiratory Muscle Dysfunction

A number of systemic myopathies feature prominent respiratory muscle involvement, including muscular dystrophies, myotonic disorders, inflammatory myopathies, periodic paralyses, metabolic storage diseases, endocrine myopathies, infectious myopathies, toxic myopathies, rhabdomyolysis, and electrolyte disturbances (Table 50.3) [16,25,82,83,96–126].

TABLE 50.3

RESPIRATORY FAILURE CAUSED BY RESPIRATORY MUSCLE DYSFUNCTION

Causes [Reference]	Salient features	Diagnostic tests	Specific treatment
Muscle dystrophies [101–105]	Proximal muscle weakness and atrophy Hereditary	Muscle biopsy Elevated CPK Genetic analysis	Supportive Duchenne: prednisone
Myotonic dystrophies [106–109]	Myotonia, ptosis Distal and facial muscle weakness and atrophy Hereditary	Muscle biopsy EMG genetic analysis	Supportive Possibly mexiletine and acetazolamide
Periodic paralyses [25,109,110]	Hypokalemic, hyperkalemic, or normokalemic Genetic Muscle weakness associated with exercise, emotional upset, cold, alcohol	Serum potassium Family history	Avoid precipitating factors Carbonic anhydrase inhibitor
Glycogen storage diseases [25,97,97,111] (Pompe and McArdle diseases)	Exercise-related muscle cramping; slowly progressive muscle weakness and atrophy	CPK, muscle biopsy with assay for acid maltase, muscle phosphorylase levels	Supportive
Dermatomyositis/ polymyositis [16,112–114]	Proximal muscle weakness Rash in dermatomyositis Difficulty swallowing	Elevated CPK, aldolase EMG Muscle biopsy	Glucocorticoids Immunosuppressants
Hyperthyroidism [115]	Thyrotoxicosis heat intolerance, tachycardia, hyperreflexia	TSH, TFTs	Propylthiouracil, methimazole See Chapter 102
Hypothyroidism [25]	Myxedema, cold intolerance Hyporeflexia, bradycardia	TSH, TFTs	Replace thyroid hormone See Chapter 103
Hyperadrenocorticalism [25,116]	Cushingoid appearance	Serum cortisol Dexamethasone suppression test, adrenal CT scan	Depends on cause
Rhabdomyolysis secondary to colchicine [117] or chloroquine toxicity [25]	Muscle pain, swelling, myoglobulinuria	↑ CPK	Supportive
Infectious myositis Trichinosis [25,118] Viral [25]	Muscle tenderness, weakness, fever	Serology Muscle biopsy	Rest Glucocorticoids, thiabendazole or mebendazole
Hypophosphatemia [99,100,119,120]	Weakness Difficulty weaning	↓ Phosphate	Replete See Chapter 105
Hypermagnesemia or hypomagnesemia [100,121,122]	Weakness Difficulty weaning	↑ or ↓ Mg^{++}	
Hypokalemia [100] Hypercalcemia [100,122]	Weakness Lethargy, confusion	↓ K^{+} ↑ Ca^{++}	Replete See Chapters 72, 105, and 116
Eosinophilia-myalgia [123–125]	L-tryptophan ingestion Muscle tenderness and weakness, fasciitis Fasciitis	Eosinophilia Muscle biopsy	Discontinue L-tryptophan Supportive
Procainamide-induced myopathy [126]	Weakness Respiratory failure	Muscle biopsy, ↑ CPK	Discontinue procainamide
Acute myopathy secondary to neuromuscular blocking agents [82,83]	Neuromuscular blocking agents Glucocorticoids Rapid onset weakness	EMG Muscle biopsy	Supportive

↓, decreased; ↑, increased; CPK, creatinine phosphokinase; CT, computed tomography; EMG, electromyography; TFT, thyroid function test; TSH, thyroid-stimulating hormone.

The clinical presentation generally is widespread skeletal muscle weakness. Muscle weakness is the inability of a muscle to generate the normal expected level of force and should be distinguished from muscle fatigue, which is the inability to generate the preexistent maximum force prior to putting the muscle under load or stress. Fatigue is reversible with rest; weakness may be reversible with reconditioning or the reversal or elimination of the causative factor (e.g. malnutrition, disuse atrophy). Respiratory muscle involvement and respiratory failure usually develop as the disease progresses. On occasion, however, respiratory failure may be the presenting manifestation of a generalized myopathy [97].

Myopathy-induced hypercapnic respiratory failure is almost invariably accompanied by a severely impaired cough mechanism and an inability to clear respiratory tract secretions [5]. Typical pulmonary function findings of respiratory muscle weakness are a decrease in maximum inspiratory and expiratory pressures and, as the disease progresses, a decrease in lung volumes [127].

The muscular dystrophies are inherited disorders that present with evidence of progressive proximal muscle weakness and atrophy [25,101]. Duchenne and Becker muscular dystrophies are caused by mutations in the dystrophin gene, located on the X chromosome [102]. Duchenne dystrophy usually presents at approximately 2 to 3 years of age and Becker dystrophy at approximately 15 to 20 years of age. The limb-girdle muscular dystrophies are a more heterogeneous group of disorders that show both autosomal recessive and autosomal dominant inheritance and include mutations in different members of the sarcoglycan complex including motilin, dysferlin, caveolin, and sarcoglycan. Myofibrillar myopathy is also associated with mutations in the motilin gene and both of these may eventuate in respiratory failure [103]. They frequently present later in adulthood than do the dystrophin-related muscular dystrophies [104]. The myotonic dystrophies are autosomal dominant disorders linked to two chromosome loci: 19q13, where a CTG repeat has been found in the intron of a serine threonine protein kinase gene, and 3q21, where a CCTG repeat has been found in the intron of zinc finger protein 9 [106,107]. The most prominent clinical features are myotonia (i.e., sustained contraction of muscles in response to direct stimulation), ptosis, prominent distal and facial muscle weakness, and atrophy [25,104,108].

The periodic paralyses are genetic disorders characterized by attacks of muscle weakness in response to a variety of precipitating factors such as exercise, emotional upset, exposure to cold, and, in some cases, exposure to alcohol [25]. Patients may exhibit hypokalemia, hyperkalemia, or normokalemia. In some patients, the disease is unmasked when they become hyperthyroid.

Glycogen storage diseases result from defects in muscle glycogenolysis or glycogen storage. Examples include acid maltase deficiency (type II) and McArdle disease (type V). Patients exhibit exercise-induced muscle cramping and slowly progressive muscle weakness, with or without atrophy [25,97,98,111]. On occasion, respiratory failure may be the presenting manifestation [97,111]. The diagnosis is confirmed by muscle biopsy and chemical assay for muscle acid maltase or phosphorylase levels [97,98].

Polymyositis and dermatomyositis are collagen vascular diseases that cause skeletal muscle inflammation. Proximal muscle weakness is prominent and usually develops over a period of weeks to months. Patients may have difficulty swallowing secondary to pharyngeal muscle involvement. Serum muscle enzyme levels are elevated. Typical EMG and muscle biopsy findings confirm the diagnosis [112]. Respiratory muscle failure is an uncommon, but not rare complication of inflammatory myositis [16,112]. Patients with polymyositis may also develop interstitial pulmonary fibrosis, bronchiolitis obliterans organizing pneumonia, and alveolar hemorrhage [113,114].

Procainamide has been reported to cause a necrotizing myopathy with diaphragm involvement and respiratory failure [126]. Although anti–double-stranded DNA and antihistone antibodies were positive, antinuclear antibodies were absent, and the muscle biopsy did not reveal an inflammatory infiltrate. Neuromuscular junction transmission was normal, suggesting that this was not a drug-induced myasthenic syndrome. Slow improvement in muscle strength followed discontinuation of procainamide in this study.

Increased Impedance to Bulk Flow

In a number of pulmonary disorders, the development of hypercapnic respiratory failure is the result of a marked increase in impedance to ventilation (e.g., increased airflow resistance in COPD or asthma or increased elastic recoil in interstitial fibrosis) that even normal respiratory muscle force generation cannot overcome [3]. It may be less widely appreciated that increases in extrapulmonary impedance to ventilation also can result in hypercapnic respiratory failure. These disorders can be divided into those involving a decrease in chest wall or pleural compliance (e.g., kyphoscoliosis or pleural fibrosis) and those involving an increase in airflow resistance, resulting from upper airway obstruction (e.g., tracheal stenosis or laryngeal edema) (Table 50.4) [5,42,43,128–189].

Chest Wall and Pleural Disorders

Kyphoscoliosis is a common cause of extrapulmonary respiratory failure [5]. The severity of the scoliosis (i.e., lateral curvature of the spine) is usually the more important factor in the development of respiratory failure than is the kyphosis (i.e., dorsal curvature of the spine) [5]. In idiopathic kyphoscoliosis, chronic hypercapnic respiratory failure generally occurs when the angle of curvature is 120 degrees or greater [5]. In contrast, in paralytic kyphoscoliosis (e.g., as a result of poliomyelitis), the angle of curvature does not reliably predict either vital capacity or hypercapnic respiratory failure [128]. This appears to be due to a greater element of muscle weakness in paralytic kyphoscoliosis [128]. Even in idiopathic kyphoscoliosis, however, the presence of markedly decreased chest wall compliance is further complicated by inspiratory muscle weakness [129] that contributes to the development of hypercapnic respiratory failure [94]. In addition, a modest element of pulmonary gas exchange abnormality is usually present [5].

Patients with kyphoscoliosis usually report progressive dyspnea on exertion and exercise limitation for a period of years before actual arterial hypercapnia develops [5]. In patients with moderately advanced kyphoscoliosis, acute hypercapnic respiratory failure may result from acute reversible complications such as pulmonary congestion, retained secretions, or pulmonary infection [130].

Massive chest wall obesity may be associated with significant hypoventilation and the development of hypercapnic respiratory failure [133]. This is termed the *obesity-hypoventilation syndrome*. The pathogenesis of respiratory failure appears to be multifactorial and includes significant reduction in chest wall compliance, decreased respiratory muscle efficiency, reduced or blunted respiratory center drive, and impaired pulmonary gas exchange as a result of pulmonary congestion [133–135].

TABLE 50.4

RESPIRATORY FAILURE CAUSED BY CHEST WALL, PLEURAL, AND UPPER AIRWAY DISEASES

Causes [Reference]	Salient features	Diagnostic tests	Specific treatment
Chest wall and pleural disorders			
Kyphoscoliosis [5,128–132]	Spinal curvature ≥120 degrees Progressive dyspnea on exertion over several years	Spinal X-ray films Restriction on PFTs	Nighttime ventilatory support
Obesity-hypoventilation [133–135]	Massive chest wall obesity ± sleep apnea	Polysomnography ↓CO_2 response curve ↓Chest wall compliance	Weight loss Nasal CPAP or BPAP
Flail chest [136]	Multiple rib fractures, paradoxic respiration ± pleuritic chest pain	Chest film	Mechanical positive-pressure ventilation
Fibrothorax [5,137–139]	Asbestos exposure, pleural infection, pleural hemorrhage, uremia, collagen vascular disease	Observation of chest wall Restriction on PFTs Decreased maximum static elastic recoil pressure	Decortication
Thoracoplasty [5]	Chest wall deformity secondary to resection of ribs	Restriction on PFTs Chest film	Supportive
Ankylosing spondylitis [5]	Limited chest expansion Apical pulmonary fibrosis Limited lumbar mobility Chronic lower back pain	PFTs (↑functional residual capacity, ↓total lung capacity) HLA-B27 Spine and sacroiliac X-ray films	Anti-inflammatory agents Flexibility exercises
Upper airway obstruction			
Acute epiglottis [140–143]	Fever, sore throat, stridor, dysphagia	Soft tissue films of neck	See Chapter 67
Acute laryngeal edema			
Angioedema/anaphylaxis [142,144–148]	Stridor in setting of *Hymenoptera* sting, contrast media, or drug administration	Other evidence of angioedema/anaphylaxis; complement levels	Epinephrine parenterally Cricothyroidotomy
Traumatic [149,150]	Stridor after endotracheal extubation	History	Inhaled racemic epinephrine Reintubation Helium–oxygen mixture
Foreign body aspiration [151–156]	Unable to speak Stridor or apnea	X-ray film helpful when foreign body below cords	Heimlich maneuver Bronchoscopy Cricothyroidotomy
Retropharyngeal hemorrhage [157]	Associated with anticoagulation or head and neck surgery Sore throat	Soft tissue film of neck CT scan or tomography	Reverse anticoagulation
Bilateral vocal cord paralysis [158–165]	Stridor Aspiration	Flow–volume loop Laryngoscopy	See text
Laryngeal and tracheal tumors [142,166–170]	Dyspnea Hoarseness; dysphonia Stridor	Flow–volume loop Tomography Laryngotracheoscopy	Laser or surgical resection, radiation
Tracheal stenosis [150,162,171–173]	Progressive dyspnea History of endotracheal intubation	Flow–volume loop Tomography	Tracheostomy Stent, resection of stenosis
Tracheomalacia [171,172]		Laryngotracheoscopy	Stent
Idiopathic obstructive sleep apnea [42,43,174–188,132]	Snoring Daytime hypersomnolence Pulmonary hypertension Cor pulmonale	Polysomnography	Nasal CPAP, bilevel CPAP Protriptyline Uvulopalatopharyngoplasty Tracheostomy Nocturnal oxygen Weight loss
Adenotonsillar hypertrophy [180]	Daytime hypersomnolence Obstructive sleep apnea stridor	Direct visualization Lateral X-ray film	Resection
Obstructive goiter [189]	Enlarged thyroid	Tomography CT scan	Suppression with exogenous thyroid hormone Resection

↓, decreased; ↑, increased; CPAP, continuous positive airway pressure; CT, computed tomography; PFT, pulmonary function test.

Upper Airway Obstruction

A variety of causes of upper airway obstruction involving the extrathoracic upper airway or intrathoracic trachea can result in the development of respiratory failure (Table 50.4).

Significant upper airway obstruction should be considered in the patient who reports dyspnea in association with inspiratory stridor (extrathoracic obstruction) or expiratory wheezing (intrathoracic obstruction), particularly if other symptoms suggest an upper airway process (e.g., dysphagia in epiglottitis). Unless the patient is acutely ill, the diagnosis can usually be confirmed by flow–volume loop analysis [190]. This technique not only demonstrates the presence of an upper airway obstruction but usually also helps determine whether it is extrathoracic or intrathoracic and variable or fixed [190]. Studies such as soft tissue neck radiographs, laryngoscopy, and bronchoscopy can identify the exact nature of the structural abnormality.

Upper airway obstruction from bilateral vocal cord paresis or paralysis may result from a variety of causes. The most common cause is trauma, particularly related to thyroid surgery [161] and, occasionally, after endotracheal intubation [162]. Other causes include tumors [142,166–170]; cricoarytenoid arthritis [160]; herpes simplex viral infection [163]; and neurologic conditions, including Guillain–Barré syndrome [160], extrapyramidal disorders such as Parkinson's disease [164], and myasthenia gravis [159]. Bilateral vocal cord paralysis should be considered when one of these conditions is present and the patient reports aspiration, dyspnea, or stridor [161]. Hoarseness is usually absent during normal speech in bilateral adductor paralysis. The results of flow–volume loop analysis can help confirm the presence of the typical extrathoracic variable obstruction associated with bilateral vocal cord paralysis [165].

Obstructive sleep apnea (OSA) is increasingly recognized as a cause of intermittent functional upper airway obstruction [3,175,176]. Although obesity is a significant risk factor, OSA can occur in its absence [175,176]. Episodic loss of pharyngeal muscle tone caused by decreased respiratory center motor output, usually during rapid eye movement sleep, results in intermittent airway obstruction [175,177]. This disturbance in respiratory center control also accounts for the mixed apneas (i.e., combination obstructive and central apneas) frequently seen in these patients [175,177].

Approximately 10% to 20% of patients with OSA have chronic alveolar hypoventilation with elevation in $PaCO_2$ even while awake. These patients frequently have concomitant COPD or morbid obesity. Hypoxemia, whether just at night or all day, eventually causes cardiac arrhythmias, pulmonary hypertension, and cor pulmonale [3,175,178,179].

The diagnosis of OSA can be established by a sleep study (polysomnography) [174,175]. Other conditions that can cause or exacerbate OSA should be excluded, including adenotonsillar hypertrophy [180]; deviated nasal septum [176]; retrognathia or micrognathia [3]; macroglossia from acromegaly [183]; endocrine and metabolic abnormalities such as hypothyroidism [67,184,185]; CNS depression from ethanol, barbiturates, and benzodiazepines [175,186]; and exogenous androgen administration [187,188] (see Chapter 69).

DIFFERENTIAL DIAGNOSIS

The major differential diagnosis of extrapulmonary respiratory failure is hypercapnic respiratory failure from intrinsic lung diseases (e.g., COPD) (Fig. 50.1). These conditions usually can be readily distinguished because they are almost always associated with a markedly elevated $P(A–a)O_2$ gradient when calculated on room air, reflecting a severe derangement of distal gas exchange. Hypercapnic respiratory failure may also result from a combination of pulmonary and extrapulmonary abnormalities. This combined diagnosis is suggested by a $P(A–a)O_2$ gradient in the range of 25 to 30 mm Hg. If the extrapulmonary abnormality is predominant, the gradient, although abnormal, is generally less than 25 mm Hg [5]. When primary pulmonary disease is severe enough to cause hypercapnia, the gradient is generally above 30 mm Hg.

TREATMENT

The treatment of extrapulmonary respiratory failure can be divided into specific and supportive therapy. Supportive therapy involves the use of noninvasive or invasive mechanical ventilatory assistance (see Chapters 58 and 59), supplemental oxygen, and techniques of airway hygiene (see Chapter 62). In addition, regardless of the primary cause of respiratory muscle weakness, malnutrition exacerbates it and nutritional replacement can increase respiratory muscle strength and function [191,192]. In selected circumstances, inspiratory resistive training of the respiratory muscles and the use of theophylline as a positive respiratory muscle inotrope have been reported to improve respiratory muscle function and associated hypercapnic respiratory failure [193–196]. Only specific forms of therapy are discussed here and in Tables 50.1 through 50.4.

Central Nervous System Depression

A description of specific treatment modalities for CNS depression is given in Table 50.1.

Peripheral Nervous System Dysfunction

Treatment for peripheral nervous system disorders is outlined in Table 50.2. In general, there is little in the way of specific therapy for established spinal cord or anterior horn cell disease. The use of phrenic nerve pacemakers for high-level cervical cord transection may help treat the resultant respiratory failure when nerve conduction studies have determined that the phrenic nerves are intact and functioning [48–50,91]. If pacing brings on OSA, tracheostomy or noninvasive positive airway pressure may be necessary.

The availability and value of specific therapy for peripheral neuropathy depend on the cause. In the case of acute Guillain–Barré syndrome, plasmapheresis or intravenous infusion of pooled gamma-globulin may be helpful when administered promptly for patients who reach or appear to be approaching the inability to walk without help or who have substantial decrease in ventilatory capacity or bulbar insufficiency (see Chapter 175 for more details on treating Guillain–Barré syndrome).

Patients with severe respiratory muscle weakness due to Guillain–Barré syndrome require supportive mechanical ventilatory assistance, usually for weeks to months, and occasionally for longer than 1 year [59]. If cranial nerve involvement is prominent, intubation for airway protection should be considered, even in the absence of overt respiratory failure. Management is complicated by autonomic nervous system dysfunction, which is commonly present and a leading cause of death in this syndrome [90]. Abnormalities of increased or decreased sympathetic and parasympathetic nervous system activity, such as hypertension, hypotension, bradyarrhythmias,

tachyarrhythmias, flushing, diaphoresis, and ileus, frequently occur [90]. Because these events are often transient, minor fluctuations in heart rate or blood pressure should not be treated. When intervention is deemed necessary, short-acting and easily titratable drugs should be used [90]. Because patients are at increased risk for deep venous thrombosis and pulmonary embolism, prophylactic anticoagulation should be administered, according to guidelines for critically-ill patients (see Chapter 52 for more details on anticoagulation in critically ill patients). Treatment of respiratory failure caused by myasthenia gravis is directed primarily at the myasthenia (see Chapter 176).

Drug-induced neuromuscular blockade often improves simply by discontinuing the offending agent [57]. Intravenous calcium gluconate may help to shorten the recovery time by reversing the presynaptic component of the neuromuscular blockade [76]. If this fails and the patient improves after an edrophonium chloride test, neostigmine bromide may be effective by reversing the postsynaptic component [52]. When myasthenia gravis is exacerbated or made manifest by a drug, therapy directed specifically at the myasthenic symptoms may be required [76].

Treatment of botulism is directed at minimizing further binding of toxin to nerve endings while supporting the patient until bound toxin dissipates [85] (see Chapter 88). Recovery of ventilatory and upper airway muscle strength in type A botulism occurs slowly; patients recover most of their strength in the first 12 weeks, but full recovery may take up to a year [86].

Respiratory Muscle Dysfunction

The treatment of myopathy depends on the cause (Table 50.3). Although the mechanism is not known, glucocorticoid therapy has resulted in some improvement in muscle strength in Duchenne muscular dystrophy [102,105]. Mexiletine and acetazolamide may be helpful in myotonic dystrophy [109].

Some patients with each of the different subtypes of periodic paralysis have responded well to acetazolamide, a carbonic anhydrase inhibitor that is kaliuretic [111]. Acetazolamide is often dramatically effective in preventing acute attacks of hypokalemic periodic paralysis, perhaps by causing a metabolic acidosis that, in turn, protects against the sudden decreases in potassium that provoke attacks. Certain patients benefit from low-carbohydrate or low-sodium diets in addition to acetazolamide. Inhalation of the β-adrenergic agonist albuterol alleviates acute attacks of weakness in some patients [111].

Polymyositis-induced muscle weakness often responds to glucocorticoids or other immunosuppressants [112,114]. Muscle weakness from hypothyroidism, hypophosphatemia, hypomagnesemia, or hypokalemia responds to replacement therapy [25,115,116,119,121,122].

The specific treatment of trichinosis is less than satisfactory [118]. Thiabendazole may eliminate intestinal worms, but only if initiated within 1 day of ingestion of larvae. Thiabendazole has no effect on the larvae that have reached the muscle and also does not appear to alter the course of established infections. The mainstays of treatment are bed rest, glucocorticoids, and anti-inflammatory analgesic agents.

Chest Wall and Pleural Disorders

Treatment for chest wall and pleural disorders is largely supportive (Table 50.4). If acute respiratory failure develops in kyphoscoliosis, reversible factors such as pulmonary congestion, infection, retained secretions, and other intercurrent illnesses should be sought and treated [130]. Episodes of acute respiratory failure in patients with kyphoscoliosis can often be managed with noninvasive positive pressure ventilation (see Chapter 59 for details of noninvasive ventilation for acute respiratory failure).

When severe kyphoscoliosis is associated with significant chronic hypercapnic respiratory failure, nocturnal noninvasive positive pressure ventilation often results in marked improvement in daytime function and gas exchange [131,197].

Upper Airway Obstruction

The first step in treating acute upper airway obstruction is to establish an adequate airway. Specific definitive therapy can then be used. In acute bacterial epiglottitis associated with significant respiratory distress, immediate steps are mandatory to prevent development of total obstruction [140]. Chapter 67 provides a complete discussion of this and other treatment issues.

Treatment of OSA is indicated when significant sleep-related apneas or hypopneas are noted in the setting of signs and symptoms such as morning headaches, daytime functional impairment, peripheral edema, cor pulmonale, and elevated hematocrit. In general, nasal continuous or bilevel positive pressure devices (continuous positive airway pressure or bilevel continuous positive airway pressure) are effective [198–200] (see Chapters 59 and 62). In OSA complicated by life-threatening arrhythmias, severe arterial hypoxemia, or severe functional impairment [3,176], tracheostomy may rarely be necessary [3,42,176]. Other treatment modalities for OSA include weight loss [201], avoidance of alcohol and sedative drugs [175,186], mandibular and tongue repositioning appliances [202], and upper airway surgery other than tracheostomy (uvulopalatopharyngoplasty, tonsillectomy, adenoidectomy, deviated septum repair), as appropriate [180,203]. When an identifiable cause of OSA is present (e.g., hypothyroidism), correction of the problem may be curative [184,185].

A summary of advances in the treatment of extrapulmonary respiratory failure is given in Table 50.5.

TABLE 50.5

ADVANCES IN THE TREATMENT OF EXTRAPULMONARY RESPIRATORY FAILURE

Disease	Treatment
Duchenne muscular dystrophy	Glucocorticoids improve pulmonary function and slow disease progression [105].
Guillain–Barré syndrome	Both plasmapheresis and IVIG are effective when started within 4 weeks of onset of symptoms [60].
Myasthenia gravis	Plasmapheresis is effective in short-term management of myasthenic crisis [74].
Trichinosis	Thiabendazole and mebendazole are effective in reducing muscle weakness in trichinosis [118].
Obstructive sleep apnea	Nasal continuous positive airway pressure is effective in the treatment of obstructive sleep apnea [200].

IVIG, intravenous immunoglobulin.

CHAPTER 51 ■ RESPIRATORY FAILURE PART VI: ACUTE RESPIRATORY FAILURE IN PREGNANCY

CHRISTINE CAMPBELL-REARDON AND HELEN M. HOLLINGSWORTH

The overall pregnancy-related maternal mortality ratio in the United States during 1991 to 1999 was 11.8 deaths per 100,000 live births [1]. Acute respiratory failure remains an important cause of maternal and fetal morbidity and mortality. Thromboembolism, amniotic fluid embolism (AFE), and venous air embolism together account for approximately 20% of maternal deaths [2], and other causes of respiratory failure probably account for another 11% [1].

This chapter focuses on the causes of acute respiratory failure that are increased in frequency during pregnancy, are unique to pregnancy, or present special management requirements during pregnancy. The spectrum of problems associated with eclampsia is discussed in Chapter 156. Management of the acute respiratory distress syndrome (ARDS) caused by sepsis, trauma, or other etiologies unrelated to pregnancy is discussed in Chapter 47. Table 51.1 lists causes of acute respiratory failure in pregnancy.

NORMAL ALTERATIONS IN CARDIOPULMONARY PHYSIOLOGY DURING PREGNANCY

Pregnancy alters respiratory physiology by causing changes in lung volumes, mechanics of ventilation, and control of respiration. Despite mucosal changes to the airway of edema and hyperemia, spirometry studies reveal no significant changes in measurements of the forced expiratory volume in 1 second (FEV_1) during pregnancy, suggesting that airway function is maintained during pregnancy. Changes in lung volume associated with gestation are relatively small: total lung capacity decreases 4% to 6%, functional residual capacity (FRC) decreases approximately 15% to 25%, and residual volume remains constant. Despite the decrease in FRC, early airway closure has not been demonstrated and specific airway conductance remains constant [3]. Diffusing capacity is elevated in the first trimester but then declines, despite continued increases in cardiac output and plasma volume.

As gestation progresses, the resting level of the diaphragm rises, but diaphragmatic excursion with tidal breathing increases. An increased tidal volume (25% to 35%) accounts for much of the 20% to 40% increase in minute ventilation and the mild respiratory alkalosis that are characteristic of early-to-middle pregnancy. An increased respiratory rate also contributes to the increased minute ventilation late in pregnancy (Fig. 51.1).

Normal carbon dioxide tension ($PaCO_2$) during pregnancy is 27 to 34 mm Hg, suggesting chronic mild hyperventilation. The degree of hyperventilation has been found to be in excess of the amount needed to compensate for increased oxygen consumption; in fact, hyperventilation develops early in gestation, before any significant increase in oxygen consumption occurs. This has been attributed to elevation in levels of progesterone, which has a known respiratory stimulating effect. The exact mechanism by which it produces this effect is not known, but it is thought to include an increase in the central chemoreflex drive to breathe and to changes in acid–base balance such that central and plasma hydrogen ion concentration is increased for any given PCO_2. In addition, pregnancy is associated with increased sensitivity to CO_2 as measured by CO_2 ventilatory response curves, reflecting the new, lower set point in $PaCO_2$, possibly mediated by estrogen and progesterone. The respiratory alkalosis seen during pregnancy causes a compensatory renal excretion of bicarbonate to maintain an arterial pH between 7.40 and 7.45.

The normal arterial oxygen tension (PaO_2) in pregnant women ranges from 100 to 110 mm Hg. Oxygen consumption increases by 20% to 33% by the third trimester, secondary to both fetal and maternal demands. This increased rate of oxygen consumption and low oxygen reserve secondary to a reduced FRC place pregnant patients at risk for the rapid onset of hypoxia.

Circulatory changes occur during gestation to supply oxygen-rich blood to the placenta and to accommodate the stress of labor and delivery. Cardiac output begins to rise in the first trimester and peaks around the 20th week of gestation at 30% to 45% above resting, nonpregnant levels (Fig. 51.2). Thus, measured cardiac output during gestation that is in the normal range for a nonpregnant patient would represent significant hemodynamic compromise for the pregnant patient and, potentially, decreased oxygen delivery for the fetus. As pregnancy progresses, cardiac output becomes dependent on body position. In the supine position, cardiac output can be reduced by 25% to 30% due to compression of the inferior vena cava by the gravid uterus and a resultant decrease in venous return. Cardiac output is higher when the pregnant woman is in the left lateral decubitus position. Estimates of expected cardiac output during gestation should be revised upward for intercurrent stresses such as fever, infection, and pain.

The gestation-related increase in cardiac output reflects a combination of increases in heart rate and stroke volume. Heart rate increases progressively throughout gestation, reaching a 20% or 15 beats per minute increase over nonpregnant levels. Stroke volume increases more rapidly at first and then stabilizes. Left ventricular compliance must increase in pregnancy because the increased stroke volume appears to be related more to left ventricular enlargement than to increased emptying. The cardiac silhouette on chest radiography may appear enlarged as a result of mild normal left ventricular enlargement and lateral and upward displacement by the gravid uterus.

Further increases in cardiac output occur during labor; cardiac output increases up to 45% over third trimester values,

and during uterine contraction, cardiac output transiently increases another 10% to 15% because of increased venous return. Another factor that may be important in patients who are sensitive to left ventricular afterload is inhibition of blood flow to the uterus during labor contractions. Because uterine blood flow at term accounts for a significant proportion of the cardiac output, marked increases in afterload during contractions and immediately postpartum may occur. During labor, contractions are associated with increased blood return from the uterus. These "autotransfusions" may reach 500 mL when the uterus contracts after parturition. This effect, however, may be offset by blood loss. In the first few minutes postpartum, cardiac output may increase as much as 80% over prelabor levels, then decrease to 40% to 50% over prelabor values by 1 hour postpartum, and finally return to nearly pre-pregnant levels by 1 to 2 weeks postpartum.

Systemic vascular resistance is reduced in pregnancy due to vasodilatation and the low resistance of the uteroplacental vascular circuit. Possible factors leading to vasodilatation

Baltimore, MD, Williams & Wilkins, 1987, p 3, with permission.]

include a reduction in vascular responsiveness to norepinephrine and angiotensin II, increased endothelial prostacyclin production, and increased nitric oxide production. The mean blood pressure remains relatively constant despite increases in cardiac output. Pressures in the right ventricle, pulmonary artery, and pulmonary capillaries are no different from nonpregnant values.

During pregnancy, there is expansion of the extracellular fluid volume, with the plasma fluid volume increasing more than the interstitial volume. Maternal blood volume reaches its peak at 32 weeks and is 25% to 52% above prepregnancy levels. The erythrocyte mass increases by 20% to 30%. However, the plasma volume increases more than the erythrocyte volume, resulting in the physiologic anemia of pregnancy.

Colloid osmotic pressure measurements during gestation reveal a mean decrease of 5 mm Hg, which reaches a plateau at 26 weeks. This parallels a decrease in serum albumin concentrations from approximately 4.0 to 3.4 g per dL. A further decline in colloid osmotic pressure of roughly 4 mm Hg occurs immediately postpartum, probably as a result of a combination of factors, such as recumbency, crystalloid administration, and blood loss. These changes may be even more marked in patients with pregnancy-induced hypertension. Neither the absolute value of colloid osmotic pressure nor the colloid osmotic pressure–pulmonary capillary wedge pressure gradient is an accurate predictor of pulmonary edema because of the multiplicity of contributing variables. However, these trends in colloid osmotic pressure should be considered when interpreting pulmonary capillary wedge pressures, especially in patients who have received large amounts of crystalloid.

DETERMINANTS OF FETAL OXYGEN DELIVERY

Oxygen delivery to fetal tissues can be affected at many levels: maternal oxygen delivery to the placenta, placental transfer, and fetal oxygen transport from the placenta to fetal tissues. The major determinants of oxygen delivery to the placenta are the oxygen content of uterine artery blood, which is determined by maternal PaO_2; hemoglobin concentration and saturation; and uterine artery blood flow, which depends on maternal cardiac output. Thus, a decreased PaO_2 can be offset somewhat

by increased blood hemoglobin concentration or by increased cardiac output. The combination of maternal hypoxemia and decreased cardiac output likely has a profoundly deleterious effect on fetal oxygenation.

Variations in maternal pH also influence oxygen delivery. Alkalosis causes vasoconstriction of the uterine artery, resulting in decreased fetal oxygen delivery. This effect is magnified by a leftward shift in the maternal oxyhemoglobin saturation curve, which increases oxygen affinity and consequently decreases oxygen transfer to the umbilical vein. Although mild maternal acidosis does not enhance uterine blood flow because the uterine vasculature is already maximally dilated, it shifts the maternal oxyhemoglobin saturation curve to the right, which leads to decreased oxygen affinity and increased fetal oxygen delivery. Maternal hypotension and increased sympathetic stimulation (exogenous or endogenous) both cause uterine arterial vasoconstriction.

The importance of maternal cardiac output is supported by the observation that women with left ventricular outflow obstruction have an increased incidence of fetal death and surviving infants have an increased incidence of congenital heart disease. Data from a sheep model, however, suggest that a decrease in uterine blood flow up to 50% for brief periods does not appreciably decrease fetal and placental oxygen uptake. Chronically decreased maternal cardiac output may have other effects, perhaps on placental development, that explain the results in women with left ventricular outflow obstruction.

The interaction of maternal and fetal circulations in the placenta most likely follows a concurrent exchange mechanism. This is less efficient than a countercurrent exchange mechanism and partly explains why the PaO_2 in the fetal umbilical vein, which carries oxygenated blood to fetus, is in the range of 32 mm Hg, far lower than uterine vein PaO_2, and why increased maternal inspired oxygen increases uterine artery oxygen tension but does not cause major increases in umbilical vein PaO_2. Despite low umbilical vein PaO_2, fetal oxygen content is actually quite close to maternal oxygen content because of the shape of the oxyhemoglobin saturation curve for fetal hemoglobin (Fig. 51.3). This is one of the major protective mechanisms for fetal oxygenation. The fetal oxyhemoglobin saturation curve is relatively unaffected by changes in pH; although acidosis may decrease maternal oxygen affinity, fetal oxygen affinity is unchanged.

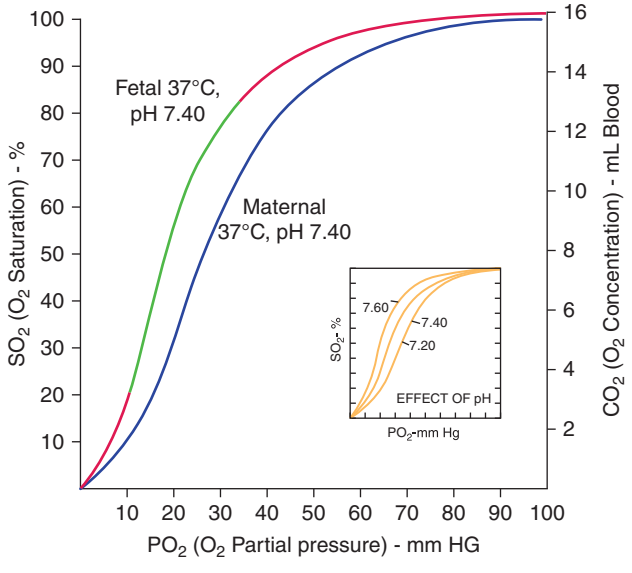

FIGURE 51.3. Oxygen dissociation (equilibrium) curves of human fetal and maternal blood. The effect of pH on the position of the curve (Bohr effect) is shown on the inset. The oxygen capacity of 16 mL per 100 mL blood on the right-hand ordinate refers to maternal blood. [Reprinted from Novy MJ, Edwards MJ: Respiratory problems in pregnancy. *Am J Obstet Gynecol* 99:1024, 1967, with permission.]

Other placental factors that determine fetal oxygenation are the amount of intraplacental shunt, degree of matching of maternal and fetal blood flows, and the presence of any placental abnormalities, such as placental infarcts. There seem to be no placental autoregulatory mechanisms that increase blood flow in response to decreased maternal PaO_2.

Mathematical models predicting the optimal apportionment of fetal cardiac output between umbilical (to collect oxygen) and systemic (to deliver oxygen) circulations have yielded values surprisingly close to those measured under normal physiologic conditions. This appears to be another compensation mechanism for the apparent inefficiency (concurrent exchange mechanism) of the placenta. One disadvantage in terms of oxygen delivery to fetal tissues is that oxygenated umbilical vein blood is mixed in the fetal inferior vena cava with deoxygenated systemic venous blood before delivery to the systemic circulation. Thus, fetal arterial blood has an even lower PaO_2 than umbilical vein blood. This is compensated for in part by a high fetal cardiac output relative to oxygen consumption, thus enhancing oxygen delivery to fetal tissues. The fetal circulation appears to have the ability to autoregulate in the face of hypoxemia to protect the brain, adrenal glands, and heart. How long this adaptation can be depended on safely before organ damage occurs is not known.

How well do the compensatory mechanisms that provide adequate oxygen supply to the fetus under normal conditions manage during maternal hypoxia? Calculation of oxygen stores in the term infant with 60% hemoglobin saturation yields a total oxygen content of 40 mL. Given an oxygen consumption of 6 mL per kg per minute, or approximately 18 mL per minute at term, this reserve lasts barely 2 minutes when the maternal oxygen supply is completely interrupted. The shape of the fetal oxyhemoglobin dissociation curve places umbilical vein PaO_2 values below 30 mm Hg on the steep part of the curve, so small changes in maternal PaO_2 may cause significant changes in fetal oxygen content. A maternal PaO_2 greater than 70 mm Hg should be maintained to prevent adverse consequences to the fetus. Concern regarding the adequacy of fetal oxygen supply is further reduced if a normal maternal PaO_2 of 90 mm Hg or greater is achieved without too great a risk of maternal barotrauma or oxygen toxicity. Extensive referencing supporting this section can be found in Chapter 50 of sixth edition [4].

CAUSES OF ACUTE RESPIRATORY FAILURE

This section describes the more common causes of acute respiratory failure in pregnancy in terms of frequency, clinical presentation, pathophysiology, and diagnosis.

Thromboembolic Disease

Fatal pulmonary embolism is a rare complication in pregnancy, but it accounts for 20% of all pregnancy-related deaths in the United States [5]. Thromboembolic complications have been estimated to occur in 0.76 to 1.72 per 1,000 pregnancies [6]. The increased frequency of thromboembolic disease in pregnancy may be attributable to a hypercoagulable state along with venous stasis. During pregnancy, there is a progressive increase in coagulation factors I, II, VII, VIII, IX, and X. There is a decrease in protein S and a progressively increased resistance to activated protein C [6]. The activity of plasminogen

activator inhibitor types 1 and 2, which are inhibitors of fibrinolysis, also increases [7]. Venous stasis may occur because of a hormonally induced dilation of capacitance veins and uterine pressure on the inferior vena cava [8]. Factors that further increase the risk of thromboembolic disease during pregnancy and the puerperium include (a) cesarean section, which has a 10 times greater risk of fatal pulmonary embolism than does vaginal delivery; (b) increased maternal age; (c) multiparity; (d) obesity, especially in association with bed rest; (e) personal or family history of thromboembolism; (f) suppression of lactation with estrogen; (g) surgical procedures during pregnancy and early puerperium; and (g) inherited thrombophilias such as deficiencies of proteins C or S, the presence of antiphospholipid antibodies, the presence of factor V Leiden, and prothrombin gene mutations [8–10].

The appropriate diagnostic steps and treatment of venous thrombosis and pulmonary embolism in nonpregnant patients are reviewed in Chapter 52. This chapter focuses on the diagnosis and management of massive pulmonary embolism associated with severe respiratory and hemodynamic compromise during pregnancy. Respiratory failure may ensue in pulmonary embolism when extensive occlusion of the pulmonary vasculature or concomitant pulmonary edema occurs. Pulmonary edema has been associated with pulmonary embolism in areas of intact blood flow and has been attributed to increased hydrostatic forces in nonoccluded vessels, vigorous crystalloid resuscitation, and increased microvascular permeability caused by platelet-derived mediators [11,12].

Although none of the symptoms, physical signs, or results of laboratory, radiographic, or electrocardiographic studies are specific for pulmonary embolism, these investigations can help rule out other diseases in the differential diagnosis. The usefulness of the serum D-dimer levels in diagnosing thromboembolic disease in pregnancy is limited because D-dimer levels are increased during normal pregnancy, with levels increasing as gestation progresses and peaking at delivery and in the early postpartum period [13,14]. Likewise, hemodynamic data obtained at pulmonary artery catheterization are more helpful in excluding other processes and in guiding hemodynamic management than in making a definitive diagnosis of pulmonary embolism.

The typical hemodynamic findings in nonpregnant patients with massive pulmonary embolism are delineated in Chapter 52. Although there are no data for pregnant patients with massive pulmonary embolism, similar findings would be anticipated because pregnancy does not significantly alter right heart and pulmonary artery pressures. Thus, in a pregnant patient with massive pulmonary embolism, pulmonary artery balloon occlusion pressure (i.e., pulmonary capillary wedge pressure) would be expected to be normal or low, mean pulmonary artery pressure moderately elevated ($\geq$35 mm Hg), and right atrial pressure moderately elevated (>8 mm Hg).

Doppler ultrasound of the lower extremities to assess for lower extremity deep venous thrombosis (DVT) may be chosen as the initial test in the evaluation for a pulmonary embolism. Further diagnostic evaluation is not required when a DVT is found in the legs, as the treatment for DVT and pulmonary embolism is the same. A negative Doppler ultrasound of the lower extremities does not rule out the presence of pulmonary embolism, so further diagnostic investigation is required. In the nonpregnant patient population, helical CT scanning with intravenous contrast has become the study of choice for pulmonary embolism. Data from PIOPED 2 determined the sensitivity and specificity of CT angiography for detecting pulmonary embolism to be 83% and 96%, respectively [15]. Pregnancy was an exclusion criteria in this study, so there is a lack of prospective data assessing CT angiography in pregnancy. However, CT angiography is now being used more commonly as the first screening examination for pulmonary embolism during pregnancy [16]. This trend is based on evidence that the dose of ionizing radiation from a helical CT scan is safe in all trimesters. The radiation dose to the fetus ranged from 0.00033 rad in the first trimester to 0.01308 rad in the third trimester. This radiation dose is comparable with the dose exposure during ventilation–perfusion scanning [17]. CT angiography also provides the opportunity of diagnosing other abnormalities that may be causing the patient's symptoms even if the scan is negative for thromboembolic disease.

Ventilation–perfusion lung scanning remains a useful diagnostic test for pulmonary embolism during pregnancy in patients who have a contraindication to radiocontrast. Pulmonary angiography may still be required for definitive diagnosis of a pulmonary embolism in some patients. Fetal exposure to radiation during imaging studies can be minimized by abdominal shielding and using brachial access.

Amniotic Fluid Embolism

AFE, also known as anaphylactoid syndrome of pregnancy, is a rare, but usually catastrophic, complication of pregnancy and delivery [18–20]. The incidence of AFE is approximately 1 in every 8,000 to 80,000 deliveries [21–23]. A retrospective, population-based cohort study of 3 million birth records in the United States reported an incidence of 7.7 cases per 100,000 births [23]. The mortality rates reported in the literature have been reported to be from 22% to 86% [21–23]. Of the women who survive AFE, only 15% of them are neurologically intact [21].

It is unknown why amniotic fluid enters the maternal circulation in some patients, although certain potential predisposing clinical factors have been suggested based on registry and cohort studies. These factors include older maternal age (mean, 32 years), multiparity (88% of cases), amniotomy, cesarean section, abruptio placentae, insertion of intrauterine fetal or pressure monitoring devices, and term pregnancy in the presence of an intrauterine device [23]. Amniotic fluid enters the maternal circulation through one of three ports: endocervical veins; uterine tears (small tears may occur in the lower uterine segment as a part of normal labor); and uterine injury secondary to iatrogenic manipulation, such as cesarean section, insertion of monitoring devices, or membrane rupture [18].

The two life-threatening consequences of AFE are cardiopulmonary collapse and disseminated intravascular coagulation (DIC). These may occur simultaneously or in sequence. The pathophysiologic process of cardiopulmonary collapse remains controversial. It is possible that amniotic fluid contains vasoactive substances or fetal antigens that provoke an abnormal hemodynamic and immunologic response in the mother that results in the AFE syndrome [24]. There may be a biphasic response to AFE with initial hypoxemia and acute pulmonary hypertension, followed by left ventricular failure. Elevation of the pulmonary balloon occlusion pressure and reduction in cardiac output and left ventricular stroke work index have been documented [25–27].

Although Morgan [28] described only a 24% incidence of pulmonary edema, an autopsy review demonstrated that most lungs exhibited pulmonary edema (10% severe, 60% moderate) [29]. Most cases are rapidly fatal, so radiographs have been infrequently obtained, which may explain the low incidence of pulmonary edema reported by Morgan [28]. The cause of pulmonary edema has variably been ascribed to vigorous fluid resuscitation, increased permeability pulmonary edema, and cardiac decompensation caused by hypoxia and tachycardia [26].

The other major consequence of AFE is coagulation failure. In 10% to 15% of patients, excessive bleeding, particularly uterine bleeding, may be the first sign of AFE. Up to 50% of

patients who survive the first 30 to 60 minutes have clinical evidence of coagulopathy, and most of the remaining patients have laboratory evidence of DIC [28]. The initiating factors precipitating DIC are not known.

The abrupt onset of severe dyspnea, tachypnea, and cyanosis during labor or the early puerperium is the classic presentation of AFE, characterizing more than one half of cases. Shock, which is out of proportion to blood loss, is the first manifestation in another 10% to 15%. Seizure activity may be the presenting sign in 30% of cases. In addition, fetal bradycardia is seen in 17% of U.S. registry cases. Bleeding is the forerunning sign in 10% to 15% of patients, and the longer the survival, the greater the likelihood that the patient will manifest respiratory failure, cardiovascular collapse, and DIC. Whatever the presenting symptom complex, 90% of cases occur before or during labor [28]. Other complications, such as acute renal failure and signs of central nervous system injury, are probably secondary to hypotension and hypoxemia. Prodromal symptoms, such as vomiting and shivering, are nonspecific and frequently associated with otherwise uneventful deliveries.

Diagnostic criteria for AFE previously rested on demonstration of fetal elements such as epithelial squamous cells from fetal skin, lanugo hairs, fat from the vernix caseosa, mucin from fetal gut, and bile-containing meconium in the maternal circulation. These elements are not pathognomonic for AFE, as these amniotic fluid components are found in the maternal circulation of healthy pregnant women without AFE [30,31]. Therefore, the antemortem diagnosis of AFE still rests predominantly on the clinical setting and the exclusion of other causes of acute respiratory failure. The role of echocardiography in the diagnosis of AFE is not yet known. Cardiac echo may show decreased left ventricular function or echodense material in the right atrium or right ventricular outflow tract [32]. A serologic assay has been developed using a monoclonal antibody TKH-2 to detect a meconium and amniotic fluid-derived mucin-type glycoprotein. This assay is reported to have a high sensitivity for detecting AFE, but it is not yet recommended for routine clinical practice [33,34].

Fetal outcome is also poor in AFE. The perinatal mortality from the national registry was 21%, with 50% of the survivors experiencing permanent neurologic injury [21].

Venous Air Embolism

Venous air embolism has been described during normal labor, delivery of patients with placenta previa, criminal abortions using air, and insufflation of the vagina during gynecologic procedures [35,36]. There are also cases reported in the literature of venous embolism occurring following orogenital sex and after the use of a birth training device designed to stretch the peritoneum to prevent perineal injury by inflating and deflating a balloon [37,38]. Venous air embolism may account for as many as 1% of maternal deaths [35]. Presumably, the subplacental venous sinuses are the sites of air entry when antepartum or peripartum air embolism occurs [35].

Sudden, profound hypotension is the most common presenting sign of venous air embolism. Cough, dyspnea, dizziness, tachypnea, tachycardia, and diaphoresis also may be noted. Hypotension is usually followed quickly by respiratory arrest. The classic sign associated with air embolism is the mill wheel murmur, which is audible over the precordium [39]; a drum-like or bubbling sound may also be heard. Electrocardiographic evidence of ischemia, right heart strain, and arrhythmias have been described, and metabolic acidosis, presumably caused by lactic acid production, may be present [39] (see Chapter 61). Transesophageal echocardiography and transthoracic echocardiography have been utilized to identify air embolism, the route of the embolism, and the severity of the air embolism [40]. Precordial Doppler ultrasound may also be used for surveillance of air embolism by detection of alterations in the ultrasonic pattern caused by the embolism [41].

The volume of air that is likely to be lethal seems to vary with the rate of infusion and patient position. Any amount greater than 100 mL may cause death, but some patients have survived after infusion of up to 1,600 mL [42]. The mechanism by which air embolism leads to noncardiogenic pulmonary edema is not known. It is thought that entrapment of air bubbles in the pulmonary circulation leads to activation of complement, neutrophil, and platelets, resulting in mediator release and then endothelial injury [43]. This inflammatory response would then precipitate noncardiogenic pulmonary edema [44].

Aspiration of Gastric Contents

Aspiration of acidic gastric contents into the tracheobronchial tree was first described in 1946 by Mendelson [45] in women during labor and delivery. Maternal deaths from pulmonary aspiration have been steadily declining as a result of changing anesthesia practices including a shift to regional anesthesia from general anesthesia for delivery [46].

At term, several factors contribute to an increased risk of aspiration of stomach contents: (a) increased intragastric pressure caused by external compression by the gravid uterus, (b) progesterone-induced relaxation of the lower esophageal sphincter, (c) delayed gastric emptying during labor, (d) supine position, and (e) analgesia-induced decreased mental status and decreased vocal cord closure [47]. The pulmonary pathophysiologic consequences of gastric aspiration are a consequence of the acidity and the particulate content of the gastric contents and the risk of bacterial superinfection. Acid aspiration causes a direct injury to the airway resulting in desquamation and loss of ciliated and nonciliated cells including the alveolar type II cells. An inflammatory response is also triggered by the acid aspiration leading to an increase in alveolar permeability with a loss in lung compliance and a decrease in ventilation–perfusion matching [47]. Inhaled particulate matter may cause acute airway obstruction and immediate death.

The volume of acid aspiration determines, in part, the rapidity of symptom onset. Aspiration of smaller volumes may go unnoticed clinically until 6 to 8 hours later, when tachypnea, tachycardia, hypoxemia, hypotension, bronchospasm, and production of frothy, pink sputum are noted in association with diffuse infiltrates on chest radiography. Progression of chest radiographic findings may continue for up to 36 hours. The clinical course may follow one of three patterns: (a) rapid improvement during 4 to 5 days; (b) initial improvement followed by deterioration caused by supervening bacterial pneumonia, with a fatal outcome in up to 60%; and (c) early death as a result of intractable hypoxia [46]. Predictors of poor outcome include low pH, large volume, and a greater amount of particulate content of the aspirate. The bacterial pathogens in this setting are usually oropharyngeal anaerobes, although the longer the patient is in the hospital before clinical development of pneumonia, the greater the likelihood of facultative, Gram-negative bacillary and *Staphylococcus aureus* infections [48].

Respiratory Infections

The prevalence of pneumonia in pregnancy ranges from 0.78 to 2.7 cases per 1,000 deliveries. The maternal mortality rate from pneumonia has decreased from 20% to 3% since the advent of antibiotics [49]. The major factors in improving fetal and maternal outcome seem to have been earlier presentation and prompt institution of antibiotic therapy. Although pneumonia rarely progresses to respiratory failure, it is advisable to

assess maternal oxygenation in all cases of maternal pneumonia. The spectrum of organisms to consider is similar to that in the nonpregnant population; the most common organisms are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Mycoplasma pneumoniae*. *Legionella* pneumonia accounts for up to 22% of community-acquired pneumonia [50] and has been reported to cause respiratory failure in pregnancy [51].

Certain other respiratory infections (e.g., influenza, varicella, coccidioidomycosis, tuberculosis, listeriosis, and severe acute respiratory syndrome [SARS]) have been associated with increased maternal and fetal morbidity and mortality. These particular infections can be virulent in the pregnant patient because of alterations in the immune status. Specifically, during pregnancy there is a decreased lymphocyte proliferative response, a decrease in the natural killer cell activity, and a decrease in the number of helper T4 cells [52]. Fortunately, the impairment in maternal immune response is mild and the increase in maternal morbidity is small.

In the influenza pandemics of 1918 and 1957, an excess incidence of influenza pneumonia was noted among pregnant women. A 50% incidence of influenza pneumonia and an overall mortality of 27% for influenza in pregnancy were found in 1918 [53]. In the 1957 pandemic, several studies noted that 50% of deaths from influenza in women of childbearing age were in pregnant patients [53]. Autopsy reports noted that the cause of death in pregnant women was respiratory insufficiency caused by fulminant influenza pneumonia, rather than secondary bacterial infection, the more common cause of death in nonpregnant influenza patients. Similarly, the new strain of influenza A (novel influenza A H1N1), identified in 2009, has been associated with increased morbidity in pregnant women [54]. During the first weeks of this outbreak, 20 cases were identified in pregnant women; three were hospitalized and one died. These women presented with the typical symptoms of cough, fever, sore pharyngitis, rhinorrhea, diarrhea, headache, and myalgias [54].

Primary varicella-zoster infections progress to pneumonia more commonly in adults than in children, although only 20% of varicella cases occur in adults [55]. Cigarette smoking appears to be an important risk factor in the progression of varicella into pneumonia [56]. Progression to pneumonia has also been noted more frequently in pregnant women in their second and third trimesters; 10% of reported cases of varicella pneumonia have occurred in pregnant women. Historically, the maternal mortality rate for varicella pneumonia in pregnancy was 41%. Utilization of antiviral therapy has led to a decline in maternal mortality now in the range of 11% to 35% [49,56]. Respiratory failure requiring mechanical ventilation may occur in 40% to 57% of pregnant patients with varicella pneumonia, with a mortality rate of 25% [49,56].

Respiratory symptoms usually develop 2 days after the onset of fever, rash, and malaise. Typical symptoms are cough, dyspnea, hemoptysis, and chest pain [56]. Generalized varicella-zoster infections may also be associated with hepatitis, myocarditis, nephritis, thrombocytopenia, and adrenal hemorrhage [56]. Varicella during pregnancy can lead to intrauterine infection, which may result in prematurity, spontaneous abortion, and stillbirth [56]. In the absence of dissemination, herpes zoster does not appear to be associated with significant maternal morbidity or evidence of fetal infection [57].

SARS is an atypical pneumonia first described in 2002 that is caused by a coronavirus [58]. Symptoms of fever, chills, rigors, headache, malaise, and myalgias develop 2 to 7 days after exposure. A nonproductive cough or dyspnea may develop over 3 to 7 days. This may progress to hypoxemia and respiratory failure. The chest radiograph may show bilateral patchy interstitial infiltrates. The overall mortality rate for SARS is 3% [58]. One review of 12 cases of SARS during pregnancy demonstrated that 33% of pregnant women required mechanical ventilation, and the maternal mortality rate was 25% [59]. Pregnant patients with suspected or probable SARS should be placed on airborne precautions in a negative pressure isolation room [60].

Maternal *Coccidioidomycosis immitis* infections are rare, with less than 1 case in every 1,000 pregnancies. Historically, *Coccidioidomycosis* infection during pregnancy has been reported as having a 20.0% dissemination rate, compared with 0.2% in nonpregnant patients; infections contracted in the second or third trimester have a higher rate of dissemination [61]. Maternal mortality and fetal loss are preventable with appropriate treatment [61]. Case reports of cryptococcosis, blastomycosis, and sporotrichosis in pregnancy are rare enough to suggest that there is no increased susceptibility to these infections [61].

Disseminated coccidioidal infection should be suspected in patients with primary or chronic progressive coccidioidal pneumonia in whom rapidly progressive respiratory failure and a clinical picture resembling miliary tuberculosis develop. Diagnosis is sometimes difficult because sputum is positive in less than 40% of cases, and complement fixation titers may be low [61,62]. Evaluation of these patients should include a careful search for extrapulmonary disease (e.g., lumbar puncture, urinalysis, culture of skin lesions) [61,62].

Respiratory failure due to infection with *Mycobacterium tuberculosis* is rare, although before the advent of effective chemotherapy, maternal and infant mortality in cases of advanced disease approached 40% [63]. Pregnancy does not alter the pathogenesis of tuberculous infection or increase the likelihood of latent tuberculosis infection progressing to active disease [64]. In addition, pregnancy does not alter the response to purified protein derivative skin testing, so all pregnant women from populations recommended for screening should have a skin test performed if one has not been done previously [65].

In 2004, 27% of acquired immunodeficiency syndrome (AIDS) cases in the United States were in adult women [66]. As the number of women infected with the human immunodeficiency virus grows, the spectrum of respiratory disease in pregnancy will include an increasing proportion of opportunistic infections and other respiratory complications related to AIDS. *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) is the most common cause of AIDS-related death in pregnant patients [67]. A review of 22 cases of *Pneumocystis jirovecci* in pregnancy found a 59% rate of mechanical ventilation and a maternal mortality rate of 50%, compared with a mortality rate of 1% to 16% in nonpregnant patients [67]. Diagnostic evaluation follows the same protocol as in a nonpregnant patient with suspected PCP. Induced sputum should be examined for the presence of *P. jirovecii*; if this is negative, fiberoptic bronchoscopy with bronchoalveolar lavage should be performed.

Listeria monocytogenes, a cause of meningitis and sepsis in immunocompromised hosts, also has a predilection for pregnant women, most commonly resulting in abortion or neonatal sepsis. The incidence of Listeria infection among pregnant women is estimated at 12 per 100,000 compared with 0.7 per 100,000 in the general population [68]. The usual sporadic incidence is two to three cases for every 1 million of the population each year, but local outbreaks may occur as a result of ingestion of contaminated cheese, cabbage, or milk [68]. In an outbreak that caused 29 fetal and neonatal deaths, maternal morbidity was limited to fever and gastrointestinal symptoms [68]. However, in a few reported cases of maternal sepsis caused by *L. monocytogenes*, ARDS has developed [69]. In these cases, the fetal outcome was excellent despite *L. monocytogenes* sepsis. Diagnosis may be problematic because of difficulties in isolating the organism from respiratory tract secretions. When *L. monocytogenes* sepsis is suspected, cultures should be obtained from the blood, sputum, rectum, cervix, and amniotic fluid [68].

Asthma

Asthma affects between 3.7% and 8.4% of pregnant women in the United States [70]. The scope of this section is limited to asthmatic exacerbations during pregnancy that lead to respiratory failure. Studies have shown that poor asthma control during pregnancy is associated with adverse fetal and maternal outcomes. Pregnant women with frequent or severe asthma attacks were more likely to have fetal complications including growth retardation, preterm birth, low birth weight, neonatal hypoxia, and perinatal mortality. The maternal complications included preeclampsia, gestational hypertension, vaginal hemorrhage, hyperemesis, and complicated labor [71]. One study reported on the pregnancy outcomes of 486 asthmatic women who were enrolled in an active asthma management program compared with nonasthmatic, pregnant controls. There were no significant differences in either the fetal or maternal outcomes between the two groups. When active management of asthma during pregnancy is provided, maternal and fetal outcomes are no different than those of healthy, nonasthmatic women [70].

The initial clinical assessment of a pregnant woman with asthma should include personal history (detailing etiologic factors and prior therapy), physical examination, and either peak expiratory flow rate or spirometric pulmonary function testing (see Chapter 48). Peak expiratory flow rates and spirometry do not change with pregnancy and advancing gestation. Therefore, peak expiratory flow rates can be used as diagnostic and monitoring tools in the care of pregnant asthmatic women [72]. Although asthma may be the most common cause of airway obstruction during pregnancy, wheezing, shortness of breath, coughing, and sensation of chest tightness are nonspecific, and several other entities may mimic asthma (see Chapter 48).

Assuming the diagnosis of asthma is secure, certain findings taken together can be used to predict which patients are likely to require hospitalization [73]. These include diaphoresis, use of accessory muscles, assumption of upright posture, altered level of consciousness, pulse rate greater than 120 beats per minute, respiratory rate greater than 30 breaths per minute, pulsus paradoxus greater than 18 mm Hg, and peak expiratory flow rate less than 120 L per minute. When the FEV_1 is no more than 15% of predicted or is less than 0.5 L, both a pulsus paradoxus of 10 mm Hg or greater and use of accessory muscles of respiration are almost always found [74,75]. Conversely, the absence of both an elevated pulsus paradoxus and use of accessory muscles usually correlates with an FEV_1 greater than 40% of predicted or greater than 1.25 L [74,75]. Peak flows have been used in the evaluation of nonpregnant patients with asthma to predict the need for arterial blood gas determination. Flows greater than 200 L per minute (50% of predicted) are virtually never associated with significant hypoxemia or hypercapnia (see Chapter 48). However, as alveolar-arterial oxygen tension gradients are known to be widened in pregnancy [3], it seems prudent to obtain arterial blood gas measurements in pregnant women with asthma who do not show a significant improvement (>20%) in peak expiratory flow rate after an initial inhaled bronchodilator treatment. Continuous oxygen saturation monitoring is also appropriate.

During acute asthma attacks, arterial blood gas measurements typically reveal mild hypocapnia ($PaCO_2$ of 35 mm Hg) and moderate hypoxemia. In pregnancy, as noted previously, the baseline $PaCO_2$ is usually already depressed [3] and probably decreases further with an acute asthma attack. The importance of this is twofold: (a) a $PaCO_2$ of 35 mm Hg during an acute attack may actually represent "pseudonormalization" caused by fatigue, inability to meet the increased work of breathing, and impending respiratory failure and (b) persistent hypocapnia with associated respiratory alkalosis (pH greater than 7.48) may result in uterine artery vasoconstriction and decreased fetal perfusion [76].

β-Adrenergic Tocolytic Therapy

β-Adrenergic agents have been used therapeutically for inhibition of preterm labor [77]. The use of relatively β_2-selective agents, such as ritodrine and terbutaline, has diminished the frequency of unacceptable maternal tachycardia, but maternal pulmonary edema has remained a serious side effect. Pulmonary edema associated with tocolytic therapy appears to be unique to pregnancy because it has not been reported when these medications are used to treat asthma. Pulmonary edema occurs in approximately 1 in 400 women who are treated with β-agonists to control premature labor [78]. Calcium-channel blockers such as nifedipine and nicardipine have also been used for tocolysis, and cases of pulmonary edema induced by calcium-channel blockers when used for tocolysis have been reported [79,80]. Other tocolytics in clinical practice include cyclooxygenase-2 inhibitors and oxytocin antagonists. These are generally more specific for inhibition of preterm labor and less toxic than the β-adrenergic agents used for tocolysis [81]. A comparative study of atosiban, a selective oxytocin antagonist, versus β-agonists found atosiban to be as effective as the β-agonists as a tocolytic agent but significantly less likely to result in maternal cardiovascular side effects [82]. Atosiban is not approved for use in the United States because of concerns regarding drug safety when used in fetuses less than 28 weeks of gestation but is available in other countries [83].

The typical symptoms and signs of β-adrenergic tocolytic-induced pulmonary edema are chest discomfort, dyspnea, tachypnea (24 to 40 breaths per minute), crackles, and pulmonary edema on chest radiography. Evidence of pulmonary edema develops relatively acutely, occasionally after only 24 hours but usually after 48 hours of β-adrenergic tocolytic therapy. A nonproductive cough is occasionally present. Wheezes, in addition to crackles, were noted in one case [80]. The size of the heart has been difficult to assess on radiographs because of the normal increase in cardiac diameter with pregnancy. The relatively rapid improvement that occurs with discontinuation of β-adrenergic tocolytic therapy (usually in less than 24 hours), the absence of hypotension and clotting abnormalities, and the lack of need for mechanical ventilation support the possibility that these cases represent a separate syndrome related to β-adrenergic tocolytic therapy.

The pathophysiologic mechanisms leading to the development of tocolytic-induced pulmonary edema are not well defined. Fluid overload is an important factor contributing to the pathogenesis. Augmented aldosterone secretion secondary to pregnancy and β-agonist stimulation causes salt and water retention [81]. Tocolytic agents also stimulate antidiuretic hormone secretion, which increases water retention [82]. There are no compelling data to support the hypothesis of cardiac failure as the etiology of tocolytic-induced pulmonary edema. Echocardiography and hemodynamic assessment of affected patients have not revealed cardiac dysfunction [81]. The rapidity of improvement after diuresis is consistent with pulmonary edema caused by increased hydrostatic pressure, rather than an increase in capillary permeability [81].

Pneumomediastinum and Pneumothorax

Pneumomediastinum is another rare complication of pregnancy. Estimates of incidence range from 1 in 2,000 to 1 in 100,000 patients [84]. It occurs most commonly in the second stage of labor and is associated with chest or shoulder pain that

radiates to the neck and arms, mild dyspnea, and subcutaneous emphysema of face and neck. Prolonged, dysfunctional labor, coughing, and severe emesis seem to be predisposing factors. Air from ruptured alveoli tracks centrally along the perivascular sheath into the mediastinum and along fascial planes into the subcutaneous tissues. Of the reported cases in pregnancy, only one patient required decompression of the mediastinum for treatment of venous obstruction [85].

Spontaneous pneumothorax with tension may occur with or without associated pneumomediastinum. It occurs rarely during pregnancy with an incidence estimated at 1 per 10,000 deliveries, but it should be considered in the differential diagnosis of respiratory failure during pregnancy [86]. Risk factors for pneumothorax include asthma, cigarette smoking, crack cocaine use, and history of pneumothorax. Pneumothoraces usually occur during labor or in the immediate postpartum period. Occurrence of pneumothorax may be caused by rupture of subpleural blebs by the changes in intrapleural pressure caused by Valsalva maneuvers during labor [86]. Symptoms of pneumothorax include sudden pleuritic chest pain, dyspnea, and cough. Hypotension may develop if a tension pneumothorax develops. The clinical significance of pneumothorax during pregnancy relates to impaired ventilation and hypoxemia, which can lead to fetal hypoxemia.

Acute Respiratory Distress Syndrome

ARDS is a type of respiratory failure caused by an inflammatory injury to the alveolar–capillary interface that leads to alveolar edema and resultant hypoxemia. The diagnosis of ARDS in pregnant patients is the same for nonobstetric patients. The criteria defined by the American-European Consensus Conference include (i) acute onset, (ii) a PaO_2/FiO_2 ratio of less than 200 mm Hg regardless of positive end-expiratory pressure (PEEP) level, (iii) bilateral infiltrates on chest x-ray, and (iv) a pulmonary artery wedge pressure of less than 18 mm Hg or the absence of clinical evidence of left atrial hypertension [87]. The pathogenesis of ARDS during pregnancy includes the same etiologies seen in the general population such as sepsis, aspiration, pancreatitis, trauma, inhalational injury, drowning, and pneumonia. Unique entities of pregnancy that may lead to ARDS include amniotic fluid embolism, eclampsia, HELLP syndrome, chorioamnionitis, and endometritis [88–91].

Published case series data report maternal mortality rates between 23% and 39%, with multisystem organ failure as the most common cause of death [90,91]. Neonatal outcomes are not well studied, but in one study of 13 women with ARDS, the perinatal fetal death rate was 23% [91]. In another published series of 10 women treated for ARDS, only 5 of the babies survived intact [91].

DIAGNOSTIC TESTING

Radiology

Evaluation of patients with respiratory failure usually requires at least one, if not sequential, chest radiographs. Potential adverse fetal effects include congenital malformation, intrauterine growth retardation, and increased risk of leukemia and other malignancies [92–94]. There is no evidence that there is an increased fetal risk of anomalies, growth retardation, or intellectual disability from radiation doses less than 0.05 Gy [93]. There may be a small increased risk of childhood leukemia, 1 in every 2,000 compared with a background rate of 1 in every 3,000 [94,95].

TABLE 51.2

FETAL RADIATION DOSE

Diagnostic test	Dose	
	mrad	μGy
Posterior-to-anterior and lateral chest radiograph	<1	10
Helical chest CT scan	0.33–13	3–131
Abdominal CT scan	250	2,500
Lung perfusion scan	6–12	60–120
Lung ventilation scan	1–19	10–190
Brachial pulmonary arteriogram	<50	<500
Femoral pulmonary arteriogram	221–374	2,210–3,740

CT, computed tomography.
Adapted from Ginsberg JS, Hirsch J, Rainbow AJ, et al: Risks to the fetus of radiologic procedures used in the diagnosis of maternal venous thromboembolic disease. *Thromb Haemost* 61:189, 1989; Bentur Y, Horlatsch N, Koren G: Exposure to ionizing radiation during pregnancy: perception of teratogenic risk and outcome. *Teratology* 43:163, 1991; Winer-Muram HT, Boone JM, Brown HL, et al: Pulmonary embolism in pregnant patients: fetal radiation does with helical CT. *Radiology* 224:487, 2002.

The National Council on Radiation Protection Handbook 54 established 5 rad (0.05 Gy or 5 cGy) as the embryonic exposure level not to exceed [94]. The estimated radiation exposures of selected procedures used in the evaluation of pregnant patients with respiratory failure are shown in Table 51.2 [95]. Portable chest radiographs performed daily for 2 weeks to assess location of endotracheal tubes and central venous catheters, as well as response of the underlying illness to treatment, would expose the fetus to approximately 7 mrad (0.07 Gy). A pregnant woman being evaluated for thromboembolic disease with a chest radiograph and helical chest CT-pulmonary angiogram would have a fetal exposure of less than 500 mrad (0.005 Gy or 0.5 cGy) [93,96].

Magnetic resonance imaging (MRI) and ultrasonography are not known to be associated with adverse fetal outcomes [96,97]. Previously, the National Radiological Protection Board had advised that MRI be avoided during the first trimester because its safety during organogenesis was unknown [98]. The American College of Radiology has subsequently published guidelines in which MRI may be considered as a nonionizing imaging study during any trimester if the risk–benefit ratio to the patient is favorable [99]. Gadolinium crosses the placenta to the fetus, so the use of gadolinium-based contrast is not recommended at any time in pregnant patients [99].

Hemodynamic Monitoring

Cardiopulmonary monitoring in critically ill patients has advanced rapidly since the introduction of flow-directed pulmonary artery catheters in 1970 [100,101]. There are no reports of specific complications of pulmonary artery catheterization pertaining to obstetric patients, who are at equal risk as nonobstetric patients for complications such as hematoma or pneumothorax at the time of insertion, balloon rupture, catheter knotting, pulmonary infarct, pulmonary artery rupture, thrombosis, embolism, arrhythmias, right bundle-branch block, valvular damage, and infection (see Chapter 4).

The changes that occur in maternal hemodynamics during pregnancy, labor, and delivery have been described. Pulmonary artery catheterization of 10 healthy pregnant patients was done at term and repeated during the nonpregnant state

to determine the hemodynamic changes in normal pregnancy. There were significant reductions in systemic and pulmonary vascular resistances, colloid oncotic pressure, and the gradient between colloid oncotic pressure and pulmonary balloon occlusion pressure in the late third trimester. There was a significant increase in heart rate and cardiac output in all pregnant patients. There was no significant change in central venous pressure, pulmonary balloon occlusion pressure, mean arterial pressure, or left ventricular stroke work index [101,102].

Potential indications for pulmonary artery catheterization in obstetric patients include the diagnosis or management of septic shock, class III and IV cardiac patients in labor, severe preeclampsia or eclampsia during labor, pulmonary edema that does not quickly respond to diuretic therapy, pulmonary hypertension, and ARDS with PEEP of more than 15 mm Hg [103].

Because of the complications that may accompany pulmonary artery catheterization, the expense of the procedure, and the lack of formal demonstration of improved morbidity or mortality related to the technique, it has been suggested that caution be exercised when choosing to proceed with pulmonary artery catheterization [103]. Clinical assessment may be inadequate in obstetric patients to differentiate between cardiogenic and noncardiogenic pulmonary edema. Both increased-permeability pulmonary edema and pulmonary edema caused by volume overload are common causes of respiratory failure in pregnancy. In addition, careful hemodynamic management is needed to maintain adequate uterine blood flow in compromised patients. Maintaining a good risk-to-benefit ratio depends on obtaining accurate information, interpreting this information in the context of the stage of pregnancy or labor, and determining the specific situations in which the information will contribute significantly to patient management.

Noninvasive hemodynamic monitoring techniques such as Doppler echocardiography, esophageal Doppler monitoring, thoracic electrical bioimpedance, arterial pressure wave form algorithms, pulse pressure variation, and stroke volume variation require further study in critically ill obstetric patients [104–107].

Fetal Monitoring

When respiratory failure occurs early in gestation, before fetal viability is ensured, and when early delivery is not an option, the best course is to focus on optimizing care for the mother and not on minute-to-minute variations in fetal heart rate. However, it is reasonable to measure and record a daily fetal heart rate to document that the fetus is alive. When she is able, the mother can report whether fetal movement is present. If respiratory failure persists for several weeks, fetal growth measurement by ultrasound may be indicated. When gestation has progressed enough for delivery by cesarean section, amniocentesis may be helpful to determine fetal maturity [108]. Continuous external fetal heart rate monitoring may be helpful during surgical procedures to alert the anesthesiologist to problems with maternal ventilation or cardiac output [109,110].

TREATMENT

Supportive Therapy

Mechanical ventilation, nutritional support, and maintaining an adequate blood pressure are important considerations in respiratory insufficiency during pregnancy.

Mechanical Ventilation

The guidelines for intubation and mechanical ventilation are essentially the same for pregnant patients as for nonpregnant patients: (a) inability to maintain a minimal PaO_2 of 60 to 65 mm Hg with supplemental oxygen, (b) uncompensated respiratory acidosis, and (c) inability to clear secretions or need to protect the airway because of altered mental status (see Chapters 1 and 58).

Pregnancy is associated with alterations in physiology that may make airway management more difficult compared with that of nonpregnant patients. Elevated estrogen levels and an increase in blood volume seen in pregnancy may contribute to mucosal edema [111,112]. Smaller endotracheal tubes sized 6 to 7 mm may be required to minimize the risk of upper airway trauma during intubation [3]. The decreased FRC in pregnancy may lower the oxygen reserve such that, at the time of intubation, a short period of apnea may be associated with a precipitous decrease in PaO_2 [3]. Therefore, before any attempt at endotracheal intubation, 100% oxygen should be administered, either by mask when the patient is able to ventilate spontaneously or by hand resuscitation bag when the patient requires assisted ventilation. However, hyperventilation to increase the PaO_2 before intubation should be avoided because the associated respiratory alkalosis may actually decrease uterine blood flow. Multiple factors place a pregnant patient at an increase risk of aspiration during intubation. These include incompetence of the gastroesophageal junction caused by the position of the gravid uterus, delayed gastric emptying during labor, progesterone-mediated smooth muscle relaxation of the gastrointestinal mucosa, and decreased lower esophageal sphincter tone [112]. During assisted ventilation and intubation, cricoid pressure with the head and neck extended can help decrease gastric inflation and prevent regurgitation into the hypopharynx [113].

Initiating mechanical ventilation follows the same general principles for pregnant patients as for nonpregnant patients, although arterial blood gas goals are different in the pregnant patient [114]. In general, the minute ventilation should be adjusted to aim for a $PaCO_2$ of 30 to 32 mm Hg, the normal level in pregnancy; marked respiratory alkalosis should be avoided because of the resultant decrease in uterine blood flow. Maternal permissive hypercapnia may also be deleterious to the fetus because of resultant fetal respiratory acidosis. The transfer of carbon dioxide across the placenta depends on the difference of 10 mm Hg between the fetal and maternal umbilical veins [115]. Plateau pressure, which reflects transalveolar pressure, should be kept under 30 cm H_2O to minimize the risk of barotrauma. Adequate fetal oxygenation requires a maternal PaO_2 of 70 mm Hg or more which corresponds to an oxygen saturation of 95% [89].

Mechanical ventilation of a pregnant patient with ARDS should follow the guidelines of the ARDS Network Study using nonpregnant predicted body weight [116]. This study has shown the efficacy of delivering tidal volumes based on ideal body weight. This strategy avoids overdistention of the lung and maintains a plateau pressure less than 30 cm H_2O. The target value for tidal volume is 6 mL per kg of ideal body weight. The respiratory rate is increased to maintain a maternal PCO_2 between 28 and 32 mm Hg while monitoring for the development of intrinsic PEEP or dynamic hyperinflation. If the pregnant patient continues to have a respiratory acidosis despite a high respiratory rate, the tidal volume may be increased as long as the plateau pressure remains less than 30 cm H_2O. In patients with ARDS who require a fraction of inspired oxygen greater than 50% to maintain a PaO_2 of 65 mm Hg or greater, or an oxygen saturation greater than 90%, consideration should be given to adding PEEP. As in nonpregnant patients, the goals are to reduce the maternal inspired oxygen

concentration to less than 50%, if possible, and to maintain adequate oxygen delivery without compromising cardiac output or risking further lung damage caused by excess intra-alveolar pressure [117]. Strict monitoring of fluid status is necessary because the hypervolemia of pregnancy may contribute to the progression of respiratory failure.

Alternative ventilation strategies for patients failing conventional ventilation modes in ARDS have not been studied in pregnancy. The routine use of airway pressure-release ventilation, high-frequency oscillatory ventilation, lung recruitment maneuvers, prone positioning, and inhaled vasodilators during pregnancy need further study before they can be recommended.

In patients with asthma, respiratory rate and tidal volume should be no greater than necessary to maintain oxygenation. Lower respiratory rates and tidal volumes help reduce airway pressures, thereby reducing volutrauma and barotrauma [116]. Inspiratory flow rates can be increased to allow adequate time for expiration. Increasing the inspiratory flow rate during volume-cycled mechanical ventilation decreases the inspiratory to expiratory ratio and mitigates air trapping. (See Chapters 47 and 58 for further discussion of mechanical ventilatory support of the patient with asthma.) Permissive hypercapnia is often necessary in patients with severe asthma to prevent volutrauma and hemodynamic compromise. There have been no reported cases of controlled hypoventilation during pregnancy, and the potential risk of fetal respiratory acidosis must be considered before instituting this therapy.

Lowering oxygen consumption by treating fever and suppressing spontaneous respiration is also helpful. Temperature regulation may be particularly important during gestation; an increased rate of congenital malformations has been associated with maternal fever, especially during the first few months of pregnancy [118]. Sedation and muscle paralysis, when indicated, are best accomplished with morphine sulfate and pancuronium bromide [119], which appear to be without adverse fetal effects except when used at the time of delivery or when used excessively, as in narcotic addiction [120]. Whether benzodiazepine use results in an increased risk of congenital malformations remains unclear, although the majority of studies are reassuring; this class of drugs is best avoided in the first trimester and used sparingly thereafter (see www.reprotox.org) [121]. Although sitting is usually the most advantageous position for weaning nonpregnant patients from mechanical ventilation, it may result in inferior vena cava compression in patients near term, in which case the lateral decubitus position is preferable. Weaning parameters for pregnant patients are not well established, but it seems reasonable to follow the same guidelines as for nonpregnant patients (see Chapter 59) [122].

Reversal of Hypotension

Supine recumbency may cause a significant decrease in venous return in women in their second or third trimesters. To counteract this, the right hip should be elevated 10 to 15 cm (15 degrees) to move the uterus off the inferior vena cava, or the lateral decubitus position should be used. As a corollary to this, if patients in the second or third trimester become hypotensive, placing them in the Trendelenburg position is unlikely to help and may actually decrease venous return because of vena cava compression.

When hypotension does not respond to reduction in uterine pressure on the vena cava, the fluid status of the patient should be assessed. If fluid boluses with 250 to 500 mL of saline do not resolve hypotension and the patient appears to be euvolemic, vasopressors should be considered. The ideal vasopressor would restore maternal blood pressure without compromising uterine blood flow. Ephedrine, which has both α- and β-stimulating effects, tends to preserve uterine blood flow while reversing systemic hypotension [3]. Phenylephrine has been used alone and in combination with ephedrine to reverse maternal hypotension associated with epidural anesthesia [123,124]. Predominantly α-adrenergic agents, such as norepinephrine, improve maternal blood pressure but decrease uterine blood flow because of uterine artery vasoconstriction. If maternal hypotension remains refractory, drugs with more α-adrenergic activity, such as epinephrine, norepinephrine, and dopamine, which do not preserve uterine blood flow, may be tried [3]. Dobutamine may also be added for life-threatening maternal hypotension when pulmonary artery pressure and cardiac output values indicate it is appropriate.

Nutrition

The importance of adequate nutrition during gestation is well recognized in that maternal weight gain correlates with fetal weight gain and a successful outcome. Maternal body stores are generally protected at the expense of fetal growth during semistarvation [125]. The duration of starvation or semistarvation that can be tolerated without ill effects on the fetus is unknown. In addition, maternal malnutrition has been shown to correlate in certain cases with intrauterine growth retardation and development of preeclampsia [126]. It is also well recognized that hospitalized patients who have experienced prolonged starvation have greater problems with wound healing and that diminished protein stores are associated with increased susceptibility to infection.

In critically ill obstetric patients, nutritional support is thought to be important for both maternal and fetal outcomes. As with nonobstetric patients, enteral nutrition is preferred over parenteral nutrition to avoid the risk of complications associated with central venous catheters, to reduce expense, and to minimize gastric mucosal atrophy [126]. Pregnancy is associated with decreased lower esophageal sphincter tone and decreased gastric motility; therefore, nasoduodenal tubes are preferred over nasogastric tubes to decrease the likelihood of reflux and aspiration, although scientific evidence for this is lacking.

Total parenteral nutrition (TPN) can provide complete nutritional support during pregnancy [127]. Given the stress of respiratory failure and its underlying causes, it seems reasonable to extend this experience with TPN to patients with respiratory failure who are unable to eat for more than 48 hours and whose gastrointestinal system cannot be used. Blood glucose levels should be measured, along with serum electrolyte concentrations, acid–base status, and renal and hepatic function. Measurement of trace element concentrations is needed for prolonged TPN. Periodic nutritional assessment should include evaluation of nitrogen balance, lymphocyte counts, transferrin, maternal weight, and fetal growth by ultrasound. If delivery occurs while the woman is receiving TPN, the neonate should be observed closely for hypoglycemia [127,128]. Vitamins should probably be replaced according to the recommended dietary allowances for pregnancy [128].

Specific Therapy

Thromboembolism

Recommendations for the treatment of venous thromboembolic disease in pregnancy have been published by the American College of Chest Physicians (ACCP) [129]. When massive pulmonary embolism is strongly suspected (>50% occlusion of pulmonary vascular bed or systemic hypotension), the major immediate goals of therapy are to (a) provide adequate oxygenation as dictated by arterial blood gas analysis, (b) treat hypotension and organ hypoperfusion by elevating right

TABLE 51.3

GUIDELINES FOR ANTICOAGULATION REGIMENS

Prophylactic LMWH: Dalteparin 5,000 units subcutaneously every 24 hours or Enoxaparin 40 mg subcutaneously every 24 hours
Intermediate-dose LMWH: Dalteparin 5,000 units subcutaneously every 12 hours or Enoxaparin 40 mg subcutaneously every 12 hours
Prophylactic UFH: Unfractionated heparin 5,000 units subcutaneously every 12 hours
Intermediate-dose UFH: Unfractionated heparin subcutaneously every 12 hours adjusted to target an anti-Xa level of 0.1–0.3 U/mL

LMWH, low-molecular-weight heparin.
Adapted from Bates SM, Greer IA, Pabinger I, et al: Venous thromboembolism, thrombophilia, antithrombotic therapy and pregnancy. American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th ed). *Chest* 133;844S, 2008.

ventricular preload with colloid or crystalloid administration and vasopressor therapy if necessary, and (c) interrupt clot propagation by immediate anticoagulation with intravenous heparin. Anticoagulation should be instituted immediately in all patients without clear contraindications, such as active bleeding, rather than delay therapy pending conclusive diagnostic studies. The therapeutic options available include subcutaneous low-molecular-weight heparin (LMWH), intravenous unfractionated heparin (UFH), or subcutaneous UFH. Heparin is not teratogenic because it does not cross the placenta. Subcutaneous LMWH is preferred because of its safety profile, ease of administration, and efficacy [129]. Meta-analysis data in nonpregnant patients has shown that patients treated with subcutaneous LMWH for pulmonary embolism had decreased mortality, a reduction in thrombus size, and were less likely to experience a major hemorrhage [130].

Intravenous UFH is recommended in pregnant patients who have persistent hypotension due to pulmonary embolism or who are considered to be at a high risk of bleeding. Intravenous UFH has a short half-life and can be reversed quickly upon discontinuation and administration of protamine [129]. UFH would also be recommended in pregnant patients with severe renal failure rather than LMWH [129]. The half-life of LMWH is decreased in pregnancy, which may lead to subtherapeutic anticoagulation levels [129]. Twice-daily regimens should be titrated to antifactor Xa levels of 0.6 to 1.0 U per mL 4 hours postinjection [129]. Measurements of antifactor Xa levels can be made every 4 to 6 weeks to verify adequate dosing [129].

When hemodynamic and angiographic information confirms massive pulmonary embolism, placement of a retrievable inferior vena filter is usually indicated to provide immediate and reliable prophylaxis against recurrent thromboembolism. In addition, thrombolytic therapy, catheter-directed thrombolysis, or surgical embolectomy may be indicated [131,132]. Thrombolysis is not indicated for submassive pulmonary embolism, because large studies have failed to document that thrombolytic therapy results in any significant improvement in mortality or morbidity compared with heparinization [131]. Specific circumstances for which thrombolytic therapy might be preferable include (a) lack of immediate availability of surgery and cardiopulmonary bypass, (b) emboli that are inaccessible to the surgeon without dissection of the lung parenchyma, and (c) the absence of large vessel puncture sites or recent surgery that would increase the risk of bleeding (see Chapter 52). One problem with instituting thrombolytic therapy is that if it is unsuccessful in achieving clot lysis sufficient to improve the hemodynamic function, subsequent endarterectomy may be impossible because of the lytic state.

Pregnancy and the immediate postpartum state are relative contraindications to thrombolytic therapy because of the risk of hemorrhage during labor, delivery, and the first several days postpartum [133]. No controlled trials of the use of thrombolytics in pregnancy have been reported, but a review of the reported cases reveals 172 women who received thrombolytics during pregnancy for various indications, including 10 cases of pulmonary embolism [134]. The intrapartum or immediate postpartum risk of hemorrhage was 8.1% if thrombolysis was performed at the time of delivery. This compares with a 2% risk of hemorrhage for pregnant patients on full-dose subcutaneous heparin for DVT. The maternal and fetal mortality rates in pregnant patients treated with thrombolytics are each 1.2%, which is similar to the 1.1% and 2.5% of heparin-treated pregnant patients. There was no increased risk of premature labor or premature rupture of membranes in pregnant patients treated with thrombolytics compared with the baseline incidence of preterm labor in the United States. In a review of 13 patients who received thrombolytic therapy for pulmonary embolism during pregnancy, there were no maternal deaths, 4 nonfatal maternal major bleeding complications, 2 fetal deaths, and 5 preterm deliveries. The authors concluded that the fetal deaths and preterm deliveries were a consequence primarily related to the pulmonary embolism rather than thrombolytic therapy [135].

Recombinant tissue plasminogen activator is the recommended agent for thrombolysis. Streptokinase does not cross the human placenta, but streptokinase antibodies do cross [134]. Tissue plasminogen activator does not cross the placenta, and the risk of allergic reactions is lower than that of streptokinase. If thrombolytic therapy is used during pregnancy, it seems reasonable to limit the duration of therapy to the time needed for restoration of acceptable hemodynamic function and to discontinue therapy at least 4 to 6 hours antepartum. Continuous uterine massage and methylergonovine maleate should be used postpartum if thrombolytic therapy was only recently discontinued. Because aminocaproic acid crosses the placenta readily and is teratogenic, aprotinin (Trasylol), which does not cross the placenta, should be used when rapid reversal of the lytic state is needed before delivery [136]. Cryoprecipitate can also be used and is preferred over fresh-frozen plasma [133].

Laboratory monitoring of the lytic state during thrombolytic infusion is not recommended, because clot lysis and risk of bleeding do not correlate well with laboratory measurement of the lytic state [131]. Following completion of thrombolysis, heparin is administered once the activated partial thromboplastin time (aPTT) and thrombin time are less than twice the normal value [131]. If delivery is anticipated in the next 6 hours, initiation of heparin is delayed until after delivery.

Surgical embolectomy may be a treatment option for massive pulmonary embolism when conventional therapy or thrombolytic therapy has failed, or if there is a contraindication for thrombolysis. There have been eight published cases in which pregnant women underwent surgical embolectomy for pulmonary embolism. There were no maternal deaths, although fetal death was reported in six cases and preterm delivery in four cases [135]. Surgical embolectomy should be reserved as a lifesaving measure for the mother due to the high incidence of fetal loss [135]. Catheter-directed therapy may include catheter-directed mechanical embolectomy and/or catheter-directed thrombolytic therapy. Among four cases using these techniques during pregnancy, one fetal death and one preterm delivery were reported [135].

Once the patient has stabilized, continuous intravenous heparin can be transitioned to subcutaneous therapy. This can be done with either LMWH or adjusted dose UFH to prolong the

aPTT 1.5 to 2.5 times control. The patient should be anticoagulated for the remainder of the pregnancy and for at least 6 weeks postpartum [129]. If the pulmonary embolism occurs late in pregnancy or in the postpartum period, anticoagulant therapy should be continued for at least 6 months and possibly longer, if persistent risk factors for a hypercoagulable state exist [129].

It is recommended that pregnant patients being treated with LMWH or UFH discontinue anticoagulation 24 hours prior to elective induction of labor [129]. If spontaneous labor occurs in a woman receiving adjusted doses of UFH, the aPTT should be monitored and corrected with protamine sulfate if delivery is near. Patients at high risk for recurrent thromboembolism during pregnancy should be placed on intravenous UFH, and this can be discontinued 4 to 6 hours prior to expected delivery. This approach minimizes the period of time without therapeutic anticoagulation [129]. The timing of reinstitution of anticoagulation following delivery will vary depending upon the type of delivery, the presence of bleeding, and the presence of a neuroaxial anesthesia catheter. As long as significant bleeding has not occurred, anticoagulation with a heparin may be resumed 6 hours after a vaginal birth or 12 hours after a cesarean section. However, after neuroaxial anesthesia, therapeutic LMWH should be administered no earlier than 24 hours postoperatively [137].

Amniotic Fluid Embolism

Treatment of AFE is limited to supportive measures aimed at providing adequate ventilation and oxygenation, maintenance of left ventricular output, blood pressure support, and management of bleeding. Most patients require intubation and mechanical ventilation. PEEP is helpful for oxygenation in some patients. No particular drug regimen has been used with any clear success to reverse pulmonary hypertension. If pulmonary capillary wedge pressures are elevated, it seems reasonable to use a diuretic to reduce hydrostatic pressures across the injured capillary endothelium. Measurement of changes in cardiac output can be used to guide this. In addition to fluid resuscitation to reverse hypotension, vasopressor therapy is frequently required with ephedrine as the first-line choice (see "Supportive Therapy" section).

Treatment of coagulopathy is likewise nonspecific. For active bleeding, transfusion with fresh-frozen plasma, cryoprecipitate, platelets, and factor replacement is indicated. Manual massage and uterotonic medications are used to reduce uterine bleeding. When uterine bleeding is refractory to these interventions, exploration for uterine tears or retained placenta should be considered. Hysterectomy may be required to control bleeding if all other medical interventions fail. There are case reports describing maternal survival from AFE following treatment with intra-aortic balloon counterpulsation, extracorporeal membrane oxygenation, and cardiopulmonary bypass [138]. In addition, one patient was treated successfully with inhaled nitric oxide, recombinant human factor VIIa, and a right ventricular assist device [139].

Venous Air Embolism

The goals of treatment are to identify the source of air entry, prevent further air entrainment, restore circulation, and remove embolized air. Placing the patient in the left lateral decubitus position may restore forward blood flow by causing the bubble of air to migrate away from the right ventricular outflow tract to a nonobstructing position [39]. Closed-chest cardiac compression has also been reported to be helpful [39]. Aspiration of air from the right atrium, right ventricle, or pulmonary outflow tract can be attempted with a central venous or pulmonary artery catheter [39]. Air bubble resorption may be accelerated by ventilating the patient with 100% oxygen to facilitate diffusion of nitrogen from the embolus. When air embolism occurs during general anesthesia, nitrous oxide should be discontinued because it has a high solubility and tends to increase the size of air bubbles in the pulmonary vasculature [39].

Patients with continued evidence of neurologic deficits or cardiopulmonary compromise because of air embolism should be considered for hyperbaric oxygen therapy. Hyperbaric oxygen accelerates nitrogen resorption, decreases air bubble size, and increases the arterial oxygen content [140]. Use of anticoagulation with heparin has been suggested to treat fibrin microemboli [39].

Aspiration of Gastric Contents

For patients with permeability pulmonary edema due to aspiration of gastric contents during labor and delivery, the main treatment is supportive care. Prophylactic antibiotics have not been found to be beneficial in aspiration pneumonitis [141]; therefore, antibiotics should be prescribed only when infection complicates the initial chemical pneumonitis. If the patient's clinical course suggests development of bacterial pneumonia, the choice of antibiotic should be guided by appropriate bacteriologic evaluation of respiratory secretions, pleural fluid (if present), and blood cultures. For patients who have been in the hospital for 48 hours or less, clindamycin or a beta lactam–beta-lactamase inhibitor combination is reasonable empiric choice to treat anaerobic organisms. Most studies have not supported an ameliorative role for glucocorticoids, despite early anecdotal suggestions of success [142–145]. Lung lavage with normal saline or alkaline solutions is not helpful and may worsen the patient's condition [145].

Respiratory Infections

Antibacterial agents to treat pneumonia during pregnancy should be selected according to the same principles used for nonpregnant patients [50]. Drugs with the least risk to fetus and mother should be chosen whenever possible. The following comments about antibiotic safety are derived from a review [146].

For community-acquired pneumonia in pregnancy, penicillins, ceftriaxone, azithromycin, and erythromycin (excluding the estolate, which is associated with an increased risk of cholestatic jaundice in pregnancy) are probably safe. Tetracycline is contraindicated because it is teratogenic and causes hepatic toxicity when administered intravenously in pregnancy. The aminoglycosides have the potential of causing eighth nerve toxicity in the fetus and should be used only when strong clinical indications exist. Serum drug levels should then be monitored closely. Sulfonamides are considered contraindicated at term because of the risk of neonatal kernicterus. Clindamycin has no reported adverse fetal effects, but experience is limited and it should be used with caution. Vancomycin hydrochloride may cause fetal renal and auditory toxicity and should be used with caution, with close monitoring of serum drug levels. Clarithromycin and levofloxacin are pregnancy risk factor class C and, therefore, should be used judiciously, weighing potential risks and benefits.

The predominant treatment of influenza pneumonia is supportive care, following the same practices as outlined for other causes of respiratory failure in pregnancy. For pregnant women who present with presumed or documented influenza pneumonia, the neuraminidase inhibitors, zanamivir and oseltamivir, are the usual first line of specific antiviral therapy [147]. These agents are active against both influenza A and B [147]. Either agent may be used, unless oseltamivir resistance is suspected, in which case zanamivir is preferred. When oseltamivir resistance is suspected, but the patient has a contraindication to zanamivir (e.g., asthma or COPD), a combination of oseltamivir and adamantine may be used. Fetal side effects have not been

reported with either neuraminidase inhibitor, although experience with them is limited.

The adamantines (amantadine and rimantadine) are considered second-line therapy after the neuraminidase inhibitors, due to the rate of resistance in influenza isolates and drug-related side effects [53]. The main indication for use of an adamantine medication is infection with an influenza A strain that is resistant to oseltamivir in a patient with a contraindication to zanamivir [53]. Amantadine hydrochloride interferes with replication and shedding of influenza A virions, thus limiting spread of the virus within the respiratory tract and has also been shown to hasten resolution of symptoms and small airway dysfunction [53]. Only a few case reports have documented amantadine use in human pregnancy [53]. The usual dosage is 200 mg per day; mild central nervous system toxicity can be limited by using a split-dosage schedule [53]. Rimantadine (pregnancy risk factor class C) is also effective for influenza A prophylaxis and treatment and is given in 100-mg doses twice daily.

The novel influenza A (H1N1) virus that appeared in 2009 is sensitive to the neuraminidase inhibitor antiviral medications such as zanamivir and oseltamivir, but it is resistant to the adamantine antiviral agents. The Centers for Disease Control and Prevention (CDC) interim guidance indicates that pregnant women with a confirmed, probable, or suspected case of influenza A (H1N1) receive empiric institution of oseltamivir for a period of 5 or more days. Treatment should be started while results from testing are pending, as the maximal clinical benefit is seen when antiviral therapy is begun within 48 hours of the onset of symptoms [54].

Intravenous acyclovir has been shown to decrease maternal mortality from varicella pneumonia from 35% to 17% [56]. Acyclovir has not been shown to be teratogenic when used during human pregnancy [148]. The recommended dosing is 10 mg per kg every 8 hours intravenously, with adjustments made for renal insufficiency. The recommended length of therapy is 7 days. Maintenance of a euvolemic fluid status minimizes renal impairment secondary to acyclovir. Initiation of acyclovir at the first evidence of respiratory system involvement in pregnant patients with cutaneous varicella infection optimizes the chances of a favorable outcome [148]. Infants born to women in whom varicella infection developed within 4 days of delivery should receive varicella-zoster immune globulin within 72 hours of birth [148].

Amphotericin B is the drug of choice for severe disseminated coccidioidal infection during pregnancy [149]. Azoles are contraindicated during pregnancy; fluconazole exposure is teratogenic in the first trimester; and voriconazole is category D due to documented fetal harm and teratogenicity. There is not enough safety data to recommend caspofungin during pregnancy [149]. Amphotericin has been used with success in disseminated coccidioidal infection during pregnancy. It crosses the placenta and is present in umbilical cord serum at a concentration one third that of the maternal serum concentration. However, it does not appear to have an adverse effect on fetal development; normal, full-term infants have been born to women who received amphotericin B during the first trimester, as well as later in gestation. Because anemia often occurs during the course of amphotericin B therapy, blood cell counts and renal function should be monitored closely [61].

Active tuberculosis has been treated with modern chemotherapeutic agents with excellent maternal and fetal outcome. The initial treatment regimen should consist of isoniazid, rifampin, and ethambutol for a minimum of 9 months [150]. In the United States, pyrazinamide is not recommended for use during pregnancy [150]. Streptomycin has been associated with fetal hearing loss and vestibular dysfunction and should be avoided [151]. Ethionamide has been identified as a teratogen [150].

Treatment of *Pneumocystis jirovecci* during pregnancy includes trimethoprim–sulfamethoxazole, with the addition of glucocorticoids for severe disease characterized by a PaO_2 less than 70 mm Hg or an alveolar-arterial oxygen gradient of more than 35 mm Hg [152]. For *L. monocytogenes*–associated pneumonia in pregnancy, high-dose ampicillin is the treatment of choice (2 g intravenously every 4 hours) [153].

Asthma

The Working Group on Asthma and Pregnancy of the National Asthma Education Program has published a report summarizing the available data on asthma medications and management during pregnancy [71]. The first priority of therapy for pregnant women with asthma is to prevent or reverse the hypoxemia that, to some degree, accompanies virtually every exacerbation of asthma. Oxygen should be used in all asthmatic patients who present to the hospital with an exacerbation; the goal oxygen saturation is 95% or higher because hypoxemia may worsen initially with bronchodilator therapy, as a result of worsening ventilation–perfusion mismatching [154]. Other therapies are directed at the rapid reversal of bronchoconstriction and airways inflammation (see Chapter 48).

Bronchoconstriction is managed with inhalation of selective β_2-agonist and anticholinergic agents, given at 20-minute intervals or continuously. Typically, nebulized medication is given prior to intubation and then switched to metered dose inhaler (MDI) after intubation. The doses of albuterol and ipratropium are the same for obstetric and nonobstetric patients presenting with status asthmaticus [71]. The effects of inhaled agents are predominantly local, which should decrease the amount of fetal exposure, and selective β_2-agonists do not adversely affect uterine blood flow. There has been no evidence of fetal injury from the use of either systemic or inhaled β-adrenergic agonists [71,155], although neonates exposed to systemic β-agonists just prior to delivery have demonstrated tachycardia, hypoglycemia, and tremor [156]. These effects do not constitute a contraindication to the use of β-adrenergic agents.

Systemic glucocorticoids should be initiated promptly in all pregnant patients presenting with an acute asthma exacerbation who are not responding to one or two inhalational treatments with a β_2-agonist [71]. Institution of glucocorticoids helps to reverse airflow obstruction and, thereby, decrease the amount of high-dose β-adrenergic agonist therapy needed. The optimal dose of systemic glucocorticoid in this setting is not known. However, the same dose ranges are used in both obstetric and nonobstetric adults, prednisone or methylprednisolone 120 to 180 mg/day in 3 or 4 divided doses for the first 48 hours and then 60 to 80 mg a day until clinical improvement is significant and the peak expiratory flow has increased to 70% of predicted or personal best [71]. Further tapering is based on the response to treatment.

Prednisone and prednisolone cross the placenta poorly [71]. In rodents that were given glucocorticoids during gestation, an increased prevalence of spontaneous abortions, placental insufficiency, and cleft palate were found; it remains controversial whether a slight increase in risk of cleft palate pertains in humans [71]. Chronic maternal ingestion of systemic glucocorticoids has been associated with lower birth weight and increased incidence of premature deliveries [157–159].

In general, intravenous theophylline is not used during treatment of acute asthma exacerbations because of the lack of evidence of benefit. The use of aminophylline in the acute treatment of asthma during pregnancy does not shorten the length of stay or the response time [71]. However, for patients who normally take theophylline, the medication is normally continued during the hospitalization. If the patient is unable to take oral medication, intravenous theophylline is usually substituted. Because theophylline toxicity can develop in the fetus

when theophylline is administered at the time of delivery [71], serum levels should be kept below 15 mg per mL. No loading dose is needed. Maintenance infusion is usually 0.5 mg per kg per hour, although concurrent cimetidine, viral infection, liver disease, heart disease, or erythromycin dictates a downward adjustment to 0.3 mg per kg per hour, and smoking or adolescence dictates an upward adjustment to 0.7 mg per kg per hour. Serum levels should be closely followed.

In patients with severe bronchoconstriction, who are refractory to inhaled nebulized albuterol sulfate, parenteral agents such as terbutaline sulfate, 0.3 mg, or epinephrine, 0.3 mL of a 1 to 1,000 solution, may rarely be given subcutaneously [71,160]. A major concern is that epinephrine may cause uterine artery vasoconstriction through its α-adrenergic effects; this potential risk would have to be balanced against the need to reverse refractory bronchoconstriction [161].

For patients who are extremely difficult to manage even with therapeutic levels of bronchodilators, high-dose glucocorticoids, and mechanical ventilation, a few less-studied therapeutic interventions such as intravenous magnesium sulfate [162] and inhaled isoflurane [163] can be considered. None of these interventions have been studied in pregnancy, so their use should be limited to situations in which the woman's life is in danger and all other forms of therapy have failed. For a full discussion, see Chapter 48.

Once a pregnant woman reaches the point of life-threatening refractory asthma, emergent delivery of the fetus by cesarean section should be considered. There have been anecdotal reports of significant maternal improvement after delivery of the fetus. The decision for urgent delivery is complicated and depends in part on the gestational age of the fetus and the clinical status of the mother [76].

Pneumomediastinum and Pneumothorax

The natural history of pneumomediastinum is spontaneous resolution within 3 to 14 days without permanent sequelae. Pneumomediastinum does not usually require drainage in adults because the air usually dissects out of the mediastinum into the subcutaneous tissues of the neck. Thus, treatment should be directed at improving any underlying predisposing cause, such as asthma, if present. Supplemental oxygen may promote reabsorption of the mediastinal air.

A spontaneous pneumothorax occupying less than 20% of the hemithorax in an asymptomatic patient not on mechanical ventilation can be monitored closely without immediate insertion of a chest tube. Supplemental oxygen should be administered to accelerate the resolution of the pneumothorax. In patients who are symptomatic, on mechanical ventilation, or have an enlarging pneumothorax, chest tube placement is mandatory. Patients whose pneumothorax develops as a complication of barotrauma during mechanical ventilation may also require adjustments in the ventilator settings to reduce airway pressures and further barotrauma.

Patients with an existing pneumothorax or history of one in the past are at increased risk of worsening or recurrence of pneumothorax during labor and delivery, particularly during the Valsalva maneuvers at parturition. Although formal evidence is lacking, use of epidural analgesia and assisted vaginal delivery is suggested to avoid prolonged Valsalva maneuvers [86]. For patients requiring cesarean section, analgesia with epidural anesthetic is preferred to general anesthesia with positive pressure ventilation.

The recurrence rate of ipsilateral spontaneous pneumothorax is 30% to 50% within 5 years without pleurodesis [164]. Pleurodesis with any tetracycline derivative through a chest tube is contraindicated in pregnancy because of possible fetal exposure. It is recommended that a minimally invasive elective video-assisted thoracoscopic surgery (VATS) with bleb resection and mechanical pleurodesis be considered in the subsequent convalescent period to prevent a recurrent pneumothoraces [86]. Thoracotomy or VATS with bleb resection and pleurodesis is indicated for pregnant patients with continued air leak and incomplete lung expansion [86]. Tocolytic therapy may be required to prevent preterm labor during this surgical intervention.

PREVENTION

Thromboembolic Disease

Preventing DVT is probably the most important intervention to reduce maternal mortality caused by pulmonary embolism. Patients who require bed rest or surgery during pregnancy should be treated prophylactically with a LMWH regimen such as dalteparin 5,000 U subcutaneously every 24 hours or enoxaparin 40 mg subcutaneously every 24 hours. In the setting of impaired creatinine clearance, UFH 5,000 U subcutaneously every 12 hours may be used [129]. Warfarin crosses the placenta and is teratogenic, so its use is contraindicated in pregnancy [165]. Patients who are receiving ongoing warfarin therapy for prior thromboembolic disease should be changed to subcutaneous heparin therapy before conception or at least before the sixth week of pregnancy. LMWH is recommended for prophylaxis and treatment because of the reduced risk of bone loss and heparin-induced thrombocytopenia as compared with UFH [129].

Pregnant women with a history of thromboembolic disease and/or hypercoagulable state should receive thromboembolic prophylaxis throughout pregnancy and for 4 to 6 weeks postpartum [129]. The ACCP guidelines recommend either prophylactic or intermediate-dose regimens of LMWH or UFH for these particular subgroups of pregnant patients (Table 51.3) [129]. Once adequate hemostasis has been accomplished postpartum, subcutaneous anticoagulation therapy can be resumed and continued until 6 weeks postpartum. Alternatively, warfarin can be added to subcutaneous heparin and the heparin stopped when therapeutic prolongation of the International Normalized Ratio (INR) is achieved.

Aspiration of Gastric Contents

Based on national surveys of obstetric practice, antacid administration, H_2 blockade, or proton pump inhibitors have been used for aspiration prophylaxis in pregnant women who require general anesthesia or analgesic therapy other than local or epidural anesthetics [47]. This is done despite the lack of complete protection achieved with gastric pH values greater than 2.5 and a recent meta-analysis that showed no evidence that any of these medications reduced the incidence of gastric aspiration [166]. Some authors recommend that all women in labor receive nothing by mouth except medications. This should probably be individualized, in view of the low risk of aspiration during spontaneous vaginal delivery in nonsedated patients and the small proportion of patients who require emergent general anesthesia. Other preventive measures that have been proposed are the use of regional anesthesia when possible, cuffed endotracheal tube, and application of cricoid pressure during intubation [46].

RESPIRATORY INFECTIONS

Immunization is the most effective method to prevent influenza pneumonia. The parenteral influenza vaccine contains inactivated virus and is not associated with adverse pregnancy

outcomes. However, it should not be given to patients with egg allergy without prior skin testing to assess safety. Influenza vaccination is recommended for all women who will be pregnant during the influenza season [53]. The parenteral vaccination should be administered between October and mid-November regardless of their trimester of pregnancy [167]. The intranasal flu vaccine should not be given to pregnant women because it is a live-attenuated virus [53,167].

β-Adrenergic Tocolytic Therapy

The epidemiologic factors that place patients at increased risk for tocolytic-induced pulmonary edema include longer duration of intravenous β-adrenergic tocolytic therapy (24 to 48 hours), large volume of crystalloid infusion, multiple gestation, concomitant sepsis, and, possibly, preeclampsia [81]. If a β-adrenergic tocolytic agent must be used, limiting the intravenous phase of β-adrenergic therapy to less than 24 to 48 hours and adjusting the dose to keep the maternal heart rate under 120 beats per minute may reduce complications. The β-adrenergic agent should be discontinued immediately at the earliest sign of respiratory distress, such as chest pain, tachypnea, dyspnea, or reduced oxygen saturation. Careful fluid balance records should be maintained, and fluid restriction and possibly diuresis should be considered when intake exceeds output by greater than 500 mL. Sodium intake should be restricted to 4 to 6 g per day. If glucocorticoids are required to enhance fetal lung development, a formulation with the lowest mineralocorticoid potency should be used. If supplemental oxygenation, discontinuation of the drug, and gentle diuresis do not result in improvement after 1 hour, insertion of a pulmonary artery catheter to guide fluid management should be considered. Clinical improvement in tocolytic-induced pulmonary edema usually occurs within 12 hours after the drug is discontinued and diuresis is begun [168].

Patients with underlying cardiac disease, particularly structural defects causing outflow obstruction, should be excluded from β-adrenergic tocolytic therapy. Patients with multiple gestation should either be excluded or undergo prophylactic pulmonary artery catheterization. Patients with severe preeclampsia would likely benefit more from early delivery than from combining the increased risks of tocolytic therapy with those of continuing pregnancy-induced hypertension.

Advances in management of pregnancy based upon randomized, controlled clinical trials are summarized in Table 51.4.

TABLE 51.4

ADVANCES IN MANAGEMENT OF ACUTE RESPIRATORY FAILURE IN PREGNANCY BASED UPON CLINICAL TRIALS

- Mechanical ventilation of a pregnant patient with ARDS should follow the guidelines of the ARDS Network Study [116]. B
- Unfractionated heparin remains the drug of choice for massive pulmonary embolism during pregnancy [129]. D
- Low-molecular-weight heparin is safe and effective in pregnancy, and may be used for anticoagulation for pulmonary embolism during pregnancy once the patient is stabilized [129]. D
- Pregnancy is a relative contraindication for thrombolytic therapy. Thrombolysis has been used safely in life-threatening pulmonary embolism during pregnancy with maternal mortality of 1% and fetal loss 6%. Recombinant tissue plasminogen activator and streptokinase are the recommended thrombolytics during pregnancy [134]. D
- Systemic glucocorticoids should be instituted in all pregnant patients with an acute asthma exacerbation who are not quickly responsive to inhaled β_2-agonist therapy [71]. D

ARDS, acute respiratory distress syndrome; B, 1 RCT trial; D, nonrandomized, contemporaneous control group.

CHAPTER 52 ■ VENOUS THROMBOEMBOLISM: PULMONARY EMBOLISM AND DEEP VENOUS THROMBOSIS

CHARLES WILLIAM HARGETT, III AND VICTOR F. TAPSON

INCIDENCE AND NATURAL HISTORY

Venous thromboembolism (VTE) includes the spectrum of deep vein thrombosis (DVT) and pulmonary embolism (PE). Embolization of material into the pulmonary venous circulation may lead to marked cardiopulmonary dysfunction and is of particular interest to the critical care practitioner. Although VTE is extraordinarily common in hospitalized patients, estimating the frequency of VTE and PE is problematic. The nonspecific clinical findings and high rate of undiagnosed events likely underestimate the true incidence of disease, whereas autopsy data may overestimate meaningful events by detecting asymptomatic cases. That being considered, the incidence of VTE is thought to be in excess of 600,000 cases per year in the United States [1]. In one population-based study with autopsy data, the annual incidences (age and sex adjusted) of DVT and PE were 48 and 69 per 100,000, respectively [2]. In a study of critically ill patients, 10% to 30% of medical/surgical intensive care unit (ICU) patients experienced DVT within the first week of admission, and approximately 60% of trauma patients had DVT within the first 2 weeks, most of which were clinically silent [3]. The prevalence of VTE as a cause of critical illness is also uncertain, but approximately 15% to 20% of patients with diagnosed PE have significant hemodynamic and/or respiratory compromise [4,5]. Untreated symptomatic PE has a mortality rate of approximately 30%, but treatment reduces this risk considerably [6–13]. Adjusting for patients with concomitant terminal illnesses, acute PE likely account for more than 100,000 deaths per year in the United States in patients with an otherwise good prognosis [14,15].

RISK FACTORS

Recognizing the presence of risk factors for VTE is essential because more than 90% of deaths due to PE occur in patients who are not treated because the diagnosis was unsuspected and thus undetected [14,15]. Virtually every risk factor for VTE can be derived from Virchow's triad of stasis, venous injury, and hypercoagulability described nearly 150 years ago (Tables 52.1 and 52.2) [16]. Common major risk factors for VTE include increased age, malignancy, surgery, hospitalization with acute medical illness, and a history of prior VTE. Critically ill patients may be at especially high risk for VTE due to severe underlying disease, immobility, and venoinvasive catheters, and the incidence of VTE increases correspondingly with the number of risk factors present.

Inherited or acquired hypercoagulable states are now recognized in more than 20% of patients with VTE and occur at an even higher rate in patients with idiopathic or recurrent VTE (Table 52.3) [17,18]. Resistance to activated protein C due to the factor V Leiden mutation is one of the most common hypercoagulable states, with a prevalence of 5% in white individuals of European ancestry, and may be present in perhaps 20% of patients with PE [19–22]. Ethnicity is a risk factor, and whites and African Americans have a significantly higher incidence of VTE as compared with Hispanics and Asians [23].

Indwelling central venous catheters (CVCs), particularly common in critically ill patients, provide a constant nidus for clot formation. Thrombosis may occur in up to 67% of patients with invasive catheters [24]. Specific risk factors for thrombotic complications of CVCs may be related to technical or host factors and include femoral vein site, duration of cannulation (>days), nighttime placement, extremes of age, and multiple lines [25–28]. The frequency of clinically meaningful complications due to CVC-related thrombosis remains unclear.

PATHOPHYSIOLOGY

The sequence of events leading to venous thrombosis is not fully understood and likely varies based on the dynamic interactions between genetic and acquired risk factors. In one proposed scheme, endothelial stimulation results from either blood

TABLE 52.1

STRONG, MODERATE, AND WEAK RISK FACTORS FOR VENOUS THROMBOEMBOLISM (VTE)

Strong risk factors (odds ratio >10)
Hip or leg fracture
Hip or knee replacement
Major general surgery
Major trauma, including spinal cord injury
Moderate risk factors (odds ratio 2–9)
Arthroscopic knee surgery
Central venous catheterization
Congestive heart or respiratory failure
Hormone replacement and oral contraceptive therapy
Malignancy (active or recently treated)
Pregnancy[a]
Paralytic stroke
Prior VTE
Thrombophilia (inherited or acquired)
Weak risk factors (odds ratio <2)
Bed rest >3 d
Prolonged immobility due to sitting (e.g., car or air travel)
Increasing age
Laparoscopic surgery
Obesity
Pregnancy[a]
Varicose veins

[a]The risk associated with pregnancy is temporal (antepartum vs. postpartum) and specific for VTE subtype (deep venous thrombosis vs. pulmonary embolism). See section "Pregnancy" for further details.
Adapted from Anderson FA Jr, Spencer FA: Risk factors for venous thromboembolism. *Circulation* 107[23, Suppl 1]:I9, 2003.

TABLE 52.2

THE PRESENCE OF RISK FACTORS IN PATIENTS TREATED FOR ACUTE VENOUS THROMBOEMBOLISM (VTE)

Risk factor	Patients (%)
Age ≥40 y[a]	88.5
Obesity	37.8
Prior VTE	26.0
Malignancy	22.3
Bed rest ≥5 d	12.0
Major surgery	11.2
Congestive heart failure	8.2
Varicose veins	5.8
Hip or leg fracture	3.7
Estrogen therapy	2.0
Stroke	1.8
Multiple trauma	1.1
Childbirth	1.1
Myocardial infarction	0.7
One or more risk factors	96.3
Two or more risk factors	76.0
Three or more risk factors	39.0

[a]Risk of VTE is particularly increased when age >70 years.
Adapted from Anderson FA Jr, Spencer FA: Risk factors for venous thromboembolism. *Circulation* 107[23, Suppl 1]:I9, 2003.

stasis-induced hypoxia or direct vein wall injury, after which point tissue factor is transferred to the endothelial cell and initiates the enzymatic cascade of coagulation reactions, leading to thrombin generation and fibrin deposition [29]. Thus, it is not surprising that many venous thrombi arise in valve pockets, where blood flow tends to stagnate, or at a specific area of vascular disruption, such as an indwelling catheter site.

Lower extremity DVT is the most frequent source of PE and, in untreated patients with proximal DVT, approximately half will develop PE [30,31]. Other sources of PE include pelvic, renal, or upper extremity veins, as well as the right heart. After traveling to the lungs, a large thrombus may occlude a major pulmonary artery and cause significant cardiovascular symptoms, or it may break up into smaller clots and travel distally, where it is more likely to produce pleuritic chest pain. Thrombi are most frequently carried to the lower lobes due to the higher blood flow. Pulmonary infarction is relatively uncommon because of incomplete vessel occlusion by emboli and bronchial artery anastomoses.

Ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch is the principal physiologic effect of PE and leads to hypoxemia in most patients. $\dot{V}/\dot{Q}$ mismatch results from increased physiologic dead space and intrapulmonary shunting, which frequently produces an elevated alveolar-to-arteriolar oxygen gradient. Concomitant physiologic responses to PE include increased minute ventilation and airways resistance, as well as decreased vital and diffusion capacities [32–36]. In patients with a potentially patent foramen ovale, progressive pulmonary hypertension may lead to a right-to-left intra-atrial shunt, resulting in worsening hypoxemia and, rarely, paradoxical embolization.

The hemodynamic response to PE may vary depending on the degree of occlusion of the pulmonary arterial circulation and on the presence of underlying cardiopulmonary disease. Physiologically, PE causes a decrease in the cross-sectional area of the pulmonary arterial bed and leads to an increase in the pulmonary vascular resistance. This impedes right ventricular outflow, leading to reduced left ventricular preload and, ultimately, a diminished cardiac output. Progressive vascular obstruction and hypoxemia stimulates vasoconstriction and a further rise in pulmonary artery pressure. The normal right ventricle fails acutely when it cannot generate a systolic pressure to overcome a mean pulmonary artery pressure greater than 40 mm Hg needed to maintain pulmonary perfusion. The normal pulmonary circulation has a large reserve capacity and more than 50% obstruction is generally required for a substantial increase in the mean pulmonary artery pressure [37,38].

TABLE 52.3

INHERITED AND ACQUIRED RISK FACTORS FOR VENOUS THROMBOEMBOLISM

Inherited	Acquired
Factor V Leiden (APC resistance)	Antiphospholipid antibody syndrome
Antithrombin deficiency	Lupus anticoagulant
Protein C deficiency	Anticardiolipin antibodies
Protein S deficiency	Hyperhomocysteinemia
Prothrombin gene (G20210A) variant	
Heparin cofactor 2 deficiency	
Dysfibrinogenemia	
Disorders of plasminogen	
Elevated factor VIII levels	
Elevated factor XI levels	

APC, activated protein C.

Patients with underlying cardiopulmonary disease have less physiologic reserve as compared with healthy individuals, and it follows that they may suffer right heart failure with a lesser degree of pulmonary vascular occlusion [39,40].

CLINICAL MANIFESTATIONS

Recognizing the presence of VTE may be challenging as neither the signs nor symptoms associated with DVT and PE are sensitive or specific for the diagnoses [13,14,41,42]. Because DVT is usually asymptomatic and most cases of fatal PE are unsuspected prior to death, the most critical step in the diagnosis of VTE is the development of a clinical suspicion of the disease [6,43,44]. This suspicion is based on the constellation of risk factors, symptoms, signs, electrocardiography, blood tests, and chest radiographic findings. Although clinical assessment alone is inadequate in diagnosing and excluding DVT and PE, both clinical gestalt and clinical prediction rules are useful in establishing a pretest probability in which patients are typically classified into three groups based on the estimated prevalence of disease (Table 52.4) [45–49]. This clinical pretest probability serves as the root of algorithms for the diagnosis of DVT and PE [50–53].

The diagnosis of VTE in the critically ill patient may be particularly challenging. Underlying systemic illnesses or other superimposed acute illness may mimic or mask the common signs and symptoms of VTE. Also, common clinical likelihood models for predicting VTE may not be valid in the ICU setting [54]. Furthermore, definitive testing for VTE may be precluded by relative contraindications, such as mechanical ventilation, shock, and renal failure.

Symptoms and Signs

Although most DVT begins in the calf, the presenting symptoms and signs are often not noted until more proximal veins are involved [55]. The initial clinical manifestations of DVT may be acute, progressive, or resolve spontaneously and may include warmth, erythema, swelling, and pain or tenderness. Pain on forced dorsiflexion of the foot (Homans' sign) is neither sensitive nor specific for DVT [42]. The differential diagnosis of DVT should always be framed by the clinical presentation and consideration of risk factors for VTE. Cellulitis, trauma, Baker's cyst, musculoskeletal pain, or asymmetric edema unrelated to DVT may all result in signs and symptoms compatible with acute DVT.

Most patients with proven acute PE present with at least one of the following: dyspnea, pleuritic chest pain, or tachypnea (Table 52.5). Other findings may include tachycardia, a loud pulmonic component of the second heart sound, fever, crackles, pleural rub, wheezing, and/or leg tenderness or swelling. Pleuritic chest pain and hemoptysis occur more commonly with pulmonary infarction due to smaller, peripheral emboli. PE must always be considered in cases of unexplained dyspnea, syncope, or sudden hypotension. Symptoms and signs of PE are nonspecific and may frequently be seen in patients with concomitant cardiopulmonary disease; these findings may be due to a coexisting disease or a superimposed acute PE. Pulmonary embolism may be confused with many conditions including pneumonia, chronic obstructive lung disease exacerbation, pneumothorax, myocardial infarction, heart failure, pericarditis, musculoskeletal pain or trauma, pleuritis, malignancy, and, occasionally, intra-abdominal processes such as acute cholecystitis.

Given the kaleidoscopic presentation of VTE and the significant associated morbidity and mortality, there should be a low threshold for the clinical suspicion of PE in the ICU. Subtle signs such as worsening hypoxemia, a reduction in arterial carbon dioxide with spontaneous respirations (especially in a patient with chronic lung disease), increased central venous or pulmonary artery pressure, or unexplained fever should all be considered potential heralds of PE. Even in the presence of alternative diagnoses, the evaluation for possible VTE may still be appropriate when suggestive signs, symptoms, and risk factors are present.

TABLE 52.4

DETERMINING THE PRETEST PROBABILITY OF ACUTE PULMONARY EMBOLISM (PE) USING A STANDARDIZED POINT SYSTEM[a]

Variable	Points
Symptoms/signs of DVT	3.0
Alternative diagnosis deemed less likely than PE	3.0
Heart rate >100 beats/min	1.5
Immobilization/surgery in previous 4 wk	1.5
Previous VTE	1.5
Hemoptysis	1.0
Recent or current malignancy	1.0
Clinical Probability	**Total Points**
Low	<2.0
Intermediate	2.0–6.0
High	>6.0

[a]Note that this scoring system has not been prospectively evaluated in patients in whom PE is considered in the intensive care unit.
DVT, deep venous thrombosis; VTE, venous thrombosis.

DIAGNOSTIC TESTS

Chest Radiograph and Electrocardiogram

Under almost all circumstances, chest radiography cannot be used for the conclusive diagnosis or exclusion of PE. The chest radiograph is abnormal in more than 80% of patients with PE, but is nearly always nonspecific, with common findings including atelectasis, pleural effusion, pulmonary infiltrates, and mild elevation of a hemidiaphragm [41,56,57]. Classic findings such as Hampton's hump (juxtapleural wedge-shaped opacity at the costophrenic angle indicating pulmonary infarction) or Westermark's sign (focally decreased vascularity distal to the occlusion) are suggestive of the diagnosis of PE but are infrequently seen. These findings may be even more difficult to appreciate on portable anteroposterior films commonly employed in the ICU. A normal chest radiograph in a patient with severe dyspnea and hypoxemia and without bronchospasm or cardiac shunt strongly suggests the diagnosis of PE [56]. In young patients with acute pleuritic chest pain, the presence of a pleural effusion raises the probability of PE [58]. Although chest radiography may be useful in excluding other thoracic conditions (e.g., pneumothorax, rib fracture, pneumonia) that may produce signs and symptoms similar to PE, it is important to remember that PE may be present with other cardiopulmonary diseases.

The electrocardiogram is commonly abnormal but findings are nonspecific in most patients with acute PE. Tachycardia, T-wave and ST-segment changes, and right- or left-axis deviation are common electrocardiography findings [41,59]. The

TABLE 52.5

SYMPTOMS AND SIGNS IN PATIENTS WITH ACUTE PULMONARY EMBOLISM WITHOUT PREEXISTING CARDIOPULMONARY DISEASE

Symptoms	Patients (%)	Signs	Patients (%)
Dyspnea	73	Tachypnea (respiratory rate ≥20 breaths/min)	70
Pleuritic pain	66	Rales/crackles	51
Cough	37	Tachycardia (heart rate >100 beats/min)	30
Leg swelling	28	Fourth heart sound	24
Leg pain	26	Increased pulmonary component of second sound	23
Hemoptysis	13	DVT	11
Palpitations	10	Diaphoresis	11
Wheezing	9	Temperature >38.5°C	7
Angina-like pain	4	Wheezes	5

	1	Cyanosis	

DVT, deep venous thrombosis.
Adapted from Stein PD, Terrin ML, Hales CA, et al: Clinical, laboratory, roentgenographic, and electrocardiographic findings in patients with acute pulmonary embolism and no preexisting cardiac or pulmonary disease. *Chest* 100:598, 1991.

classic patterns of S1Q3T3; right ventricular strain; and new, incomplete, right bundle branch block are less commonly seen but may be more frequent with massive PE and cor pulmonale. A subepicardial ischemic pattern (T-wave inversion in the precordial leads) seems to correlate with the severity of PE and degree of right ventricular dysfunction [60].

Radiographic and electrocardiographic abnormalities are quite common in patients diagnosed with PE. Although these findings are nonspecific, it follows that a completely normal chest radiograph and electrocardiogram decrease the likelihood of PE.

Arterial Blood Gas and End-Tidal Carbon Dioxide

Arterial blood gas analysis is frequently used in assessing the severity of cardiopulmonary disease but is of limited value in diagnosing PE. Only about 85% to 90% of patients with proven PE have hypoxemia and an elevated alveolar–arterial difference [41,56,61,62]. Hypoxemia is almost uniformly present when there is a hemodynamically significant PE. Interestingly, however, in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study, there was no difference in either PaO_2 or $P(A\text{-}a)O_2$ between patients with or without PE, reflecting the common gas-exchange abnormalities present in multiple cardiopulmonary conditions. Due to increased ventilation, patients with PE will generally have a normal or reduced arterial carbon dioxide tension. Physiologic changes in PE may be particularly variable in young patients and those without underlying lung or heart disease. In any case, arterial blood gas values are of insufficient discriminant value to exclude the diagnosis of PE.

As a function of alveolar dead space, end-tidal CO_2 is a physiologically intuitive marker of pulmonary arterial blood flow that unfortunately has been of limited utility in identifying patients with PE [63–67]. End-tidal CO_2 may be physiologically insensitive for PE because of incomplete vessel occlusion by thrombus and also because of decreased ventilation at embolized areas due to local bronchoconstriction. Other cardiopulmonary conditions may alter the difference between the $PaCO_2$ and the end-tidal CO_2, decreasing the specificity for PE.

D-Dimer

Plasma measurements of D-dimer (a specific derivative of cross-linked fibrin) have been extensively studied in patients with acute DVT and PE [68–70]. Multiple inexpensive D-dimer tests are available, but rapid enzyme-linked immunosorbent assays are preferred. When used in the outpatient setting, D-dimer measurements are very sensitive and have shown a high negative predictive value in excluding the presence of VTE when used in concert with a low clinical pretest probability [51,71]. The low specificity of D-dimer testing for VTE (i.e., many conditions are associated with elevated levels) makes it less useful in unselected and hospitalized patients [72]. It follows that the positive predictive value of an elevated D-dimer for VTE is low and should not be used in isolation to initiate further evaluation.

Cardiac Troponin and Brain Natriuretic Peptide

Troponin is specific for cardiac myocyte damage, and patients with right ventricular strain due to acute PE may sometimes have elevated troponin T and I levels [73,74]. Patients with PE and elevated troponins are more likely to have elevated right ventricular systolic pressures, right ventricular dilation/hypokinesis, and are at increased risk for cardiogenic shock. Not surprisingly, a positive troponin is more common with large clot burdens and confers an increased risk of death [75,76]. Although an elevated troponin may hint at a potential

diagnosis of PE in the appropriate clinical setting, a normal value is not sufficiently sensitive to rule out PE.

Plasma brain natriuretic peptide (BNP) is released in response to increased cardiac-filling pressure and can serve as a supplementary tool for evaluating right ventricular function in patients with acute PE. BNP appears elevated in the majority of cases of PE with right ventricular overload and may help in risk stratification [77–79]. However, because plasma BNP levels rise in a variety of cardiopulmonary conditions and are affected by several physiological factors, they are not diagnostic for PE.

Ventilation/Perfusion Scanning

Despite the increased use of contrast-enhanced spiral computed tomography (CT) of the chest, $\dot{V}/\dot{Q}$ scanning is still frequently used in suspected PE. $\dot{V}/\dot{Q}$ scans may be deemed normal or, when abnormal, are conventionally read as showing low, intermediate, or high probability of PE. A normal scan essentially excludes the diagnosis of PE. Otherwise, $\dot{V}/\dot{Q}$ scanning can be combined with clinical suspicion in a Bayesian fashion to improve the accuracy of diagnosis. In general, the predictive value of a $\dot{V}/\dot{Q}$ scan is highest with a concordant clinical likelihood assessment. In the PIOPED study, when the clinical suspicion of PE was high, PE was present in 96% of patients with high-probability lung scans [5]. However, in patients with a high clinical pretest probability for PE, 66% of patients with intermediate probability scans and 40% of patients with low probability scans were subsequently diagnosed with PE by pulmonary angiography. This emphasizes that low- and intermediate-probability $\dot{V}/\dot{Q}$ scans are nondiagnostic when there is a high clinical suspicion for PE. In the setting of a low clinical pretest probability for PE, a normal or low-probability $\dot{V}/\dot{Q}$ scan correctly excluded PE in more than 95% of cases. Because PE is commonly found in low- or intermediate-probability $\dot{V}/\dot{Q}$ scans, such findings are generally considered nondiagnostic and further evaluation is often appropriate.

Although $\dot{V}/\dot{Q}$ scanning can be successfully used in the intensive care setting, ventilation scans generally cannot be performed on mechanically ventilated patients, and the availability of bedside scintigraphic perfusion imaging has decreased [5,80,81]. The optimal scenario for the $\dot{V}/\dot{Q}$ scan is in the patient with a clear chest radiograph and without underlying cardiopulmonary disease. Large PE, however, are occasionally identified with portable perfusion scans based upon very large perfusion defects in ICU patients.

Chest Computed Tomographic Angiography

During the past decade, $\dot{V}/\dot{Q}$ scanning has decreased in favor of contrast-enhanced computed tomographic angiography (CTA) of the chest that may reveal emboli in the main, lobar, or segmental pulmonary arteries. The reported sensitivity and specificity of single-slice helical CTA has ranged from 53% to 100% and from 81% to 100%, respectively [82]. Visualization of segmental and subsegmental pulmonary arteries is substantially better with newer multidetector scanners as evidenced by the PIOPED II study, where the specificity of chest CTA was 95% and the sensitivity 83% [83]. As with $\dot{V}/\dot{Q}$ scanning, diagnostic testing with CTA is best used in the context of a pretest clinical assessment of probability of PE. In the PIOPED II, in patients with a high or intermediate clinical probability of PE as measured by the Wells score, abnormal findings on CTA had a positive predictive value of 96% and 92%, respectively. In patients with a low clinical likelihood of PE, normal findings on CTA had a 96% negative predictive value. PIOPED II generally supports the use of multidetector CTA as stand-alone imaging for suspected PE in the majority of patients. However, the 17% false-negative rate emphasizes that CTA still fails to detect emboli that may be better visualized by $\dot{V}/\dot{Q}$ scanning or traditional angiography. Many of these may be peripheral subsegmental PE, for which there is no consensus regarding treatment [84]. It nevertheless follows that a normal CTA in the context of a high clinical probability of PE is insufficient in excluding PE and such patients warrant further investigation.

A benefit of CTA for suspected PE over other diagnostic modalities is that it provides visualization of potential nonvascular pathology such as musculoskeletal or airway abnormalities, lymphadenopathy, pleural or pericardial disease, or parenchymal lesions such as consolidation or a lung tumor. CTA also has the advantage of rapid performance. Disadvantages of CTA include the risk of adverse reactions to contrast (such as anaphylaxis or nephrotoxicity) and lack of portability. ICU patients frequently have a prohibitive creatinine clearance.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has excellent sensitivity and specificity and may allow the simultaneous detection of DVT and PE [85–87]. Disadvantages of MRI include performance time and difficult utilization in the critically ill or ventilated patient.

Echocardiography

Although echocardiography (echo) is insensitive for the diagnosis of PE, it has several important roles in the evaluation of PE. The speed and portability of echo make it particularly useful in patients who are suspected of having PE and who are too unstable for further evaluation with CTA or $\dot{V}/\dot{Q}$ scan. In addition, echo has proven helpful for risk stratification in patients with proven PE, and serial examinations may demonstrate interval change in cardiac function [88–90]. Also, an initial diagnostic scan may be useful in identifying other causes of shock such as aortic dissection and cardiac tamponade.

Transthoracic echocardiographic signs of acute PE include dilatation and hypokinesis of the right ventricle, paradoxical motion of the interventricular septum, tricuspid regurgitation, and lack of collapse of the inferior vena cava (IVC) during inspiration [91]. McConnell's sign (free wall of the right ventricle hypokinesis that spares the apex) may be a more specific finding [92]. Rarely, direct visualization of thrombus may guarantee the diagnosis.

Pulmonary Angiography

Pulmonary artery angiography is extremely sensitive and specific in confirming or excluding acute PE and remains the "gold standard" diagnostic technique. Like many tests, however, angiography may be limited by interobserver agreement and technical factors [93]. In 1,111 cases from the PIOPED study, 3% of studies were nondiagnostic and 1% was incomplete, usually due to a complication. Although complications are more common in the ICU, angiography is generally deemed quite safe, with major morbidity and mortality rates of 1% and 0.5%, respectively [93]. Serious complications include respiratory failure (0.4%), renal failure (0.3%), and hemorrhage requiring blood transfusion.

Pulmonary angiography is frequently reserved for patients in whom preliminary noninvasive testing has been

nondiagnostic. There is a growing consensus that clinically stable patients with nondiagnostic chest imaging may alternatively safely undergo further noninvasive study such as lower extremity evaluation in lieu of direct angiography [53,83,94–96]. For unstable patients in the ICU setting, angiography can be performed at the bedside using a pulmonary artery catheter and portable fluoroscopy in some centers [97].

Detection of Acute Deep Venous Thrombosis

In the critical care setting, the search for DVT can be especially useful in that it may establish a presumptive diagnosis of PE and direct therapy. The available technology used to pursue the diagnosis of DVT has expanded considerably, and each modality has advantages and limitations. Impedance plethysmography (IPG) is a portable test that employs electrical current to estimate venous outflow obstruction during sequential inflation and deflation of an occlusive thigh cuff. Although early studies were favorable, subsequent studies suggest that the sensitivity of IPG for proximal DVT is only about 65% [98–101]. Even in ideal hands, IPG may fail to detect nonocclusive or duplicated bilateral thrombi. It is essentially not used at all anymore.

Venous ultrasonography is the preferred noninvasive test for the diagnosis of symptomatic proximal DVT, where it has a weighted sensitivity and specificity of 95% and 98%, respectively [102]. For diagnosis of a first symptomatic proximal DVT, ultrasound has a positive predictive value of 97% and a negative predictive value of 98% [103]. Although it is generally appropriate to initiate or withhold treatment based on the result of the examination, an exception would be when the result is discordant with the clinical assessment. For instance, a negative compression ultrasound in the context of a high clinical suspicion for DVT would warrant further investigation such as venography, MRI, or CT venography (CTV). The combination of compression and Doppler ultrasonography is also accurate in detecting upper extremity DVT [104]. Limitations of venous ultrasonography include insensitivity for asymptomatic DVT and pelvic vein clots, operator dependence, and difficulty distinguishing acute from chronic DVT in symptomatic patients.

MRI and CTV are being increasingly employed to diagnose DVT. MRI is highly accurate and has multiple advantages, including excellent resolution of the IVC and pelvic veins, accuracy in diagnosing upper extremity DVT, concurrent thoracic as well as bilateral examination, differentiating acute from chronic disease, and lack of exposure to ionizing radiation [85–87,105]. However, MRI is expensive, time-consuming, not portable, and is restricted in patients with metallic devices or claustrophobia. As with MRI, CTA/CTV has the advantage of evaluating both PE and DVT in a single study. CTV is accurate in the detection of DVT and may be particularly useful in imaging the pelvis and upper thighs [106,107]. In the PIOPED II, concurrent leg evaluation with CTV increased the sensitivity of CTA from 83% to 90%, although the small improvement in overall diagnostic yield may not warrant the additional irradiation associated with CTV [83]. Contrast venography is rarely done anymore.

Special Diagnostic Considerations: Massive Pulmonary Embolism

Patients with suspected massive PE may present with severe hypoxemia and/or hypotension and a timely diagnosis is essential as perhaps two thirds of patients with ultimately fatal PE will die within 1 hour of presentation [108]. Diagnostic evaluation must be performed rapidly, but cardiopulmonary instability may limit the patient's ability to undergo transport or testing. In such cases, venous ultrasonography or echo in the acutely unstable patient may offer compelling evidence for VTE. Portable perfusion scans are more likely diagnostic (high probability) than when a less extensive clot burden is present. As noted, bedside angiography can sometimes be performed in the ICU using a pulmonary artery catheter and portable fluoroscopy. When obtainable, helical CTA is very unlikely to be negative in the setting of massive PE.

Diagnostic Algorithm

During the last 2 decades, considerable progress in technology and clinical research methods have led to marked improvements in the diagnosis of VTE [109,110]. The constellation of advances has decreased the complexity and uncertainty found in traditional diagnostic approaches. Despite this, however, the morbidity and mortality of VTE remains high. Although consensus guidelines exist for the standard diagnostic approach to VTE, there is no single, best approach that is always agreed on [95]. Also, not all of the new data regarding the evaluation of VTE may be applicable to patients in the ICU setting, and future studies will continue to define each modality in this context. Figures 52.1 and 52.2 illustrate the diagnostic algorithms for suspected PE in stable and unstable ICU patients, respectively.

TREATMENT

The primary goal of treatment of DVT is the prevention of thrombus extension and PE. Anticoagulation is the standard of care in patients with acute VTE, but other options in the treatment of PE include thrombolytic therapy, IVC filter placement, and surgical embolectomy. Each approach has specific indications as well as advantages and disadvantages. Table 52.6 lists the evidence-based advances in VTE management as they apply to critical care.

Anticoagulation

The anticoagulation regimens for the treatment of DVT and uncomplicated PE are generally similar. Although anticoagulants do not directly dissolve preexisting clot, they prevent thrombus extension and indirectly decrease clot burden by allowing the natural fibrinolytic system to proceed unopposed. When there is a strong clinical suspicion of PE, anticoagulation should be instituted immediately and before diagnostic confirmation, unless the risk of bleeding is deemed excessive.

Unfractionated Heparin

Therapy with unfractionated heparin (UFH) reduces the extension and recurrence of symptomatic proximal DVT as well as mortality in acute PE [111,112]. UFH is usually delivered by continuous intravenous infusion, and therapy is monitored by measurement of the activated partial thromboplastin time (aPTT) [113]. "Traditional" or physician-directed dosing of heparin often leads to subtherapeutic aPTT results, and validated dosing nomograms are generally favored [114,115]. Nomogram dosing reduces the time to achieve therapeutic anticoagulation that may be important in reducing the risk of recurrent VTE [116]. UFH should be administered as an intravenous bolus of 5,000 U followed by a continuous infusion maintenance dose of 30,000 to 40,000 U per 24 hours (the lower dose being used if the patient is considered at risk for bleeding) [117]. Two alternative dosing regimens include a 5,000-U bolus followed by 1,280 U per hour, or a bolus of 80 U

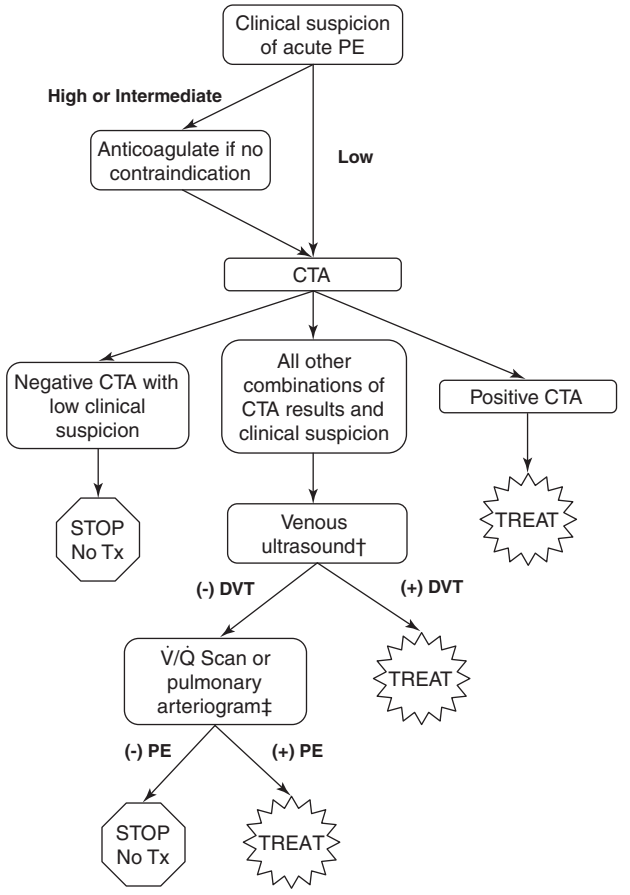

FIGURE 52.1. A contrast-enhanced computed tomographic angiography (CTA) of the chest-based algorithm for suspected acute pulmonary embolism (PE) in stable intensive care unit (ICU) patients. Contrast-enhanced CT scans may not be feasible in patients with significant kidney dysfunction or severe contrast allergy. Clinical probability scores and rapid enzyme-linked immunosorbent assay D-dimer testing are not included due to insufficient validation in the ICU setting. Appropriate supportive therapy is assumed. †Prior addition of CT venography during CTA would obviate the need for venous ultrasound. Ultrasound of the upper extremities should be considered in the presence of an invasive catheter or local symptoms of DVT. ‡The ventilation/perfusion V̇/Q̇ scan may be particularly useful when the chest radiograph is clear and when no underlying cardiopulmonary disease is present. Unfortunately, the V̇/Q̇ scan is often nondiagnostic, even when PE is present. DVT, deep venous thrombosis; Tx, treatment.

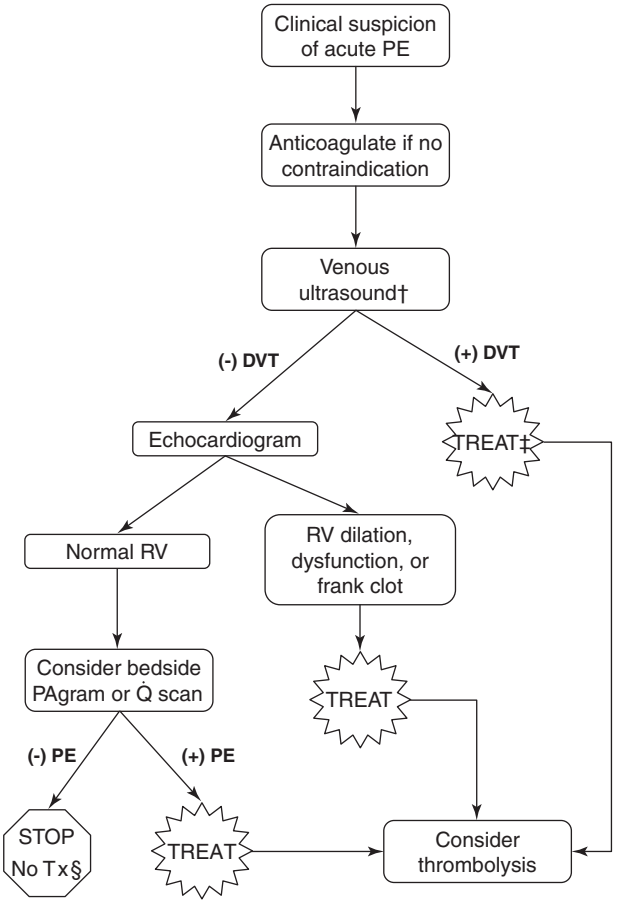

FIGURE 52.2. Diagnostic algorithm for suspected acute pulmonary embolism (PE) in unstable intensive care unit (ICU) patients. Unstable implies that the patient cannot be safely transported for testing such as chest computed tomography. Clinical probability scores and rapid enzyme-linked immunosorbent assay D-dimer testing are not included due to insufficient validation in the ICU setting. Appropriate supportive therapy is assumed. †Ultrasound of the upper extremities should be performed in the presence of an invasive catheter or local symptoms of deep venous thrombosis (DVT). ‡Consider inferior vena cava filter in the setting of massive PE with DVT when it is believed that any further emboli might be lethal and thrombolytic use is prohibited. §Stop anticoagulation after a negative pulmonary artery angiogram (PAgram) or a normal or low-probability perfusion Q̇ scan. RV, right ventricle; Tx, treatment.

per kg followed by 18 U per kg per hour [114,115]. Following initiation, the aPTT should be measured at 6-hour intervals until it is consistently in the therapeutic range of 1.5 to 2.0 times control values, which corresponds to a heparin level of 0.2 to 0.4 U per mL as measured by protamine sulfate titration [113]. Further adjusting of the UFH dose should be weight based. In patients deemed to have heparin resistance (requiring >35,000 U of UFH per day to achieve a therapeutic aPTT), antifactor Xa levels may be used to guide effective therapy [118].

Low-Molecular-Weight Heparin

Multiple clinical trials have demonstrated that low-molecular-weight heparin (LMWH) is at least as safe and effective as UFH for the treatment of acute VTE [119,120]. LMWH preparations offer several advantages over UFH, including greater bioavailability, longer half-life, lack of need for an intravenous infusion, and a more predictable anticoagulant response to weight-based dosing. LMWH can be administered subcutaneously once or twice per day and does not require monitoring of the aPTT. Monitoring antifactor Xa levels (typically 4 hours following injection) may be reasonable in certain settings such as morbid obesity, very small patients (<40 kg), pregnancy, renal insufficiency, or with unanticipated bleeding or recurrent VTE despite appropriate weight-based dosing [113,121–123]. Because the anticoagulant effect of UFH is short acting and can be rapidly reversed, it is often preferred over LMWH in the ICU, where patients are at increased risk for bleeding and may be undergoing fibrinolysis or need frequent procedures.

Fondaparinux is a highly bioavailable synthetic polysaccharide derived from heparin that is effective in the initial treatment and prophylaxis for VTE [124]. Fondaparinux does not appear to interact with platelet factor 4 so that heparin-induced thrombocytopenia (HIT), while it is possible, appears to be an exceedingly unlikely event. Its long half-life and renal clearance make it impractical for the ICU, and its anticoagulant effect is not reversible.

TABLE 52.6

ADVANCES IN THE PREVENTION AND INITIAL MANAGEMENT OF VENOUS THROMBOEMBOLISM (VTE) BASED ON RANDOMIZED CONTROLLED CLINICAL TRIALS AND RELEVANT TO INTENSIVE CARE

1. For patients with objectively confirmed DVT or PE, treat with SC LMWH or IV UFH (Grade 1 A).[a]
2. For patients with a high clinical suspicion of DVT or PE and in the absence of contraindications, treat with anticoagulants while awaiting the outcome of diagnostic tests (Grade 1C+).
3. In patients with VTE requiring large daily doses of UFH without achieving a therapeutic aPTT, anti-Xa levels should guide anticoagulant dosing (Grade 1B).
4. In patients with DVT or PE, thrombolytic treatment (Grade 2B) and mechanical (Grade 2C) or surgical embolectomy (Grade 2C) should be reserved for selected, highly compromised patients on a case-by-case basis and not performed routinely.
5. In the absence of contraindications, systemic thrombolytic therapy may be appropriate in selected patients with massive or submassive PE (Grade 2B).
6. For most patients with DVT or PE, routine use of an IVC filter in addition to anticoagulants is not recommended (Grade 1A).
7. IVC filter placement may be appropriate in patients with a contraindication to or a complication of anticoagulation, as well as in those with recurrent VTE despite adequate anticoagulant therapy (Grade 2C).
8. On admission to a critical care unit, all patients should be assessed for their risk of VTE. Accordingly, most patients should receive thromboprophylaxis (Grade 1A).
9. For patients who are at high risk for bleeding, mechanical prophylaxis with graded compression stockings and/or intermittent pneumatic compression is recommended until the bleeding risk decreases (Grade 1C+).[b]
10. For ICU patients who are at moderate risk for VTE (e.g., medically ill or postoperative patients), prophylaxis with low-dose UFH or LMWH is recommended (Grade 1A).
11. For critical care patients who are at higher risk, such as following major trauma or orthopaedic surgery, LMWH prophylaxis is recommended (Grade 1A).

[a] All graded recommendations in the table are based on available clinical trial data from the seventh American College of Chest Physicians consensus [143,154]. Even the non–grade A recommendations represent the standard of care in most clinical settings.
[b] In general, intermittent pneumatic compression is recommended over graded compression stockings in the intensive care unit, although few data are available for a firm recommendation.
aPTT, activated partial thromboplastin time; DVT, deep venous thrombosis; ICU, intensive care unit; IV, intravenous; IVC, inferior vena cava; LMWH, low-molecular-weight heparin; PE, pulmonary embolism; SC, subcutaneous; UFH, unfractionated heparin.
Adapted from Kearon C, Kahn SR, Agnelli G, et al. Antithrombotic therapy for venous thromboembolic disease. American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th ed). *Chest* 2008; 133:454S–545.

Warfarin

For the same reasons as LMWH, warfarin therapy is less frequently used as therapeutic anticoagulation for ICU patients. Also, oral warfarin therapy must take into account many drug and food interactions, as well as genetic variations in drug metabolism. When warfarin is employed, administration should generally overlap with therapeutic heparin anticoagulation. In patients with thrombophilia (protein C or S deficiency), warfarin may cause a transient hypercoagulable state due to the abrupt decline in vitamin K-dependent coagulation inhibitors. With warfarin therapy, it is recommended that a heparin preparation be employed for at least 5 days and maintained at a therapeutic level until two consecutive international normalized ratio values of 2.0 to 3.0 have been documented at least 24 hours apart [125].

Novel Agents

Extraordinary advances in the understanding of thrombosis have led to the development of several novel anticoagulant therapies. Lepirudin (recombinant hirudin), argatroban, desirudin are direct thrombin inhibitors that make them unique in their ability to inactivate fibrin clot-bound thrombin. The first of these two drugs are Food and Drug Administration (FDA)-approved parenteral drugs used for the treatment of HIT [124]. A disadvantage of the direct thrombin inhibitors is lack of reversibility. Other agents, including oral direct factor Xa inhibitors such as rivaroxaban and apixaban and new direct thrombin inhibitors such as dabigatran, are currently being evaluated.

Special Case: Central Venous Catheter–Related Thrombosis

Upper extremity thrombosis is common in the critically ill patient and is most often related to a CVC. CVC-related thrombosis should generally be treated similarly to uncomplicated DVT, but with an additional emphasis on prompt catheter removal once the diagnosis is established. The risk of clot embolization that accompanies CVC extraction is outweighed by the risk for chronic thrombotic complications and potential infection.

Complications of Anticoagulation

Hemorrhage and HIT are the major complications of anticoagulation. A pooled analysis of 11 clinical trials involving approximately 15,000 patients treated with either UFH or LMWH reported the frequency of major bleeding at 1.9% and a fatal hemorrhage rate of 0.2% [119]. Protamine may rapidly neutralize the anticoagulant effect of UFH, although allergy, hypotension, and bradycardia are possible adverse reactions to administration. The anticoagulant effect of LMWH is partly but not completely reversed by protamine [113].

HIT is an antibody-mediated adverse drug reaction that may lead to venous and arterial thrombosis. The principal clinical feature of HIT syndrome is the development of an otherwise unexplained drop in platelet count (absolute thrombocytopenia or more than 50% decrease if the platelet nadir remains in the normal range) following exposure to heparin. HIT generally develops 5 to 10 days after the initiation of heparin but may occur earlier in the setting of prior heparin exposure [126]. Although relatively infrequent, HIT is one of the most serious causes of thrombocytopenia in the ICU, and careful evaluation and consideration is warranted in this setting [127,128].

Thrombolytic Therapy

Thrombolytic agents may accelerate thrombus resolution by activating plasminogen to form plasmin resulting in fibrinolysis as well as fibrinogenolysis. The case for thrombolysis is the strongest in patients with massive PE complicated by shock, where the mortality rate may be more than 30% [129–132]. A positive troponin may suggest the diagnosis of acute PE. In proven PE, it appears to portend a poor prognosis. In one large study, of 737 patients presenting to the emergency department with proven PE, troponin T was measured in 563 and was elevated in 27% [132]. In-hospital survival was 79% in troponin-positive patients compared with 94% in troponin-negative patients ($p < 0.001$). One-year survival was 71% in troponin-positive patients compared with 90% in troponin-negative patients ($p < 0.001$). Elevated troponin levels predicted a fourfold increased risk of in-hospital death and threefold higher risk of 1-year mortality, even after adjustment for the most important other risk factors for death in this population.

Without question, thrombolytic therapy has been shown to accelerate clot lysis in PE and lead to a more rapid resolution of abnormal right ventricular dysfunction [4,133–136]. Evidence of a survival benefit, however, has been generally lacking, primarily because large randomized studies have not included all important potential predictors of death such as severe hypoxemia, *severe* right ventricular dysfunction, and residual clot burden in the legs. Accepting the limitations of registry data, a recent analysis of the International Cooperative Pulmonary Embolism Registry (ICOPER) nonetheless showed that thrombolysis for massive PE did not reduce mortality or the rate of recurrent PE at 90 days [137]. Thrombolytic treatment in patients with acute submassive PE (echocardiographic evidence of right ventricular dysfunction without hypotension) may offer no survival benefit but may prevent clinical deterioration and the need for escalation of care [138]. The decision for thrombolysis should be made on a case-by-case basis. Even in the setting of a relative contraindication, thrombolytic therapy may be reasonable when a patient is extremely unstable from life-threatening PE.

Each of the FDA-approved thrombolytic agents is administered at a fixed dose, making measurements of coagulation unnecessary during infusion (Table 52.7). Tissue-type plasminogen activator (2-hour infusion) is most commonly used. Shorter regimens and even bolus dosing may be favored in cases of unstable patients with massive PE. Following infusion of thrombolytics, the aPTT should be measured and repeated at 4-hour intervals until the aPTT is less than twice the upper limit of normal, after which continuous intravenous UFH should be administered without a loading bolus dose. Although thrombolytics have been administered as local intrapulmonary arterial infusions, standard systemic intravenous therapy appears adequate in most cases [139–141].

Thrombolytic therapy is contraindicated in patients at high risk for bleeding (Table 52.8). Intracranial hemorrhage is the most devastating (and often fatal) complication of thrombolytic therapy and occurs in 1% to 3% of patients [11,142]. Invasive procedures should be minimized around the time of therapy to decrease the risk of bleeding. A vascular puncture above the inguinal ligament can lead to retroperitoneal hemorrhage that is often initially silent but may be life-threatening. Although there is some rationale for thrombolytic therapy in DVT, such use is controversial and current guidelines are generally not supportive [143]. Systemic thrombolysis decreases the incidence of postthrombotic syndrome and perhaps the risk of recurrent DVT, but at an unacceptable increase in the rate of major hemorrhage [144]. Catheter-directed thrombolysis is increasingly common and appears to be a safer alternative for the management of extensive, symptomatic DVT [145].

In summary, there has been increasing interest in risk-stratifying patients with acute PE to determine when a more aggressive approach should be undertaken [143].

TABLE 52.7

FOOD AND DRUG ADMINISTRATION–APPROVED THROMBOLYTIC THERAPY REGIMENS FOR ACUTE PULMONARY EMBOLISM

Drug	Protocol
Streptokinase	250,000 U IV (loading dose during 30 min); then 100,000 U/h for 24 h
Urokinase[a]	2,000 U/lb IV (loading dose during 10 min); then 2,000 U/lb/h for 12 to 24 h
tPA	100 mg IV during 2 h

[a]Limited availability.
IV, intravenous; tPA, tissue-type plasminogen activator.

TABLE 52.8

CONTRAINDICATIONS TO THROMBOLYTIC THERAPY IN PULMONARY EMBOLISM

Absolute	Relative
Previous hemorrhagic stroke	Bleeding diathesis/thrombocytopenia
Intracranial surgery or pathology, including trauma	Recent major trauma, internal bleeding, or nonhemorrhagic stroke
Active internal bleeding	Uncontrolled severe hypertension
	Cardiopulmonary resuscitation
	Recent major surgery[a]
	Pregnancy

[a]This time frame may depend on the type of surgery, associated bleeding risk, and the level of critical illness.

Inferior Vena Cava Interruption

Primary indications for IVC filter placement include contraindication to anticoagulation and failure of therapy as defined by recurrent VTE or significant bleeding [143]. Alternative rationales for use currently lack support from well-designed clinical trials. The Prévention du Risque d'Embolic Pulmonaire par Interruption Cave (PREPIC) study has validated the common thinking that, in patients with acute proximal DVT, IVC filter placement decreases the rate of PE (6.2% vs. 15.1%) [146]. Unsurprisingly, this benefit is countered by an increased risk of recurrent DVT in patients with IVC filters that arguably may cause as much morbidity as nonfatal PE. Filter placement appears to have no effect on mortality.

A number of IVC filter designs exist and they can be inserted via the jugular or femoral veins. As noted, thrombosis is a primary complication of filters, and all patients should receive extended anticoagulation when able to do so. Insertion-related complications and filter migration may also occur. More recently, temporary filters have been employed in patients in whom the risk of bleeding appears short term.

Pulmonary Embolectomy

Given its high morbidity and mortality, surgical embolectomy has traditionally been a treatment of last resort, often reserved for patients with documented central PE and refractory cardiogenic shock despite maximal therapy. Contemporary studies show improved outcomes and suggest that emergency surgical pulmonary embolectomy may be feasible in carefully selected patients and with an experienced surgical team [147]. Percutaneous embolectomy is a less well-studied method of improving hemodynamics by reducing the burden of central pulmonary artery thromboembolism.

Special Therapeutic Considerations: Massive Pulmonary Embolism

In cases of massive PE, therapy should progress as directed by clinical likelihood and the diagnostic results. The mere suspicion of massive PE warrants immediate supportive therapy. Cautious infusion of intravenous saline may augment preload and improve impaired right ventricular function. Dopamine and norepinephrine are favored if hypotension remains, and combination therapy with dobutamine may boost right ventricular output, although it may exacerbate hypotension [148]. Supplemental oxygen and mechanical ventilation may be instituted as needed to support respiratory failure. Anticoagulation, thrombolytic therapy, and pulmonary embolectomy should be considered and employed as previously described.

CLINICAL COURSE AND PREVENTION

Course

VTE is associated with several main sequelae: nonfatal recurrent VTE, postthrombotic syndrome, chronic PE with pulmonary hypertension, and the most feared event, fatal PE. Death occurs in approximately 6% of DVT cases and 12% of PE cases within 1 month of diagnosis [23]. The overall crude 3-month mortality rate for patients in the ICOPER was 17.4% [11]. In the PIOPED study, the overall 3-month mortality rate was approximately 15%, but only 10% of deaths during the first year of follow-up were attributed to PE [13].

Most patients who survive an acute episode of VTE suffer no long-term sequelae. During the initial 3 months of therapeutic anticoagulation for patients with proximal DVT, approximately 4% will have a recurrent episode of VTE, and about 1 in 250 will develop fatal PE [149]. The incidence of severe postthrombotic syndrome is about 3% after 1 year and 9% after 5 years, even with the use of graduated compression stockings [150]. About 3% to 4% of PE patients will develop chronic thromboembolic pulmonary hypertension [151].

Prevention

Although VTE prophylaxis unequivocally reduces the incidence of disease for those at risk, such measures appear to be grossly underused [152,153]. This may be particularly true in hospitalized medical patients; a heterogeneous group in whom the risk for VTE and the data for prophylaxis have traditionally lagged behind surgical practice [153]. Three well-designed, placebo-controlled studies in acutely ill medical patients have demonstrated a substantial decrease in asymptomatic DVT or symptomatic VTE with pharmacologic (LMWH, dalteparin, or fondaparinux) prophylaxis [154–156]. Combining all three trials, VTE prophylaxis reduced the frequency of asymptomatic DVT or symptomatic VTE by about 50%, and the risk of major bleeding was not increased. Intermittent pneumatic compression devices should be used when prophylactic anticoagulation is contraindicated, and it may be reasonable to employ both methods in patients deemed to be at exceptionally high risk for VTE. Essentially all critically ill patients require some form of VTE prophylaxis. Multiple regimens are FDA approved, and prophylactic therapy must be individualized to the patient and the clinical setting.

VENOUS THROMBOEMBOLISM IN PREGNANCY

VTE is a leading cause of death in pregnant women, in whom the age-adjusted risk of VTE is at least five times higher compared with nonpregnant women [1,157]. DVT is more common during the antepartum period and occurs with almost equal frequency in each of the three trimesters. In contrast, the incidence of PE is highest immediately postpartum.

In pregnancy, venous stasis arises due to increased venous distensibility and capacity as well as compression of large veins by a gravid uterus. Pregnancy is a hypercoagulable state, accompanied by changes in the coagulation and fibrinolytic systems. Obstetrical factors such as prolonged bed rest and instrument-assisted or cesarean delivery may also increase the risk of VTE.

The diagnosis of VTE during pregnancy is complicated by maternal physiologic changes and the reluctance of physicians to expose a fetus to ionizing radiation. As in nonpregnant patients, many symptoms, signs, and preliminary tests are nondiagnostic for VTE. In general, the evaluation for VTE in pregnancy should emphasize the early use of noninvasive studies of the legs. When ultrasonography does not demonstrate DVT, the diagnostic algorithm is similar to that described for nonpregnant patients. Although radiation exposure should be minimized to decrease the risk of fetal injury, a firm diagnosis is important because of the short- and long-term treatment implications.

Therapy for VTE in pregnancy is generally similar to that in nonpregnant women, except that warfarin should be avoided because it is teratogenic and can cross the placental barrier. LMWH has been shown to be safe in pregnancy and is often preferred as long-term therapy; warfarin may be employed postpartum [158]. Due to the risk of maternal hemorrhage and fetal demise, pregnancy is a relative contraindication for thrombolytic therapy. That being considered, controlled trials are lacking in this area, and thrombolysis may rarely be appropriate in cases of massive PE with hemodynamic instability. The indications for IVC filter placement in pregnant women are the same as in nonpregnant patients. Finally, VTE prophylactic therapy may be appropriate for pregnant women deemed at high risk for VTE, such as those with a history of prior VTE or in patients with an inherited or acquired thrombophilia.

NONTHROMBOTIC PULMONARY EMBOLI

Although thrombotic PE is the most common and important syndrome characterized by embolization of material into the pulmonary circulation, nonthrombotic pulmonary emboli may rarely occur in certain clinical settings. Fat embolism syndrome most commonly occurs after blunt trauma complicated by long-bone fractures. The characteristic findings of dyspnea, axillary and subconjunctival petechiae, and alterations in mental

status generally occur between 12 and 48 hours after the primary event [159]. Cardiopulmonary derangement is likely due to venous obstruction by neutral fat and to a vasculitis and capillary leak syndrome caused by free fatty acids. The diagnosis of fat embolization syndrome is clinical; however, the identification of fat droplets within cells recovered by bronchoalveolar lavage may be helpful [160]. Therapy is generally prophylactic and supportive as more specific treatments have shown limited benefit. The syndrome is usually mild and the prognosis good.

Amniotic fluid embolism is uncommon, but it represents one of the leading causes of maternal death in the United States [161]. The condition may occur during or shortly after either spontaneous or cesarean delivery and there exist no consistent identifiable risk factors. Clinical hallmarks include hypoxemia, cardiogenic shock, altered mental status, and disseminated intravascular coagulation. The diagnosis is clinical and the therapy is primarily supportive. Amniotic fluid embolism is frequently fatal and permanent neurologic deficits are found in 85% of survivors [161].

Septic PE usually presents as multiple bilateral peripheral nodules that are often poorly marginated and may have cavitary changes. Right-sided endocarditis and septic thrombophlebitis are the most common source of septic pulmonary emboli [162]. Fever, rigors, and pleuritic chest pain may be more impressive in septic PE as compared with bland PE. Treatment centers on appropriate anti-infective therapy, but anticoagulation and surgical management may be appropriate in some circumstances. Intensive care is generally not necessary unless there is significant associated cardiopulmonary dysfunction.

Air embolism requires communication between the air and the venous circulation when venous blood pressure is below atmospheric pressure. Predisposing settings include invasive procedures, barotrauma, and the use of indwelling catheters. Air may gain entry into the arterial system by incomplete filtering of a large air embolus by the pulmonary capillaries or via paradoxical embolization through a patent foramen ovale [163]. The clinical picture is critical in raising the suspicion of disease as the signs and symptoms are generally nonspecific. Immediate Trendelenburg and left lateral decubitus positioning may open an obstructed right ventricular outflow tract, and air aspiration should be attempted if there is a CVC in the right atrium. Administration of 100% oxygen aids in bubble reabsorption via nitrogen washout, and hyperbaric oxygen therapy may also be beneficial.

Other miscellaneous nonthrombotic causes of pulmonary vascular obstruction include cancer cells, schistosomal disease, and inorganic material such as talc crystals or various fibers.

CHAPTER 53 ■ MANAGING HEMOPTYSIS

RICHARD S. IRWIN AND KIMBERLY A. ROBINSON

OVERVIEW

Hemoptysis is defined in *Stedman's Medical Dictionary* as "the spitting of blood derived from the lungs or bronchial tubes." This common symptom may be the primary reason for seeking consultation in approximately 8% to 15% of an average chest clinic population. It elicits great apprehension in the patient and is likely to prompt early medical attention. The basis for this fear is the presumption that the hemoptysis is caused by a serious disease (e.g., cancer) and that it signals impending massive bleeding. The patient may describe an associated burning pain, vague discomfort, or bubbling sensation in the chest and shortness of breath. Hemoptysis may be scant, producing the appearance of streaks of bright red blood in the sputum, or profuse, with expectoration of a large volume of blood.

Massive hemoptysis is defined as the expectoration of 600 mL of blood within 24 to 48 hours and occurs in 3% to 10% of all patients with hemoptysis [1]. *Nonmassive hemoptysis* produces a quantity smaller than massive hemoptysis and greater than blood streaking. Dark red clots may also be expectorated when blood has been present in the lungs for days.

Pseudohemoptysis, on the other hand, is the expectoration of blood from a source other than the lower respiratory tract. It may cause diagnostic confusion when patients cannot clearly describe the source of their bleeding. Pseudohemoptysis may occur when blood from the oral cavity, nares, pharynx, or tongue drains to the back of the throat and initiates the cough reflex; when blood is aspirated into the lower respiratory tract in patients who have hematemesis; and when the oropharynx is colonized with a red, pigment-producing, aerobic, Gram-negative rod, *Serratia marcescens* [2]. This colonization may occur in hospitalized or nursing home patients who have received broad-spectrum antimicrobial agents and/or mechanical ventilatory support. Other rare causes of pseudohemoptysis are self-inflicted injuries or other bizarre tactics in the malingering patient seeking hospitalization and rifampin overdose (red man syndrome). The causes and distinguishing features of pseudohemoptysis are listed in Table 53.1.

This chapter deals with managing hemoptysis in the intensive care unit (ICU) in the context of a general discussion of hemoptysis. The management of tracheoartery fistula, traumatic rupture of the pulmonary artery due to balloon flotation catheters, and diffuse intrapulmonary hemorrhage are highlighted.

ETIOLOGY

Hemoptysis can be caused by a wide variety of disorders (Table 53.2) [3]. Although the incidences of the causes of hemoptysis have been described in several populations of patients, we are not aware of any study that has reported the most frequent causes of hemoptysis in critically ill patients.

The etiology of hemoptysis is considered here in three general categories: nonmassive, massive, and idiopathic. Patients in the ICU frequently have nonmassive hemoptysis, and the spectrum of the causes of hemoptysis in these patients probably differs little from that reported in major series. Commonly, the causes include trauma (secondary to suctioning), overzealous anticoagulation, and infection. Unlike the general ICU patient, patients with massive hemoptysis are frequently in the ICU because of their hemoptysis and thereby constitute a different subgroup of patients.

Nonmassive Hemoptysis

Although bronchitis, bronchiectasis, pneumonia, lung carcinoma, and tuberculosis have always been among the most common causes of hemoptysis, their incidence has varied depending on the study population and era. For example, in the immunocompromised patient, *Pneumocystis jiroveci*, fungal disease, *Mycobacterium tuberculosis*, and *Mycobacterium avium intracellulare* may be at the top of the differential diagnosis [4–8].

Although bleeding from tracheoartery fistula complicating tracheostomy, rupture of pulmonary artery from a balloon flotation catheter, and diffuse intrapulmonary hemorrhage may be submassive, they are discussed in the following section.

Massive Hemoptysis

The more frequent causes of massive hemoptysis likely to be seen in the ICU are listed in Table 53.3. Virtually all causes of hemoptysis may result in massive hemoptysis, but it is most frequently caused by tuberculosis, bronchiectasis, lung abscess, and lung cancer [5,6]. Infection is also the cause of bleeding from aspergilloma [9] and cystic fibrosis [10]. Idiopathic hemoptysis is less frequent in patients with massive hemoptysis and usually constitutes less than 5% of cases [4].

TABLE 53.1

DIFFERENTIAL FEATURES OF PSEUDOHEMOPTYSIS

Cause	History	Physical examination	Laboratory tests
Upper respiratory tract	Little or no cough; epistaxis, bleeding from gums when brushing teeth	Gingivitis, telangiectasias, ulcerations, lacerations, or varices of the tongue, nose, or naso-, oro-, or hypopharynx	Observing actively bleeding lesion
Upper gastrointestinal tract	Coffee-ground appearance of blood due to mixture with HCl; usually lacks the bubbly, frothy appearance of bloody sputum; nausea, vomiting, or history of gastrointestinal disease	Epigastric tenderness; signs of chronic liver disease	Acid pH of blood; blood in nasogastric aspirate; barium swallow, esophagoscopy, and gastroscopy
Serratia marcescens	Previous hospitalization, broad-spectrum antibiotics, mechanical ventilation	Normal	No red blood cells in red sputum; culture of organism
Malingering	Psychiatric illness; unconfirmed history of massive hemoptysis at midnight	Normal unless self-induced lesions seen; patients unable to cough up blood on command (patients with true hemoptysis will)	True hemoptysis usually must be ruled out (see Table 53.4)

Rupture of a pulmonary artery complicates balloon flotation catheterizations in less than 0.2% of cases [11,12]. It is fortunate that it is uncommon because it carries a mortality rate approximating 40% [12]. With the less frequent use of this procedure, this complication will likely become even more rarely seen. *Tracheoartery fistula* is also an unusual but devastating condition, complicating approximately 0.7% of tracheostomies [13]. *Diffuse intrapulmonary hemorrhage*, usually due to an immunologically mediated disease, should also be considered in the differential diagnosis of massive hemoptysis in the ICU.

Idiopathic Hemoptysis

Using the systematic diagnostic approach outlined later and in Tables 53.4 and 53.5, the cause of hemoptysis can be found in most instances. In 2% to 32% of patients (average, 12%) [14], the cause cannot be determined. This condition, called *idiopathic* or *essential hemoptysis*, is seen most commonly in men between the ages of 30 and 50 years. Prolonged follow-up studies with rare exceptions usually fail to reveal the source of bleeding, even though 10% of patients continue to have occasional episodes of hemoptysis [15]. In a subset of patients, Dieulafoy disease of the bronchus (i.e., an abnormal superficial vessel contiguous to the epithelium of the bronchial mucosa) has been demonstrated at pathologic examination when surgery has been performed for massive bleeding [16].

PATHOGENESIS

To appreciate fully the pathogenesis of hemoptysis, it is necessary to review briefly the normal anatomy of the nutrient blood supply to the lungs [17]. The bronchial arteries are the chief source of blood of the airways (from mainstem bronchi to terminal bronchioles); the supporting framework of the lung that includes the pleura, intrapulmonary lymphoid tissue; and large branches of the pulmonary vessels and nerves in the hilar regions. The pulmonary arteries supply the pulmonary parenchymal tissue, including the respiratory bronchioles. Communications between these two blood supplies, bronchopulmonary arterial and venous anastomoses, occur near the junction of the terminal and respiratory bronchioles. These anastomoses allow the two blood supplies to complement each other. For instance, if flow through one system is increased or decreased, a reciprocal change occurs in the amount of blood supplied by the other system [18]. Arteriographic studies in patients with active hemoptysis have shown that the systemic circulation (bronchial arteries) is primarily responsible for the bleeding in approximately 92% of cases [19].

The pathogenesis of hemoptysis depends on the type and location of the disease [20]. In general, if the lesion is endobronchial, the bleeding is from the bronchial circulation, and if the lesion is parenchymal, the bleeding is from the pulmonary circulation. Moreover, in chronic diseases, repetitive episodes are most likely due to increased vascularity in the involved area [21].

In bronchogenic carcinoma, hemoptysis results from necrosis of the tumor, with its increased blood supply from bronchial arteries, or from local invasion of a large blood vessel. In bronchial adenomas, bleeding is usually from rupture of the prominent surface vessels. In bronchiectasis, granulation tissue often replaces the normal bronchial wall and, with infection, this area can become irritated and bleed. In acute bronchitis, bleeding results from irritation of the unusually friable and vascular mucosa [20].

The mechanism of hemoptysis in mitral stenosis is controversial, but the most likely explanation is rupture of the dilated varices of the bronchial veins in the submucosa of large bronchi [22] due to pulmonary venous hypertension. Pulmonary venous hypertension may also be responsible for the bleeding in congestive heart failure because it is associated with widening of the capillary anastomoses between bronchial and pulmonary arteries [21].

Hemoptysis in pulmonary embolism may be due to infarction, with necrosis of parenchymal tissue, or due to hemorrhagic consolidation secondary to increased bronchial artery blood flow, which forms collaterals with the pulmonary circulation to bypass the obstructing clot [23].

TABLE 53.2

CAUSES OF HEMOPTYSIS[a]

- Tracheobronchial disorders
  - Acute tracheobronchitis
  - Amyloidosis
  - Aspiration of gastric contents
  - Bronchial adenoma
  - Bronchial endometriosis
  - Bronchial telangiectasia
  - Bronchiectasis
  - Bronchogenic carcinoma
  - Broncholithiasis
  - Chronic bronchitis
  - Cystic fibrosis
  - Endobronchial hamartoma
  - Endobronchial metastases
  - Endobronchial tuberculosis
  - Foreign body aspiration
  - Mucoid impaction of the bronchus
  - Thyroid cancer
  - Tracheobronchial trauma
  - Tracheoesophageal fistula
  - Tracheoartery fistula
- Cardiovascular disorders
  - Aortic aneurysm
  - Bronchial artery rupture
  - Congenital heart disease
  - Congestive heart failure
  - Coronary artery bypass graft
  - Fat embolization
  - Hughes-Stovin syndrome
  - Mitral stenosis
  - Neonatal intrapulmonary hemorrhage
  - Postmyocardial infarction syndrome
  - Pulmonary arteriovenous fistula
  - Pulmonary artery aneurysm
  - Pulmonary embolism
  - Pulmonary venous varix
  - Schistosomiasis
  - Subclavian artery aneurysm
  - Superior vena cava syndrome
  - Thoracic endometriosis
  - Tumor embolization
- Hematologic disorders
  - Antithrombotic therapy
  - Disseminated intravascular coagulation
  - Leukemia
  - Thrombocytopenia
  - Hemophilia
- Localized parenchymal diseases
  - Acute and chronic nontuberculous pneumonia
  - Actinomycosis
  - Amebiasis
  - Ascariasis
  - Aspergilloma
  - Bronchopulmonary sequestration
  - Coccidioidomycosis
  - Congenital and acquired cyst
  - Cryptococcosis
  - Exogenous lipoid pneumonia
  - Histoplasmosis
  - Hydatid mole
  - Lung abscess
  - Lung contusion
  - Metastatic cancer
  - Mucormycosis
  - Nocardiosis
  - Paragonimiasis
  - Pulmonary endometriosis
  - Pulmonary tuberculosis
  - Sporotrichosis
  - Thoracic splenosis
- Diffuse parenchymal disease
  - Disseminated angiosarcoma
  - Drugs[b] (Alemtuzumab, abciximab, gemtuzumab, anti-CD 33 monoclonal antibody)
  - Farmer's lung
  - Goodpasture's syndrome
  - Idiopathic pulmonary hemosiderosis
  - Immunoglobulin A nephropathy
  - Inhaled isocyanates
  - Charcoal lighter fluid injection
  - Legionnaires' disease
  - Mixed connective tissue disease
  - Mixed cryoglobulinemia
  - Polyarteritis nodosa
  - Scleroderma
  - Systemic lupus erythematosus
  - Trimellitic anhydride toxicity
  - Viral pneumonitis
  - Wegener's granulomatosis
  - Isolated pulmonary pauci-immune capillaritis
  - Pulmonary capillaritis associated with systemic vasculitides
  - Bone marrow transplantation
  - Lysinuric protein intolerance
- Other
  - Idiopathic
  - Iatrogenic
    - Bronchoscopy
    - Cardiac catheterization
    - Needle biopsy of lung

TABLE 53.3

COMMON CAUSES OF MASSIVE HEMOPTYSIS

Infectious
Bronchitis
Bronchiectasis
Tuberculosis
Cystic fibrosis
Aspergilloma
Sporotrichosis
Lung abscess
Pneumonia in human immunodeficiency virus–infected patients
Malignant
Bronchogenic cancer
Metastatic cancer
Leukemia
Cardiovascular
Arteriobronchial fistula
Congestive heart failure
Pulmonary arteriovenous fistula
Diffuse parenchymal disease
Diffuse intrapulmonary hemorrhage
Trauma
Iatrogenic
Pulmonary artery rupture
Malposition of chest tube
Tracheoartery fistula

In tuberculosis, bleeding can occur for a variety of reasons [24]. In the acute parenchymal exudative lesion, scant hemoptysis may result from necrosis of a small branch of a pulmonary artery or vein. In the chronic parenchymal fibroulcerative lesion, massive hemoptysis may result from rupture of a pulmonary artery aneurysm bulging into the lumen of a cavity [25]. The aneurysm occurs from tuberculous involvement of the adventitia and media of the vessel [26]. When a healed and calcified tuberculous lymph node erodes the wall of a bronchus because of pressure necrosis, the patient may cough up blood as well as the calcified node (broncholith). In endobronchial tuberculosis, hemoptysis may result from acute tuberculous ulceration of the bronchial mucosa. In healed and fibrotic parenchymal areas of tuberculosis, bleeding may arise from irritation of granulation tissue in the walls of bronchiectatic airways in the same areas.

TABLE 53.4

ROUTINE EVALUATION OF HEMOPTYSIS

History
Physical examination
Complete blood cell count
Urinalysis
Coagulation studies
Electrocardiogram
Chest radiographs
±Flexible bronchoscopy[a]

[a] Although flexible bronchoscopy should not be performed in patients with some conditions (e.g., pulmonary embolism, aortopulmonary fistula), it should be routinely considered (see text).

TABLE 53.5

SPECIAL EVALUATION OF HEMOPTYSIS

Tracheobronchial disorders
Expectorated sputa for tubercle bacilli, parasites, fungi, and routine cytologic testing
Bronchoscopy
High-resolution chest CT scan
Cardiovascular disorders
Echocardiogram
Arterial blood gases on 21% and 100% oxygen
Ventilation and perfusion lung scans, venous duplex scanning
Pulmonary angiogram, MRI, spiral chest CT scan with contrast
Aortogram, CT scan with contrast
Cardiac catheterization
Hematologic disorders
Coagulation studies
Bone marrow
Localized parenchymal diseases
Expectorated sputa for parasites, tubercle bacilli, fungi, and routine cytologic testing
Chest CT scan and MRI
Aspergillus precipitins in serum
Lung biopsy with special stains
Diffuse parenchymal diseases[a]
Expectorated sputa for cytologic testing
Blood urea nitrogen, creatinine, antinuclear antibody, rheumatoid factor, complement, cryoglobulins, lupus erythematosus preparation
Serum for circulating antiglomerular basement membrane antibody and antineutrophilic cytoplasmic antibody
Serum for precipitins for hypersensitivity pneumonitis screen
Acute and convalescent serum antibody studies for Legionnaires' disease and respiratory viruses
Lung or kidney biopsy with special stains, including immunofluorescence

[a] Diffuse implies involvement of all lobes.
CT, computed tomography; MRI, magnetic resonance imaging.

In traumatic *rupture of the pulmonary artery* by a balloon flotation catheter, risk factors include pulmonary hypertension, distal location of the catheter tip, excessive catheter manipulation in an attempt to obtain a pulmonary artery-occluded pressure measurement, a large catheter loop in the right ventricle, and advanced age [12].

In *tracheoartery fistula* complicating tracheostomy, bleeding is due to trauma from the tracheostomy cannula or balloon [13]. Bleeding usually is due to rupture of the innominate artery. The fistula can form at three tracheal locations: the stoma, the intratracheal cannula tip, and the balloon. Trauma at the stoma is caused by pressure necrosis, usually because the tracheostomy was created too low (below the fourth tracheal ring); at the cannula tip because of excessive angulation of the cannula; and at the balloon site due to pressure necrosis caused by use of excessive inflation pressures.

Diffuse intrapulmonary hemorrhage associated with immunologic diseases is due to an inflammatory lesion, usually of the capillaries [27–31].

DIAGNOSIS

General Considerations

The success rate in determining the cause of hemoptysis is excellent but variable. If one accepts the diagnosis of idiopathic (essential) hemoptysis as a distinct entity [15], the cause of hemoptysis can be determined in nearly 100% of cases [14]. The diagnostic work-up of hemoptysis involves routine (Table 53.4) as well as special evaluations (Table 53.5). Routine evaluations are initially performed in every patient, whereas special studies are ordered only when the clinical setting suggests they are indicated. In general, each category of disease (Table 53.2) has its special studies (Table 53.5).

Routine Evaluation

As in any diagnostic problem, a detailed history and physical examination must be performed. These should be performed in a systematic fashion to rule not only in the common causes of hemoptysis but also in the category of the cause (Table 53.2).

Although the amount of bleeding usually is not indicative of the seriousness of the underlying disease process, a history of the frequency, timing, and duration of hemoptysis may be helpful. For example, repeated episodes of hemoptysis occurring during months to years suggest bronchial adenoma and bronchiectasis [20], whereas small amounts of hemoptysis occurring every day for weeks are more likely to be caused by bronchogenic carcinoma [32], as hemoptysis is generally a late finding in these patients. Hemoptysis that coincides with the menses (catamenial) suggests the rare diagnostic possibility of pulmonary endometriosis [33,34], whereas bleeding associated with sexual intercourse [35] or other forms of exertion suggests passive congestion of the lungs.

Although hemoptysis may be a symptom at any age, it is distinctly uncommon in the young. When hemoptysis is present before the third decade of life, it suggests an acute tracheobronchitis, a congenital cardiac or lung defect, an unusual tumor, cystic fibrosis, a blood dyscrasia, or infectious pneumonia. No matter what the age, if a patient with pneumonia who is undergoing appropriate therapy has hemoptysis that persists for more than the usual 24 hours, an endobronchial lesion or coagulopathy should be suspected.

A travel history can often be helpful in bringing certain endemic diseases to mind. This is true of coccidioidomycosis and histoplasmosis in the United States; paragonimiasis and ascariasis in East Asia; and schistosomiasis in South America, Africa, and East Asia.

Chronic sputum production before hemoptysis suggests a diagnosis of chronic bronchitis, bronchiectasis, and cystic fibrosis. The presence of orthopnea and paroxysmal nocturnal dyspnea makes likely the diagnoses of passive congestion of the lungs from mitral stenosis and left ventricular failure. A history of antithrombotic therapy suggests an intrapulmonary bleed from too large a dose or recurrent pulmonary embolism from too small a dose. The possibility of pulmonary embolism should always be considered when a patient who presents with hemoptysis has been at increased risk for deep venous thrombosis [36].

The possibility of traumatic rupture of a pulmonary artery due to balloon flotation catheterization should always be considered when these catheters are used [11,12].

Although tracheoartery fistula must be considered in the differential diagnosis of hemoptysis in every patient with a tracheostomy, it is an infrequent cause in this setting. When it occurs, the onset is almost always at least 48 hours after the procedure [13]. Although the peak incidence is between the first and second week and 72% of fistulas bleed during the first 21 days after tracheostomy, hemorrhage from this complication can also occur as late as 18 months after the procedure [13]. There is a sentinel bleed in 34% to 50% of cases [13]. Before 48 hours, bleeding from the stoma is usually due to capillary bleeding from inadequate hemostasis. Whenever hemoptysis occurs in a patient with an endotracheal tube or tracheostomy in place, trauma from suctioning should be considered, especially when coagulation is abnormal.

Although patients with diffuse intrapulmonary hemorrhage typically have hemoptysis, they occasionally do not expectorate at all but just complain of dyspnea [37], fever, cough, and malaise. Therefore, lack of hemoptysis does not rule out a substantial intrapulmonary hemorrhage [37].

The diagnosis of trimellitic anhydride–induced pulmonary hemorrhage should be suspected in workers exposed to high-dose trimellitic anhydride fumes. Exposure occurs when heated metal surfaces are sprayed with corrosion-resistant epoxy resin coatings. The syndrome requires a latent period of exposure and appears to be antibody mediated [38,39]. Respiratory failure with pulmonary infiltrates and hemoptysis has also been reported in a patient with a documented exposure and antibodies to isocyanates [40].

In a patient with the triad of known upper airway disease, lower airway disease, and renal disease, systemic Wegener's granulomatosis should be suspected. Pulmonary hemorrhage can occur at any point during the course of the illness in the patient with systemic lupus erythematosus (SLE) and can also be the initial manifestation of the disease [41]. Goodpasture's syndrome (antibasement membrane antibody–mediated disease) typically occurs in young men [42], and it has been reported to be associated with influenza infection [43], inhalation of hydrocarbons [44], and penicillamine ingestion [45]. Therefore, it should be considered in these historical contexts.

Diffuse alveolar hemorrhage should be suspected in patients who have undergone recent hematopoietic stem cell transplantation when they present with cough, dyspnea, hypoxemia, and diffuse pulmonary infiltrates. This typically occurs with marrow recovery. It has been reported to occur in approximately 20% of patients during autologous bone marrow transplantation, and it was associated with an 80% mortality rate [46]. Lung tissue injury, inflammation, and cytokine release are implicated in the pathogenesis of diffuse alveolar hemorrhage in hematopoietic stem cell transplant patients.

Physical examination may be helpful in several ways. Inspection of the skin and mucous membranes may show telangiectasias, suggesting hereditary hemorrhagic telangiectasia, or ecchymoses and petechiae, suggesting a hematologic abnormality. Pulsations transmitted to a tracheostomy cannula should heighten suspicion, or risk, of a tracheoartery fistula. Inspection of the thorax may show evidence of recent or old chest trauma, and unilateral wheeze or rales may herald localized disease such as bronchial adenoma or carcinoma. Although pulmonary embolism is not definitively diagnosed on physical examination, tachypnea, phlebitis, and pleural friction rub suggest this disorder. If crackles are heard diffusely on chest examination, passive congestion as well as other diseases causing diffuse intrapulmonary hemorrhage should be considered (Table 53.2). Careful cardiovascular examination may rule in mitral stenosis, pulmonary artery stenosis, or pulmonary hypertension.

The routine laboratory studies listed in Table 53.4 are useful for the following reasons. The complete blood cell count results may suggest the presence of an infection, hematologic disorder, or chronic blood loss. Sputum should be sent for Gram stain and culture, including studies for acid-fast organisms. In

addition, sputum should be sent for cytological evaluation if the patient is a smoker and older than 40 years [47]. Idiopathic hemosiderosis or other causes of diffuse intrapulmonary hemorrhage (Table 53.2) may present only with diffuse pulmonary infiltrates and iron deficiency anemia from chronic bleeding into the lungs. Urinalysis may reveal hematuria and suggest the presence of a systemic disease associated with diffuse parenchymal disease (e.g., pulmonary renal hemorrhage syndrome due to SLE, Goodpasture's syndrome, systemic Wegener's granulomatosis, and other systemic vasculitides; Table 53.2). Although there is simultaneous evidence of clinical involvement of the lungs and kidneys in 33% of cases of Goodpasture's syndrome, there can be clinical lung involvement without renal disease in 33% and clinical renal involvement without lung disease in 33% [48,49].

Coagulation studies may uncover a hematologic disorder that is primarily responsible for the hemoptysis or that contributes to excessive bleeding from another disease. The electrocardiogram may help suggest the presence of a cardiovascular disorder. Although as many as 30% of patients with hemoptysis have negative chest radiographs [3], routine posteroanterior and lateral films may be diagnostically valuable.

When pulmonary tumor or infection is not readily apparent, there are other radiographic signs that may help to elucidate the cause and source of bleeding. Radiopaque foreign bodies may give rise to hemoptysis even years after entry into the lungs. One may note the disappearance of a calcified mediastinal lymph node after it has eroded the bronchial wall and is expectorated as a broncholith. Aortic or pulmonary aneurysms may erode into the bronchial tree. Single or multiple pulmonary cavities may suggest pulmonary tuberculosis, fungal disease, parasitic disease, acute or chronic lung abscess, neoplasm, septic pulmonary emboli, or Wegener's granulomatosis. The finding of a mass within a cavitary lesion raises the possibility of a fungus ball (aspergilloma), whereas localized honeycombing may be indicative of bronchiectasis. The presence of a new infiltrate localized to the area subtending a balloon flotation catheter suggests a rupture of the pulmonary artery [11,12]. The appearance of a new air-fluid level in a preexisting cavity or cyst suggests the location of the source of bleeding, as does a nonsegmental alveolar pattern that clears within a few days. A solitary pulmonary nodule with vessels going toward it suggests an arteriovenous fistula. In patients with hemoptysis due to pulmonary embolism, a parenchymal density abutting a pleural surface with evidence of pleural reaction or effusion is usually present [36]. The cardiac silhouette, vascular or parenchymal patterns, and the presence of Kerley B lines may be useful in documenting cardiovascular disease.

When the chest radiograph shows diffuse pulmonary infiltrates, hemorrhage from bleeding disorders (e.g., thrombocytopenia in the compromised host), lung contusion from blunt chest trauma, freebase cocaine use, and passive congestion of the lungs should be considered, in addition to the diseases listed under "Diffuse Parenchymal Disease" in Table 53.2. In the earliest stages of diffuse intrapulmonary hemorrhage, chest radiographs may appear normal, but usually the hemorrhage first appears in a diffuse alveolar pattern. This progresses to a mixed alveolar–interstitial pattern and then, when bleeding ceases entirely, to an interstitial pattern, as hemosiderin deposition accumulates.

Bronchoscopy

Even if the history, physical examination, and chest radiograph are normal, or there is an "obvious" cause of hemoptysis on the chest radiograph, bronchoscopy is invaluable not only for accurate diagnosis but also for precise localization of the pulmonary hemorrhage. It is not uncommon for bronchoscopy to establish sites of bleeding different from those suggested by chest radiography [50,51]. Bronchoscopy may not be needed in patients with stable chronic bronchitis with one episode of blood streaking, particularly if associated with an exacerbation of acute tracheobronchitis, or in patients in whom the site of bleeding was recently documented by bronchoscopic examination. In addition, patients with acute lower respiratory tract infections, and patients with obvious cardiovascular causes of hemoptysis, such as congestive heart failure and pulmonary embolism, may not require bronchoscopic examination.

In localizing the bleeding site, the best results are obtained when bronchoscopy is performed during or within 24 hours of active bleeding. The bleeding site can be localized in up to 93% of patients with a flexible bronchoscope and in up to 86% with the rigid instrument [51,52]. When the procedure is done within 48 hours, localization of bleeding can drop to 51% [53]. When bronchoscopy is done after bleeding has ceased, accurate localization is likely to be reduced even further [52]. Although the flexible bronchoscope is usually the instrument of choice in diagnosing lower respiratory tract problems, rigid bronchoscopy is preferred in cases of massive, uncontrolled hemorrhage because patency of the airway is maintained more effectively during the procedure (see Chapter 9). There are data that show that obtaining high-resolution chest computed tomography scanning before bronchoscopy may enhance the yield of bronchoscopy [53]. With the exception of tracheoartery fistula, the tracheobronchial disorders that can be diagnosed by a bronchoscopic examination are listed in Table 53.2.

Bedside bronchoscopy should not be performed to rule in the diagnosis of tracheoartery fistula [13]. In tracheostomized patients with hemoptysis, bronchoscopy should be performed to rule out other causes, such as bleeding from suction ulcers, tracheitis, or lower respiratory tract disorders. If no other cause for hemoptysis can be found and bleeding has stopped, or anterior and downward pressure on the cannula on the stomal site or overinflation of the tracheostomy balloon slows down or stops the bleeding, a surgical consultation should be sought immediately and the patient brought to the operating room for examination in a more controlled environment. *As long as tracheoartery fistula remains a diagnostic possibility, the tracheostomy balloon should not be deflated, and the tracheostomy tube should not be removed without protecting the airway below the tracheostomy tube.*

When there is no active bleeding, bronchoscopy with bronchoalveolar lavage can be helpful in suggesting diffuse intrapulmonary hemorrhage. Return of bright red or blood-tinged lavage fluid from multiple lobes from both lungs and lack of change in the appearance of fluid during serial lavage processes suggests an active, diffuse intrapulmonary hemorrhage; hemosiderin-laden macrophages (i.e., siderophages) on cytologic analysis from these same specimens suggest bleeding that has been ongoing. Because healthy subjects may have siderophages in their alveoli, the diagnosis of diffuse alveolar hemorrhage requires a substantial number of siderophages to be recovered by bronchoalveolar lavage (≥20% of total alveolar macrophages) [54]. Because carbon monoxide–diffusing capacity is increased due to binding of carbon monoxide by intra-alveolar red blood cells for 24 to 48 hours after bleeding stops, this test may be helpful in suggesting intra-alveolar hemorrhage in the stable patient without hemoptysis.

Although the definitive diagnosis of bronchiectasis can be made by high-resolution chest computed tomography scan, bronchiectasis is visible on routine chest radiographs in 80% to 88% of cases, and bronchoscopy can localize the bleeding to the corresponding abnormal areas [55].

Angiography

Angiography can determine the site of bleeding in 90% to 93% of cases. When performed routinely, diagnostic angiography establishes a diagnosis not identified by bronchoscopy in only 4% of patients [52]. Technetium-labeled colloid and red blood cell studies have rarely been shown to add any information that cannot be obtained by chest computed tomography scanning and bronchoscopy. Although angiography may not be initially helpful in confirming rupture of the pulmonary artery due to balloon flotation catheterization if the rent has sealed, it can be extremely helpful in detecting a pseudoaneurysm that has formed in the healing process [12]. Identification of an unstable lesion is important because it should be obliterated to prevent future rupture and death [12]. Angiography has not been useful in diagnosing tracheoartery fistula [13].

Special Evaluation

Depending on the results of the initial evaluation and the possible categories of cause of hemoptysis (Table 53.2), additional diagnostic evaluations should be systematically performed (Table 53.5).

The diagnosis of Goodpasture's syndrome is made by demonstrating linear deposition of immunoglobulin (Ig) G along the basement membrane of the lung or kidney and the presence of high titers of circulating anti–basement membrane antibody in the blood. Antibodies from patients with traditional Goodpasture's syndrome react with the α_3(IV) chain of type IV collagen. Although Goodpasture's syndrome is typically associated with IgG, there are also reports of a pulmonary-renal hemorrhagic syndrome associated with IgA [56]. The importance of this observation is that the immunoserologic testing must be designed to include both immunoglobulins [56]. Goodpasture's syndrome can also be mimicked by fibrillary glomerulonephritis [57].

Definitive diagnosis of the pulmonary vasculitides depends on histologic examination, including special stains and cultures that rule out tuberculosis and fungal diseases. Pulmonary capillaritis with hemorrhage has been reported in an ever-increasing number of conditions [27–31]. The diagnosis can sometimes be made on transbronchial biopsy, thus avoiding the need for open lung biopsy [30], but care must be taken to exclude infectious etiologies by using special stains. Antineutrophil cytoplasmic autoantibodies are helpful in diagnosing Wegener's granulomatosis and following disease activity [58]. The complete evaluation of Wegener's granulomatosis, SLE, and mixed cryoglobulinemia is reviewed in Chapters 193 and 196. The diagnostic features of polyarteritis nodosa, the hypersensitivity vasculitides, giant cell and Takayasu's arteritis, and Behçet's disease are also presented in detail in Chapter 196. In all of these, pulmonary involvement is rare. Several cases of Henoch-Schönlein syndrome, one of the hypersensitivity vasculitides, have been reported with severe alveolar hemorrhage, including one in which immunofluorescent stains of the lung revealed granular deposits of IgA consistent with an immune complex mediation [59]. Alveolar hemorrhage has also been reported with Behçet's syndrome [60]. Giant cell arteritis involvement of the lung is suggested by upper respiratory tract symptoms of sore throat and hoarseness [61].

Although high levels of IgG, IgA, and IgM antibody to trimellitic-coupled protein and trimellitic-conjugated erythrocytes have been found in patients with trimellitic anhydride-induced pulmonary disease [38,39], the diagnosis can be made clinically by obtaining a history of the exposure and ruling out other diseases (Table 53.2).

It is important to be aware that diseases may be considered and therefore evaluated in more than one category. For instance, a patient with hemoptysis due to overzealous antithrombotic therapy may be evaluated in three categories: (a) a hematologic disorder that may cause, (b) localized, and (c) diffuse parenchymal disease. A patient with chronic bleeding from the tracheobronchial disorder of diffuse bronchial telangiectasis could present with diffuse as well as localized parenchymal disease (aspiration hemosiderosis). A patient with long-standing passive congestion of the lungs, a cardiovascular disorder, might present with diffuse pulmonary hemosiderosis, whereas a patient with acute pulmonary edema usually presents with diffuse pulmonary infiltrates.

DIFFERENTIAL DIAGNOSIS

In evaluating patients with hemoptysis, it is necessary to rule out the causes of pseudohemoptysis. Features that can help to differentiate the causes of pseudohemoptysis from one another and pseudohemoptysis from true hemoptysis are found in Table 53.1 (see Chapter 146 for an in-depth discussion of epistaxis). In addition to history and routine physical examination, it is important to perform a meticulous examination of the nose and entire pharynx, preferably with a nasopharyngoscope. Unless the cause of pseudohemoptysis is definitively determined, the spitting up of blood must be assumed to be true hemoptysis. An upper-airway lesion must not be assumed to be the cause of the bleeding unless it is seen bleeding actively at the time of examination.

TREATMENT

The treatment of hemoptysis can be divided into supportive and definitive categories. In prescribing definitive therapy, it is important to consider the cause, the amount of bleeding, and the patient's underlying lung function.

Supportive Care

Supportive care usually includes bed rest and mild sedation. Drugs with antitussive effects (e.g., all narcotics) should not be used. An effective cough may be necessary to clear blood from the airways and avoid asphyxiation. Drugs with antiplatelet effects also should not be used. Depending on the results of pulse oximetry or arterial blood gas analysis, supplemental oxygen should be given. If bleeding continues and gas exchange becomes further compromised, endotracheal intubation and mechanical ventilation may become necessary. To facilitate flexible bronchoscopy with a sufficiently large suction port, an endotracheal tube with an internal diameter of 8 mm or greater should be used, if possible. Other respiratory adjunctive therapy, such as chest physiotherapy and postural drainage [62], should be avoided. Fluid and blood resuscitation should be given when indicated.

The amount of hemoptysis should be continuously quantitated until it stops. The amount helps determine the patient's subsequent care.

Definitive Care

Nonmassive Hemoptysis

In patients with scant or frank (submassive) hemoptysis, treatment is directed at the specific cause. For instance, suppurative bronchiectasis is treated with antibiotics plus a mucociliary escalator drug (e.g., theophylline [63], β-adrenergic agonists).

Chronic bronchitis associated with cigarette smoking is treated with a mucociliary escalator and cessation of cigarette smoking. Broad-spectrum antibiotic therapy should be considered if hemoptysis occurs in the context of an acute exacerbation of chronic bronchitis. In severe exacerbations in ICU patients, Gram-negative enteric rods, *Pseudomonas aeruginosa*, *Stenotrophomonas maltophilia*, and penicillin-resistant *Streptococcus pneumoniae* may be playing a role approximately 30% of the time [64]. Cystic fibrosis is treated with appropriate antibiotics to cover the likely pathogens [65], plus a mucociliary escalator. Bronchial adenoma and bronchogenic carcinoma should be resected whenever possible. Recently, radiofrequency ablation has been used in stages III and IV non–small cell lung cancer for palliation of hemoptysis, cough, and pain, as reduction in tumor volume can lead to symptomatic improvement. However, hemoptysis has been reported as a complication of radiofrequency ablation in 0% to 12% of cases [66]. Congestive heart failure is treated with combinations of drugs for preload and afterload reductions, mitral stenosis with diuretics, and pulmonary embolism with anticoagulation. There are no data showing that patients with hemoptysis due to pulmonary embolism bleed more with anticoagulation. Therefore, do not initially withhold treatment or undertreat these patients with nonmassive hemoptysis. The effects of overzealous anticoagulation are treated with cessation of blood thinning and perhaps fresh-frozen plasma and vitamin K. Tuberculosis is treated with antituberculous drugs (see Chapter 87). Appropriate antibiotic therapy is prescribed for acute infectious pneumonias (see Chapter 68).

Massive Hemoptysis

In patients with massive hemoptysis, treatment is directed not only at the specific cause but also at abrupt cessation of bleeding. Death from massive hemoptysis is predominantly due to asphyxiation, and the likelihood of death appears directly related to the rate of bleeding [1]. Urgent management in all cases of massive hemoptysis must emphasize protecting the uninvolved lung from aspiration of blood and tamponading the bleeding site.

When tracheoartery fistula may be present, the following steps should be considered. If bleeding is immediate and profuse, there may be time only to overinflate the balloon, tamponading the potential bleeding site at the balloon, and apply downward and forward pressure on the top of the tracheostomy tube, tamponading the potential bleeding site at the stoma. If the arterial rupture is at the cannula tip, these efforts are not helpful. If bleeding stops or slows down either by these efforts or spontaneously, an endotracheal tube should be placed distal to the tip of the tracheostomy tube and a surgical consultation requested immediately. Ideally, a surgeon should be present when the tracheostomy tube is removed; should crisp bleeding start again, the surgeon can attempt to finger-tamponade/compress the bleeding artery (usually the innominate) by bluntly dissecting down the anterior tracheal wall and behind the sternum to the vessel. The vessel, once reached, can be compressed against the back of the sternum [13]. When the situation has been stabilized, clots can be gently suctioned from the distal trachea and the patient taken to the operating room for definitive repair. A review of the definitive surgical options can be found elsewhere [13].

When bleeding originates from below the primary carina, the bleeding lung should be kept dependent to minimize aspiration of expectorated blood. Numerous techniques have been advocated to help minimize aspiration and have proved helpful. A bronchoscopically positioned endobronchial balloon may provide effective tamponade. Hemoptysis due to bleeding from all lobes except the right upper lobe, because of the acute angle takeoff, has been managed with balloon occlusion [67]. This technique involves positioning a balloon to completely occlude a bronchus, thus allowing the lung to collapse distally. Small-caliber catheters with balloons can be inserted in segmental airways with bronchoscopy. Placement of a double-lumen endotracheal tube, which intubates each mainstem bronchus separately, is helpful, but the tubes can be difficult to place, and once in position, their small diameter may prevent subsequent diagnostic flexible bronchoscopy. In cases of persistent massive hemoptysis, diagnostic considerations may need to be delayed because placement of a double-lumen endotracheal tube may be necessary to ensure patient survival.

Urgent treatment to stop massive hemoptysis may involve laser bronchoscopy, iced saline lavage, angiographic embolization, supportive treatment only, or surgical resection. Use of laser to stop hemoptysis can be successful in patients with cancer, but recurrence of bleeding within a few weeks is typical. No large studies of patients with massive hemoptysis have been reported. Because laser is useful only in patients with proximal airway lesions and is difficult to use during massive hemoptysis, laser therapy will probably not evolve into a common therapeutic tool for these patients [67].

Bronchoscopically directed iced-saline lavage of the bronchi leading to the site of hemorrhage has been reported to be successful in stopping hemorrhage in an uncontrolled series [67]. In addition, in a small number of patients, bronchoscopy-guided topical hemostatic therapy using oxidized regenerated cellulose has been successful in controlling life-threatening hemoptysis [68].

Angiography can identify the bleeding site in more than 90% of cases [19,52], and, when combined with an embolization procedure, has been successful in initially stopping bleeding in massive hemoptysis in 77% to 95% of cases [69]. Several angiographic sessions may be required, and systemic and pulmonary vessels may need to be studied. Approximately 16% of patients bleed again within 1 to 4 days, and multiple procedures are frequently necessary [19,70,71]. Once active bleeding ceases, 20% of patients bleed again during the next 6 months [72] and 22% of patients by 3 to 5 years [19]. More recent studies have shown similar results [69]. Angiographic embolization has been achieved with the use of polyurethane particles, polyvinyl alcohol particles, and steel coils. Sclerosing agents have led to subsequent massive lung necrosis and should be avoided [19]. Although early studies included several cases complicated by accidental embolization of the spinal artery, the prevalence is less than 1% and occurs when the spinal artery arises from the bronchial artery [70]. Other complications, such as pleurisy or hematoma formation, are infrequent and usually minor [19].

In patients with hemoptysis due to trauma, urgent thoracotomy has been advocated, with the recommendation that it is performed with the patient in the supine position to minimize aspiration, and that the bronchovascular trunk of the involved lung is clamped while the patient is stabilized to minimize the chance of air embolism while on positive-pressure ventilation [73].

Survival from iatrogenic rupture of the pulmonary artery has been reported. Several urgent maneuvers may prove helpful, and balloon tamponade and selective intubation should always be attempted. Balloon tamponade of the ruptured vessel with the Swan-Ganz balloon has been helpful [74]. With the balloon deflated, the catheter should be withdrawn 5 cm and the balloon inflated with 2 mL of air and allowed to float back into the hemorrhaging vessel to occlude it. Ideally, patients should immediately be intubated in the mainstem bronchus opposite the involved lung to minimize aspiration. In most patients, death from pulmonary artery rupture occurs before the bleeding lung can be identified. Because the catheter usually floats to the right pulmonary artery, when it is not known which pulmonary artery has been ruptured, selective intubation

of the left mainstem bronchus or placement of a double-lumen endotracheal tube should be attempted. Selective intubation of the left mainstem bronchus can be facilitated by using a bronchoscope or suction catheter designed specifically to enter the left lung. All patients who stop bleeding require angiographic evaluation to help localize the arterial tear and check for the formation of a pseudoaneurysm [12]. At the time of angiography, embolization of the affected vessel should be performed if a pseudoaneurysm or a tear is found. Hemoptysis from a pseudoaneurysm usually occurs in the first day after formation but may occur weeks later [11,12].

The role of emergency surgery for hemoptysis has changed during the past 20 years since the first report of bronchial artery embolization. Bronchial artery embolization has increasingly become first-line treatment for control of massive hemoptysis [74]. Nonetheless, surgery remains the procedure of choice when massive hemoptysis is due to arteriovenous malformations, leaky aortic aneurysm, hydatid cyst, iatrogenic pulmonary rupture, chest trauma, bronchial adenoma, and fungal balls resistant to medical therapy [70].

In patients with cystic fibrosis, even with normal lung function, resection should be avoided because repeated episodes in other areas are likely to occur. A patient with a 1-second forced expiratory volume of less than 2 L or a maximum voluntary ventilation of less than 50% of predicted should not undergo surgery unless split-lung function studies reveal that the patient is not likely to be left a respiratory cripple due to disabling dyspnea.

With respect to surgery, it is clear that no treatment preference can be recommended for all patients on the basis of reported studies. The trials of therapy span different decades of practice, have widely differing causes of hemoptysis in their populations, and use several different definitions for massive hemoptysis. A review of the literature suggests the following strategy: (a) patients who are not candidates for surgery because of their pulmonary function, general medical condition, or diffuse nature of their lesions should be treated with selective embolization; (b) resectional surgery should be performed in operable patients when surgery is the definitive treatment for the underlying disease; and (c) all potentially operable patients who continue to bleed at rates of more than 1 L per day despite supportive, conservative care and subsequent embolization should undergo surgical resection. The correct therapy in a given patient depends on the cause of the bleeding, lung function, availability of resources, and local expertise.

In patients with diffuse intrapulmonary hemorrhage, selective arterial embolization and surgery are not options. Recombinant factor VIIa has been used successfully for treatment of diffuse alveolar hemorrhage due to disseminated aspergillosis, bone marrow transplantation, small-vessel vasculitis, and cystic fibrosis [75,76]. For immunologically mediated diseases, corticosteroids, cytotoxic agents, and other interventions (e.g., plasmapheresis in Goodpasture's syndrome) are available (see Chapter 196).

When corticosteroid therapy is given alone for critically ill patients with immunologic lung diseases, the dose is 1 mg per kg per day of intravenous methylprednisolone or the equivalent dose of another corticosteroid. Larger doses, on the order of 7 to 15 mg per kg per day for 1 to 3 days, have been recommended to control progressive pulmonary hemorrhage and hypoxemia of Goodpasture's syndrome, SLE, and the vasculitides (see Chapter 193 and 196) [42]. In general, corticosteroids should be administered initially in round-the-clock divided doses until substantial improvement has occurred. They can then be given once per day and tapered as the patient's condition dictates.

When combined corticosteroid and cytotoxic drug therapy is given, it is usually prescribed for immunologic lung diseases due to the vasculitides (e.g., Wegener's granulomatosis, rheumatoid vasculitis) and Goodpasture's syndrome. For details regarding specific therapy for these conditions, see Chapters 193 and 196.

CHAPTER 54 ■ ASPIRATION

KIMBERLY A. ROBINSON AND RICHARD S. IRWIN

Aspiration is defined in *Webster's New Universal Unabridged Dictionary* as inhaling fluid or a foreign body into the bronchi and lungs [1]. The foreign material may be particulate matter, irritating fluids (e.g., HCl, mineral oil, animal fat), or oropharyngeal secretions containing infectious agents. Although infectious pneumonias can be caused by inhaling air-containing organisms (e.g., infectious aerosols), aspiration of oropharyngeal contents or regurgitated gastric material is the primary manner in which bacterial pathogens are introduced into the lower respiratory tract. In fact, studies indicate that 5% to 15% of cases of community-acquired pneumonia are aspiration pneumonia [2]. The medical literature is not as precise, however, in defining aspiration-induced pulmonary injury or diagnosing its occurrence. For instance, the term *aspiration pneumonia* strongly denotes infectious sequelae to the aspiration event. However, there is a wide spectrum of conditions that result from aspirating foreign matter with varying clinical courses, not all of which are caused by infection [3–5]. It is difficult to predict exactly which course a patient will follow after an event. Although aspiration of a large volume of sterile gastric contents will likely lead to a chemical pneumonitis, aspiration of contaminated gastric contents will more likely

TABLE 54.1

Diffuse aspiration bronchiolitis
Tracheobronchitis
Tracheoesophageal fistula
Chronic persistent cough
Bronchorrhea
Drowning

result in an infectious pneumonia. Although the frequency of all clinically significant aspirations in the intensive care unit (ICU) setting is not known, a review of Table 54.1 suggests that aspiration syndromes are common causes of pulmonary disease in the critically ill patient. An in-depth discussion of drowning can be found in Chapter 54.

NORMAL DEFENSES AGAINST ASPIRATION AND THE MANNER IN WHICH THEY MAY FAIL

Pathogenesis

Syndromes caused by aspiration are determined by (a) the material aspirated, (b) the amount aspirated, and (c) the state of the patient's defenses at the time of the event. An understanding of the normal defenses and how and when they become impaired is also the cornerstone for an understanding of the pathogenesis of the various aspiration syndromes.

Because gastric acid prevents bacterial growth, the gastric contents are sterile under normal conditions [6]. Nevertheless, it has long been thought that the pH of aspirated contents determined the clinical course, with lower pH aspirates portending a worse outcome. Elevation of gastric pH to protect the lung was cited as one reason to use prophylactic antacids in the critically ill patient. However, colonization of the stomach by pathogenic organisms may occur when the gastric pH is artificially elevated [7,8]. Therefore, routine intratracheal instillation of prophylactic antacids to minimize aspiration-related lung injury is not recommended. There is conflicting data as to whether or not proton pump inhibitors and H2 blockers increase the risk of pneumonia [9,10]. Continued use of prophylactic acid suppression to prevent gastric bleeding and ulceration is another issue entirely and is discussed in Chapter 92.

Upper Gastrointestinal Defenses

Gastrointestinal mechanisms normally work in a coordinated, synchronized fashion. The teeth break up large food particles, and the tongue propels fluid and masticated food into the hypopharynx. As the hypopharyngeal muscles prepare to move food into the esophagus, the epiglottis covers the laryngeal inlet and the vocal cords close and the upper esophageal sphincter (cricopharyngeus muscle) relaxes. Pharyngeal swallowing initiates primary peristaltic waves in the esophagus that carry fluid and food through a relaxed lower esophageal sphincter (LES) into the stomach. After the bolus enters the stomach, the LES then contracts and prevents, although not entirely, gastroesophageal reflux (GER).

Even in the absence of known trauma or neurologic insult that could affect the swallowing cascade, some of the previously mentioned defenses may become impaired with increasing age or during sleep leading to silent aspiration. The vocal cords close much more slowly after the age of 50 years and may not close at all during sleep or with sedation irrespective of age. Furthermore, the cough response to airway irritation is also decreased during sleep compared with the waking state and may be totally absent during rapid eye movement sleep. In fact, it has been estimated that half of all healthy adults aspirate oropharyngeal secretions during sleep [3].

The risk of aspirating fluid and food is increased when the normal swallowing and upper gastrointestinal mechanisms fail to work in a coordinated, synchronized manner. Failure to adequately masticate one's food, such as in the edentulous or sedated patient, establishes a high risk for aspiration [11]. Aspiration also may occur when the bolus cannot readily be cleared from the pharynx owing to neuromuscular disorders of any cause [12–15]. Structural abnormalities like Zenker's diverticulum places a patient at risk of aspiration because the diverticulum may empty "late" after the swallowing effort is completed, at the time when the vocal cords are abducted. Conditions in which vocal cord closure becomes excessively delayed (e.g., old age, debilitation, sedation, the presence of a tracheostomy, and after endotracheal extubation) place patients at high risk for aspiration.

Regurgitation and subsequent aspiration of stomach contents also occur in elderly, sedated, or sleeping patients, especially when their upper esophageal sphincter and LES have been rendered incompetent by an oral or nasogastric tube [16,17]. The risk of aspiration is enhanced when such a patient remains in the supine position [18], a scenario often encountered in the ICU setting.

Respiratory Defenses

For infectious agents to enter the lower respiratory tract (e.g., below the vocal cords), they must first escape aerodynamic filtration in the nose, mouth, and larynx. Particles larger than 10 μm in diameter never reach the lower respiratory tract because they are filtered out of the airstream in the upper airway. Particles between 2 and 10 μm in diameter can reach the airways, and those between 0.5 and 1.5 μm in diameter can reach the alveoli. This is particularly relevant as most bacteria are within this size range. Although mucociliary clearance removes the larger particles [19] from the larger airways, additional defense mechanisms are needed to clear the smaller particles. This is accomplished in respiratory bronchioles and alveoli primarily by the alveolar macrophages, aided by neutrophils [20]. Infectious agents are detoxified by lysozymes as part of the cellular clearance mechanism [21]. Enzymes secreted by alveolar macrophages, neutrophils, and proteases in mucus also contribute to the detoxification process.

The first line of defense is mucociliary clearance. The respiratory filtration system and mucociliary clearance may become overwhelmed with large-volume fluid and food aspiration or with large amounts of inhaled infectious agents. Respiratory defenses may also become ineffective in the following settings: inhalational or systemic general anesthesia, endotracheal intubation, endotracheal suctioning, hypercapnia and hyperoxia, smoking, asthma, chronic bronchitis, cystic fibrosis and bronchiectasis, and respiratory infections with viruses and *Mycoplasma pneumoniae*.

In the absence of mucociliary clearance, the airways can still be cleared of excessive secretions and foreign bodies if the patient has an effective cough [19]. However, cough is not a primary defense mechanism and only provides clearance when mucociliary clearance is inefficient or overwhelmed. An effective cough and rapid closure of the vocal cords might also limit the consequences of GER of gastric contents to a chemical laryngitis. Alternatively, an effective cough with slow closure of the vocal cords might limit the inhalational injury to a chemical tracheobronchitis. An effective cough is determined both by good expiratory flow rates and respiratory muscle strength [22]. Thus, cough may be ineffective in patients with severe asthma, chronic obstructive pulmonary disease, respiratory neuromuscular disorders, painful incisions, or in those receiving excessive sedation and analgesia with antitussive effects.

When the mechanical defenses are overwhelmed, alveolar macrophages represent the initial phagocytic response. These cells also trigger additional inflammatory and immune responses by secreting cytokines. This response is followed by the influx of neutrophils into the alveolar spaces. Neutrophils are critical for the eradication of bacterial agents and therefore any impairment in their function would be detrimental [20]. Aspirated bacteria cause infectious pneumonia when the alveolar phagocytes become impaired, such as in alcoholism, pH less than 7.2, acute alveolar hypoxia, alveolar hyperoxia, corticosteroid therapy, respiratory viral infections, hypothermia, starvation, and exposures to nitrogen dioxide, sulfur dioxide, ozone, and cigarette smoking on a long-term basis [3].

Immunologic defenses such as complement and immunoglobulins augment the nonimmunologic mechanisms previously mentioned by opsonizing bacteria for the alveolar phagocytes [23,24]. Although the role of immunologic defenses against infectious particles is sketchy, it is believed that they are important in augmenting and occasionally directing the alveolar phagocytes. For instance, patients with hereditary and acquired immunologic abnormalities, such as immunoglobulin G and complement deficiencies, are susceptible to frequent and often severe bacterial pneumonias. For a more complete list of references for this section, please refer to the previous edition of this chapter published in *Irwin and Rippe's Intensive Care Medicine*, sixth Edition [3].

PREVALENCE OF ASPIRATION IN THE CRITICALLY ILL

Aspiration should be considered in all ICU patients with a pulmonary problem. This is especially true for the elderly, debilitated, or sedated patient with unexplained deterioration in pulmonary status. Oral or nasal enteral feeding tubes that compromise the LES, anticholinergics that decrease gastric motility, history of dysphagia, and neck hyperextension increase the probability. The presence of an endotracheal tube or tracheostomy tube poses a high risk for aspiration and its consequences.

Translaryngeal Intubation

Clearly, no one to feed a patient with an oral or nasal endotracheal tube in place, given the obvious mechanical barrier and distortion of the swallowing structures. What is often less intuitive is that dysphagia may persist for a variable time after the endotracheal tube has been removed. It has been suggested that the swallowing reflex can be impaired for up to 48 hours after short-term extubation, but gradually improves within a week [25]. Recent data suggest that the addition of routine flexible endoscopic evaluation of swallowing (FEES) aids in the identification of patients who are at high risk of aspirating after endotracheal intubation [26–29]. Awake, postsurgical patients who were intubated for less than 28 hours for coronary artery bypass were evaluated for aspiration. Of the 24 patients examined immediately after extubation, 50% aspirated, whereas 25% and 5% aspirated when tested 4 and 8 hours, respectively, after extubation. Patients who were intubated for a longer duration of, on average, 6.3 ± 3.1 days also demonstrated a high incidence of aspiration when evaluated 2 to 3 days after extubation [30]. Twelve of the 22 patients aspirated when evaluated by modified barium swallow/video fluoroscopy (MBS/VF).

The basis of aspiration in patients who had translaryngeal intubation can be partially explained by well-documented changes of laryngeal and pharyngeal structure and function after extubation. Impaired laryngeal elevation, penetration, and pooling in the valleculae and pyriform sinuses can be witnessed on MBS/VF. Direct laryngoscopy revealed varying degrees of laryngeal edema in 94% of patients, in which 64% took up to 4 weeks to resolve [31]. Edema of the arytenoids, inflammation of the posterior aryepiglottic folds, and false vocal cords have also been described when evaluated 24 hours after decannulation [3]. Should aspiration occur, ciliary clearance and other respiratory defenses might not respond appropriately due to the physical insult of the endotracheal tube.

Tracheostomy Intubation

Patients with a tracheostomy tube, with or without dependence on mechanical ventilation, are also at high risk for aspiration. The tracheostomy tube interferes with proper laryngeal elevation that is necessary for effective glottic closure during swallowing [32], and an inflated cuff can compress neighboring swallowing structures, most notably the esophagus. Bronchoscopic evaluation of patients with chronic tracheostomy tubes often reveals laryngeal, pharyngeal, and subglottic edema, presumably owing to the irritation of pooled secretions. These anatomic changes may exacerbate dysphagia. In one study, despite a normal clinical bedside evaluation, a high clinical suspicion for aspiration prompted an MBS/VF examination, in which 63% of a selected group silently aspirated [33]. Another study evaluating the outcome of an MBS/VF examination of patients with chronic tracheostomies discovered that 50% aspirated, and 77% of the aspiration events were silent. These studies stress that bedside evaluation alone is insufficient to diagnose aspiration in these high-risk patients.

Enteral Feeding Catheters

Many patients in an ICU have nasal or oral gastric tubes for nutritional support. The mere presence of an oro- or nasogastric feeding tube increases the risk of reflux and aspiration by compromising the integrity and proper functioning of the LES by two mechanisms. First, the catheter prevents closure of the sphincter by direct mechanical interference. Second, the irritation of the pharynx by the tube promotes LES relaxation through vagally mediated pharyngeal mechanoreceptors [34]. In addition, the presence of a nasogastric feeding tube is associated with Gram-negative bacterial contamination of the oropharynx, which, when aspirated, can result in severe clinical deterioration [35].

Varying the size of the enteral feeding catheters and adjusting the location of the distal tip have been used in an attempt to minimize aspiration. However, decreasing the size of a nasal or oral tube for enteral feeding does not reduce GER or microaspiration events [36]. Small-bore feeding tubes appear to provide no added benefit with respect to reflux events, even when advanced to the postpylorus position [17,37]. Patients

with long-standing swallowing defects or on prolonged mechanical ventilation may be candidates for percutaneous gastrostomy or jejunostomy tubes; however, even percutaneous enteral feeding tubes alter lower esophageal tone and allow for reflux [38]. This manner of enteral feeding is not completely protective against aspiration despite bypassing the LES. In fact, patients fed by gastrostomy tubes have the same incidence of pneumonia as those fed by nasogastric tubes [39,40]. However, early gastrostomy may reduce the frequency of ventilator-associated pneumonia as compared with nasogastric tubes in stroke or head injury patients [41]. Feeding tubes offer no protection against colonized oral secretion or aspiration of gastric contents that, in the presence of tube feeds, have an increased pH and are often colonized with bacteria. Furthermore, although a percutaneous jejunostomy tube may minimize the large-volume aspiration events, it is a misconception that it prevents aspiration or decreases its incidence relative to a percutaneous gastrostomy tube [42].

Although there is little agreement over what constitutes excessive gastric residual volumes that place a patient on enteral feeds at increased risk of aspiration, some authors cite 200 mL for nasogastric tubes and 100 mL with percutaneous gastrostomy tubes [43]. If life-threatening aspiration events continue to occur, it may become necessary to consider performing a tracheostomy and close off the laryngeal inlet with a purse-string suture in nonverbal patients who enjoy eating by mouth.

TABLE 54.2

MODALITIES FOR DIAGNOSING ASPIRATION SYNDROMES[a]

History
Physical examination
Baseline examination
Observation of patient drinking water
Chest radiographs
Lower respiratory studies
Expectorated samples
Bronchoscopy
Protected specimen brush with quantitative cultures
Bronchoalveolar lavage
Lung biopsy
Upper gastrointestinal studies
Contrast films
Endoscopy
Esophageal manometry
GE scintiscan
24-Hour esophageal pH/impedance monitoring
Speech and swallow evaluation
FEES or modified barium swallow/video fluoroscopy

[a]The order of when and in whom to order these tests will depend on the patient populations and their presentations.
FEES, flexible endoscopic evaluation of swallowing; GE, gastroesophageal.

DIAGNOSIS OF AN ASPIRATION SYNDROME

Aspiration syndromes are underdiagnosed. Failure to make the diagnosis probably stems from the glut of articles in the 1970s, stressing the importance of anaerobic aspiration infections. In addition, diagnostic failures may be ascribed to a widespread tendency to consider only infectious pulmonary complications of aspiration, an overreliance on inaccurate sputum sampling techniques such as expectorated sputum, and the misconception that aspiration must be witnessed before it can be assumed to have occurred.

Bedside Evaluation

Table 54.2 outlines all the studies that may be necessary to diagnose aspiration syndromes accurately (see "Differential Diagnosis and Treatment" section). In addition to taking a history and performing a physical examination, the physician should watch the patient swallow from a glass of water, when appropriate, to uncover an obvious swallowing problem. Although the bedside evaluation is not sensitive, a pharyngeal problem may be evident by watching the patient cough, sputter, and tilt his or her neck and head in an unnatural posture.

Gag Reflex

Although the gag reflex is frequently assessed in clinical practice to predict the adequacy of swallowing and mental alertness, and by inference the potential risk of aspiration, theoretical considerations and the paucity of studies do not support this practice [44–46]. It should not be assumed that testing for an intact gag reflex helps assess swallowing for the following reasons: (a) the stimuli and the neuromuscular processes involved in gagging and swallowing are in opposite directions, (b) the normal stimulus for swallowing food does not normally stimulate gagging, (c) many healthy individuals who do not have a gag reflex can swallow normally, and (d) there are no studies that show that the presence or absence of a gag can predict adequacy of swallowing. In support of this viewpoint, 11 patents without prior neurologic disorders were examined for swallowing safety with an MBS/VF examination after prolonged translaryngeal intubation [47]. Although more than half had an intact gag, swallowing dysfunction was seen in all and frank aspiration in 25% of patents.

Modified Barium Swallow/Video Fluoroscopy

Although observing patients can be useful when there is obvious difficulty during swallowing, aspiration is often silent in the critically ill patient. The incidence of silent aspiration in stable patients receiving long-term mechanical ventilation via a tracheostomy is high, between 63% and 77%, as determined by MBS/VF [33,48]. Therefore, bedside evaluation alone, particularly in these high-risk populations, is insensitive; a negative bedside examination should be confirmed by a more objective method to evaluate aspiration.

Currently, the MBS/VF study remains the gold standard in the evaluation of possible aspiration because it defines the pharyngeal anatomy with swallowing of a radiopaque contrast material, and the swallowed bolus is followed in "real time" under fluoroscopy. Findings indicative of swallowing dysfunction that can be assessed by MBS/VF examination include premature leakage of oral contents into the pharynx, penetration of swallowed material into the nasopharynx during a swallow, retention of material in the valleculae and pyriform recesses, and laryngeal penetration and aspiration [49]. Also, the elevation and tilting of the larynx that accompanies a normal swallow can be observed easily. Lower esophageal diseases, such as reflux or obstruction, can also be observed with the MBS/VF study. Various consistencies of barium are used in this MBS/VF

evaluation, such as thin liquids, paste consistency, and solid food.

The MBS/VF examination, however, has multiple limitations. MBS/VF is personnel-intensive, requires transporting patients to the radiology department, and exposes patients to radiation. In addition, patients must adhere to a defined body position to accommodate the fixed fluoroscopy setup, which may not be possible for all patients. MBS/VF requires the delivery of barium-covered food or liquid to evaluate proper swallowing function and cannot evaluate a "dry swallow." Thus, aspiration and resulting deterioration may occur as a consequence of the examination itself.

Ideally, a speech and swallowing evaluation should be ordered whenever a patient is undergoing an MBS/VF examination so that a speech pathologist can accompany the patient to the examination. Then, specific recommendations can be made to prevent or minimize aspiration. Recommendations may consist of eliminating oral feeding or instituting various swallowing strategies such as the chin tuck, multiple swallows, turning of the head, or changing the consistency of solids and liquids.

Flexible Endoscopic Evaluation of Swallowing

Evaluation of swallowing under flexible endoscopic visualization has been shown to be sensitive in discerning a delay in swallowing initiation, penetration, aspiration, and pharyngeal residue [29,50–53]. The potential advantages include reduced cost and decreasing waiting time as compared with an MBS/VF evaluation. Patients avoid radiation exposure, and the examination can be performed at the bedside in varying body positions. FEES also allows visualization of pharyngeal secretions as well as identifying the source of the secretions that cannot be seen during MBS/VF. Potential risks associated with the procedure include gagging, laryngospasm, vasovagal syncope, topical anesthetic adverse reactions, and epistaxis [50]. Furthermore, esophageal pathology and reflux cannot be concurrently evaluated as in MBS/VF.

FEES has now been extensively used in medical and surgical inpatients and, more specifically, in recently extubated ICU patients [26,54]. In 2001, the Evidence-Based Practice Center published data with regard to prevention of pneumonia in stroke patients [55]. In a long-term care facility, when FEES was used to evaluate for and manage dysphagia, there were no cases of aspiration pneumonia. There were 11 cases of pneumonia documented in those patients who did not undergo FEES during the 6-month study period [55]. Concurrent evaluation by FEES and MBS/VF has demonstrated that FEES is as sensitive, if not more so, as MBS/VF. Therefore, it may be a useful diagnostic adjunct in selected immobile ICU patients.

Culture Evaluation

Even when history or physical examination uncovers a swallowing defect, determining that an aspiration event has already occurred may also prove challenging. Furthermore, an infectious process is not always established with each aspiration event. It is often difficult to distinguish between an inflammatory or "chemical" pneumonitis and an infection because both may present with fever, cough, and an infiltrate on a chest radiograph. If an infection is suspected, identification of the responsible organism is oftentimes elusive because routine expectorated sputum smears and cultures are inaccurate. Specimens obtained from quantitative bronchoalveolar lavage or telescoping plugged catheters at bronchoscopy can help to identify the lower respiratory tract infectious agent more accurately and are used preferentially, although they require an invasive procedure and moderate sedation. When accurate lower respiratory sampling techniques are used and the culture and smear results are negative, in a patient who has not recently received antibiotics, an exogenous lipoid pneumonia or chemical pneumonitis must be considered [56].

Detection of Aspirated Enteral Feeds

With respect to bedside methods for detecting aspiration in tube-fed patients, two methods have predominated, neither test is sufficiently sensitive to be recommended and both are problematic. In the first, blue food coloring or methylene blue is added to enteral feeds and the tracheal secretions are assessed for blue discoloration. Potential problems with this method include tissue absorption of the dye as well as increased risk of infection if the dye is contaminated. The second method tests tracheal secretions with glucose oxidase reagent strips for aspirated carbohydrates. The glucose method is nonspecific because varying concentrations of glucose have been recovered from tracheal secretions in nonfed, parenterally fed, and enterally fed patients. [57]. Therefore, the glucose test lacks specificity.

DIFFERENTIAL DIAGNOSIS AND TREATMENT

Treatment of the various aspiration syndromes should be prophylactic as well as specific. As previously mentioned, a formal speech and swallowing evaluation should be obtained whenever a swallowing condition is suspected or diagnosed. Specific recommendations can often be made to mitigate or eliminate aspiration from dysphagia. Precautionary rather than reactionary measures are likely to be far more effective, with less associated morbidity and mortality. However, the only preventive interventions that have been proven effective in the acute care setting include withholding oral feeding in sedated patients to prevent aspiration [58] and elevating the head of the bed to at least 45 degrees to decrease GER and minimize subsequent aspiration [18].

A tracheoesophageal fistula is a rare complication resulting from injury to the posterior tracheal wall. This can occur from excessive endotracheal tube cuff pressure, direct injury during placement of a percutaneous tracheostomy, or erosion from the tip of a tracheostomy tube. In a mechanically ventilated patient, a tracheoesophageal fistula may present with increased secretions, evidence of aspiration of gastric contents, recurrent pneumonias, a persistent cuff leak, or severe gastric distention. Once a patient is extubated, the most frequent symptom is coughing after swallowing. The diagnosis can be made by bronchoscopy and esophagoscopy, or by computed tomography scan of the mediastinum. Although definitive repair often requires surgical intervention, aspiration can be minimized by placing the cuff of the tracheostomy tube distal to the fistula [59].

Although a cuffed endotracheal tube does not offer complete protection against aspiration, all patients with severely altered consciousness and enteral feeding tubes in place should be prophylactically intubated, whenever possible, for airway protection. Furthermore, once a patient is extubated, oral intake should not be resumed until an MBS/VF or FEES examination demonstrates swallowing competency [48]. Prophylactic antibiotics, corticosteroids [60], postpyloric feeding [42], gastric promotility agents, or gastric acid suppression cannot be routinely recommended at this time to prevent or minimize aspiration [5]. GER disease with aspiration can be treated with a variety of measures, including head-of-the-bed elevation; a high-protein, low-fat antireflux diet; nothing to eat or drink for

2 to 3 hours before recumbency; no snacking between meals; acid suppression; and prokinetic drugs. If these measures fail, surgery with fundoplication may become necessary [58].

Mendelson Syndrome

Mendelson syndrome is synonymous with the acute respiratory distress syndrome [3] owing to the parenchymal inflammatory reaction caused by a large volume of aspirated liquid gastric contents. After an aspiration event, clinical status and radiographic changes progress within the next 24 to 36 hours. Contrary to the general view that gastric aspirates with pH greater than 2.5 are benign, the same syndrome can occur at a pH of 5.9 [61]. Patients who develop this syndrome invariably have a marked disturbance of consciousness, such as sedative drug overdose or general anesthesia that interferes with vocal cord protection. The subsequent clinical course can include death in 30% to 62% of cases. Once liquid gastric content aspiration has occurred and the acute respiratory distress syndrome has supervened, ventilatory and medical strategies appropriate for treating the acute respiratory distress syndrome become the focus of care. Despite their frequent use, parenteral corticosteroids have not been shown to be helpful [3]. Antibiotics are indicated only when the syndrome is complicated by infection.

Foreign Body Aspiration

Aspiration of solid particles causes varying degrees of respiratory obstruction. Most cases occur in children. When foreign bodies are inhaled into the tracheobronchial tree, 38% of patients give a clear diagnostic history, 22% give a history of an acute choking and coughing episode, and 40% complain of cough and dyspnea and are heard to wheeze. Although the chest radiograph may demonstrate the foreign object, atelectasis, or obstructive emphysema, it is normal in 80% of the cases.

Food asphyxiation is obstruction by food of the upper respiratory tract, usually at the level of the hypopharynx. It may occur whenever and wherever people eat, including hospitalized patients. In restaurants, it is called the *café coronary* because it is often mistaken for a heart attack [62]. Food asphyxiation should be suspected in middle-aged or elderly patients with poor dentition or dentures that impair chewing adequately or in those sedated by alcohol or other drugs who attempt to swallow solid food. One key to a large foreign body aspiration that may obstruct the larynx or trachea is that the patient cannot speak. Particles that reach the lower respiratory tract and do not totally obstruct the trachea can be removed by coughing or bronchoscopy. Those that totally obstruct the trachea must be removed immediately by subdiaphragmatic abdominal thrusts and finger sweeps in the unconscious individual and chest thrusts in the markedly obese person and women in advanced stages of pregnancy [63].

Bacterial Pneumonia and Lung Abscess

Although not widely appreciated, most bacterial pneumonias are a consequence of aspiration of oropharyngeal infectious material in association with impairment of lower respiratory tract defenses [64]. Preexisting gingival disease is a prominent risk factor for anaerobic infections. The risk of aspiration pneumonia is lower in edentulous patients and in those who receive aggressive oral care [65]. Community-acquired pneumonia can occur when bacteria colonize the oropharynx prior to aspiration and are unable to be cleared by mucociliary clearance and detoxification by the alveolar phagocytes that have been rendered ineffective. Normal respiratory defenses and mucociliary clearance may be compromised by a preceding viral infection or underlying medical conditions that predispose to a bacterial "superinfection" [23]. Anaerobic pneumonia or lung abscess probably occurs in alcoholics with pyorrhea because an overwhelming number of anaerobes are aspirated [66]. Because cough is suppressed, the aspirate is not readily cleared and airways are temporarily obstructed. Distal to this obstruction, anaerobes may not be killed by alveolar phagocytes that are probably rendered ineffective owing to alcohol and acute local hypoxia. Community-acquired aspirational bacterial pneumonias are most commonly due to *Streptococcus pneumoniae* and other aerobic bacteria and anaerobes [67]. Nosocomial aspiration bacterial pneumonias, in contrast, are most commonly due to facultative, enteric Gram-negative bacilli and *Staphylococcus aureus* in 50% to 75% of cases [68,69]; anaerobes play little to no role at all. The intubated patient is particularly susceptible to aspiration pneumonia because the endotracheal or tracheostomy tube bypasses the aerodynamic filtration protection of the upper respiratory tract and physically hinders mucociliary clearance. The intubated patient who requires a narcotic is at even greater risk because cough is also suppressed.

Once a bacterial pneumonia or lung abscess is suspected, the causative organism(s) should be identified and appropriate antibiotic therapy given (see Chapters 68 and 77). To help prevent future anaerobic infections, periodontal disease must be definitively treated and the alcoholic persuaded to stop drinking.

Chemical Pneumonitis

Reminiscent of a chemical burn, airway and parenchymal injury may develop after an aspiration event that triggers a cascade of inflammatory mediators [5]. Fever, cough, rales, sputum production, hypoxemia, and infiltrates on chest radiograph may all be presenting signs and symptoms that are nonspecific. What distinguishes this syndrome from the other aspiration sequelae, however, is the rapid, self-limited course and clinical resolution over several days without the need for antimicrobial therapy. Infectious aspiration pneumonia may not be a primary event but may develop as a superinfection of aspiration-induced pulmonary injury, depending on the contents of the aspirated material and the patient's underlying clinical condition.

Exogenous Lipoid Pneumonia

Exogenous lipoid pneumonia is the result of aspirating any kind of oil- or fat-based substance. Examples of aspirated fatty substances that have led to an exogenous lipoid pneumonia include mineral oil, animal oil (e.g., cod liver oil, milk products), vegetable oil [70], and formula feedings [71]. Conditions more likely to be complicated by exogenous lipoid pneumonia include pharyngeal swallowing disorders, Zenker's diverticulum, cricopharyngeal achalasia, scleroderma involving the esophagus, epiphrenic diverticulum, esophageal carcinoma, esophageal achalasia, and GER disease [72]. Although patients with exogenous lipoid pneumonia usually do not appear toxic, the clinical presentation occasionally cannot be distinguished from that of acute bacterial pneumonia. The varying clinical presentation depends in part on the type of oil aspirated [70]. Aspiration of mineral oil is less likely to produce a toxic reaction than animal fat.

The important clues to the diagnosis must come from the history, physical examination, and upper gastrointestinal studies. The presence of food particles in a bronchoscopy specimen is diagnostic. Although fat stains performed on unfixed

expectorated sputum, bronchoalveolar lavage specimens, or lung biopsy may reveal numerous lipid-laden alveolar macrophages, this finding only supports the diagnosis of exogenous lipoid pneumonia. Lipid-laden macrophages can also arise from an endogenous source or represent a nonspecific response of the lung to injury [56]. Quantitative cultures obtained with telescoping plugged catheters at bronchoscopy may be needed to rule out a bacterial infection, and lung biopsy may be needed to rule out cancer and to make the appropriate diagnosis. After the diagnosis is made, however, the inciting agent is usually identified with pointed questioning of patient practices.

If not diagnosed promptly, recurrent aspirations of lipid or small amounts of liquid gastric contents, or both, can present as recurrent hemoptysis, recurrent pneumonias, chronic interstitial fibrosis, bronchiolitis, or bronchiectasis [4,70]. Rarely, exogenous lipoid pneumonias are complicated by organisms of the *Mycobacterium fortuitum* complex [73]. Although corticosteroids may be helpful in cases of acute lipid aspiration, acute exogenous lipoid pneumonias usually resolve on their own. The key to therapy is to prevent recurrences. For example, the constipated patient must stop nocturnal mineral oil ingestion.

Tracheobronchitis

Tracheobronchitis must be considered, not only in outpatients with GER and chronic, persistent cough [74] but also in hospitalized patients. Examples of conditions that predispose to an aspiration tracheobronchitis include a debilitated state, the postoperative period, endotracheal intubation, recent extubation, and neuromuscular diseases [3]. Aspiration tracheobronchitis should be suspected in patients with cough, wheeze, and bronchorrhea, defined as expectoration of more than 30 mL of phlegm in 24 hours. Treatment is the same as described previously in "Exogenous Lipoid Pneumonia" section. In general, the bronchorrhea will disappear when oral intake is halted.

CHAPTER 55 ■ DROWNING

NICHOLAS A. SMYRNIOS AND RICHARD S. IRWIN

OVERVIEW

Drowning is the seventh most common cause of unintentional injury death in the United States [1]. In 2005, 3,582 people died from drowning in the United States [2]. The incidence of fatal drowning declined from 2.7 per 100,000 in 1983 to 1.21 per 100,000 in 2005. Drowning is most common in men, children younger than 14 years, Native Americans, and African Americans [2]. The states with the highest drowning rates are Alaska and Mississippi [3]. Statistics on nonfatal drowning are less exact because many nonfatal drowning victims do not seek medical attention. Estimates on the incidence of nonfatal drowning vary widely enough that a definitive statement cannot be made at this time.

The official nomenclature for submersion injuries has changed. Based on the results of a consensus conference held as part of the World Conference on Drowning in 2002, appropriate references to submersion injuries use the terms *fatal drowning* to describe death by submersion in water and *nonfatal drowning* to describe at least temporary survival after respiratory impairment from submersion in water [4]. However, some reports continue to use the terms *drowning* and *near-drowning* as synonyms for fatal drowning and nonfatal drowning, respectively. In addition, the terms *submersion* and *immersion* continue to be used to describe both fatal and nonfatal drowning together.

ETIOLOGY AND PATHOGENESIS

The following are considered risk factors for drowning.

Alcohol

Ethanol use is the major risk factor in submersion accidents. Thirty percent to 70% of drownings are associated with alcohol consumption [5–7]. Alcohol use seems to be an issue in drowned men in particular [8]. Alcoholic beverages reduce the ability to deal with emergency situations by depressing coordination, increasing response time, and decreasing awareness of stimuli. Furthermore, alcohol consumption by a potential rescuer or by the adult responsible for supervising a child in the water can destroy that person's ability to function effectively, often resulting in a double tragedy [7]. In addition, alcohol is

frequently a factor in drownings that result from automobile accidents [9].

Inadequate Adult Supervision

Children die in water because adults do not supervise them well enough. The backyard pool and family bathtub are common sites of pediatric drowning [10–14]. Lack of appropriate precautions and supervision play a major role in most of these cases. Studies have shown lower rates of drowning in areas where swimming pools are required by law to be surrounded by a fence [15,16]. The fence must completely isolate the pool from unsupervised access by children to be effective. Appropriate sign posting in hazardous areas, effective educational programs on the dangers of water recreation, and the presence of lifeguards also minimize risk and improve survival [10,17,18].

Inattentive guardians also contribute to bathtub-related drownings. In one study, all bathtub-related submersions in children younger than 5 years occurred while the child was bathing unattended or with another young child [19]. The use of infant bath seats, while providing some sense of security to parents, may actually predispose to submersion accidents as the child may slip and become trapped by the seat, making it impossible to escape the water [20]. The practice of leaving infants to bathe in the custody of a toddler is inappropriate and should be discouraged [11,12]. Immersion in large industrial buckets used for home cleaning may also make up a substantial percentage of drownings of infants and toddlers [21].

Child Abuse

Unfortunately, submersion injuries in children are sometimes inflicted intentionally. One study indicated that 29% of all nonfatal pediatric drownings in bathtubs were purposely caused to inflict harm on the child. Another 38% of all nonfatal pediatric drownings revealed evidence of severe neglect [22]. In general, these children are younger than average for submersion injuries, and many have signs of previous abuse on close examination.

Seizures

Drowning is 15 to 19 times more common in people with epilepsy than in the general population [23]. In one study, a history of seizure disorder was found in 17 of the 293 cases of drowning that were reviewed [9]. This contrasts with the prevalence of seizures of 6 per 1,000 in the general population. Poor adherence to anticonvulsant regimens often plays a role. Many drownings of epileptic children occur in the bathtub [24]. Seizures that include a tonic component may be the most dangerous to victims. Tonic seizures include a forced exhalation component that increases body density and causes the victim to sink. When the tonic component relaxes, the negative intrathoracic pressure leads to an inhalation that will then be composed of water [25]. The intensity of supervision needed by epileptics in a water environment is frequently underestimated.

Boating Accidents

Of the 710 boating fatalities in the United States in 2006, 70% were due to drowning [2]. Both alcohol intake and failure to use personal flotation devices contributed to these deaths [9,26]. A blood alcohol level of 0.10 g per 100 mL is estimated to increase the risk of death associated with boating by a factor of 10 [6].

Aquatic Sports

Water-related activities produce approximately 140,000 injuries annually. Diving, surfing, and water skiing account for 77% of the 700 spinal cord injuries produced annually by aquatic sports. Diving and sliding headfirst produce the most serious injuries as a result of striking the bottom or side of a shallow body of water [10]. Patients who experience these injuries are at subsequent risk of drowning. In addition, injuries associated with the use of personal watercraft contribute to drowning incidence [27].

Drugs

Centrally acting drugs not only can cloud the sensorium, causing disorientation and inducing sleep, but also impair coordination and reduce the ability to swim. Existing data implicate both legal, therapeutic medications and illegal drugs [9,28].

PATHOPHYSIOLOGY

General Considerations

Two mechanisms produce the major pathologic changes responsible for morbidity in drowning: anoxia and hypothermia.

Anoxia

Most drownings are thought to follow a common pattern [29]. The drowning sequence begins with a period of breath holding because the victim's mouth and nose are below the level of the water. This voluntary breath holding is often followed by an intense laryngospasm that prevents breathing. This laryngospasm is usually due to water present in the pharynx or larynx. This prolonged inability to breathe renders the patient hypoxemic and hypercapnic. The laryngospasm eventually abates, followed by involuntary breaths with aspiration of varying amounts of water. In addition, water may be swallowed that is eventually regurgitated and aspirated. Eventually, the victim becomes unconscious and cardiac arrest occurs.

Hypothermia

The impact of hypothermia is complex. Survival after extremely long submersion is generally considered possible only when the victim has been submerged in icy water. There are reports of survival in children submerged up to 66 minutes [30–32]. Most authors believe that to achieve such spectacular survivals after long submersions, the core body temperature must be reduced quickly and the brain's metabolic activity slowed down in equally rapid fashion to prevent hypoxic damage to the brain. Factors that make this more likely in children include the increased relative body surface area, thin layer of subcutaneous fat, and smaller head size. In addition, children may ventilate water earlier in their submersion, and they may retain more water in the upper airway [33]. These factors may also play a role in rapid cooling.

On the other hand, humans tolerate hypothermia poorly. In the most well-known example, the deaths after the sinking of the *Titanic* occurred not because of inability to float in most cases but because of hypothermia caused by exposure to extremely cold water. Changes in human metabolism in response to hypothermia occur in two phases: the shivering phase and the nonshivering phase. Shivering occurs at a central temperature of 30°C to 35°C. The nonshivering phase occurs below 30°C, when muscle contractions nearly cease and oxygen consumption and metabolic rate decrease.

Shivering and voluntary muscular movements, which in a cold dry environment work together to increase heat production with minimal increase in heat loss, are ineffective in cold water [34]. Both shivering and voluntary muscular movements increase blood flow to the extremities, thereby increasing conductive heat loss. Voluntary movements of the extremities also stir the surrounding water and can increase heat loss from convection [35]. Body type may also play a major role. Obese men tolerate submersion in cold water longer than thin men due to increased insulation from body fat [36]. Water nearly eliminates the insulative function of clothing by replacing the air between the fibers, thereby increasing heat conductance.

Submersion in very cold water can acutely lead to death in three ways. First, a vagally mediated asystolic cardiac arrest may occur (immersion syndrome) [37]. Second, hypothermia produces an increased tendency toward malignant arrhythmias separate from this immediate response. Cardiac arrest from ventricular fibrillation is common at core temperatures below 25°C, and asystole occurs at less than 18°C [38]. These arrhythmias may be refractory to resuscitative efforts until the body temperature has been increased. Third, a decrease in core temperature can cause loss of consciousness and aspiration from the victim's inability to keep the head above water. This leads to aspiration of water and the sequence of events described previously.

Pulmonary Effects

The effects of aspiration of various water solutions on lung injury have been studied in animals [39,40]. Sterile water was found to be the most disruptive of pulmonary function. Normal and hypertonic saline solutions also cause significant increases in $(P_A\text{-}a)O_2$ gradient and shunt fraction, with a decrease in the PaO_2 to FIO_2 ratio. Decreases in arterial oxygen saturation and dynamic compliance as well as increases in minute ventilation, mean pulmonary artery pressure, and shunt fraction are seen in sheep after bilateral aspiration of either fresh- or seawater [40].

On a microscopic level, freshwater and saline solutions may cause their adverse pulmonary effects by different mechanisms. Atelectasis due to increased surface tension, bronchoconstriction, and noncardiogenic pulmonary edema all play a role in the development of hypoxemia at different times after freshwater aspiration [40,41]. Freshwater acts in part by inactivating surfactant in the alveoli and in part by damaging type-II pneumocytes, thereby preventing the production of surfactant for up to 24 hours [42,43]. The combination of these effects may damage the alveolar capillaries and interstitium and lead to the acute respiratory distress syndrome (ARDS). Hypertonic seawater may draw additional fluid from the plasma into the alveoli, thereby causing pulmonary edema despite a decreased intravascular volume [39]. The fluid-filled alveoli are then unavailable for efficient gas transfer, and a ventilation–perfusion mismatch occurs. This fluid may also damage the type-II pneumocytes by hypoxic and osmotic effects [41]. Aspiration of gastric contents and particles in the water complicates both fresh- and saltwater drowning. In clinical practice, the difference in the situation caused by freshwater and saltwater aspirations is small. In both cases, pulmonary edema causes decreased respiratory system compliance and hypoxemia. Unless specific therapies are developed that target the different mechanisms, there is probably little advantage in emphasizing the described differences.

Several other mechanisms of lung injury may occur with nonfatal drowning. Bacterial pneumonia, barotrauma, mechanical damage from cardiopulmonary resuscitation (CPR), chemical pneumonitis, centrally mediated apnea, and oxygen toxicity can cause respiratory deterioration in the postresuscitation period [41]. These must be considered along with ARDS in cases of respiratory distress occurring 1 to 48 hours after the event.

Neurologic Effects

The pathologic effects that most affect prognosis in drowning are related to the central nervous system (CNS). Cerebral injury is produced as a result of anoxia due to gas exchange impairment and subsequent cardiopulmonary arrest.

Anoxic damage begins 4 to 10 minutes after cessation of cerebral blood flow in most situations [44]. The actual time course and clinical significance of anoxia in a specific drowning victim is notoriously uncertain in cases of drowning because of the emotional condition of the witnesses and because the impact of hypothermia is difficult to judge [45].

Many drowning victims suffer neurologic impairment. Victims display pathologic features similar to those of patients with anoxic encephalopathy from other causes, including diffuse cerebral edema, focal areas of necrosis, mitochondrial swelling, and other ischemic changes [46]. These changes occur primarily in the cerebral cortex, hippocampus, and cerebellum.

In addition to death, severe anoxic encephalopathy with persistent coma, seizures, delayed language development, spastic quadriplegia, aphasia, and cortical blindness have been reported as sequelae of submersion accidents [47–50]. Therefore, a great deal of effort has gone into trying to establish a means to predict the ultimate neurologic outcome of drowning victims. Studies have proposed the following as means of predicting outcomes: (a) the presence of purposeful movements and normal brainstem function 24 hours after submersion [51]; (b) the Glasgow Coma Scale score and Pediatric Risk of Mortality index on admission to the intensive care unit [52]; (c) cardiovascular status on admission to the emergency department and neurologic status on admission to the intensive care unit [53]; and (d) shorter submersion and resuscitation times and recovery of cardiac and neurologic function in the field [54]. Despite this, it remains impossible to predict outcomes with uniform accuracy in individual patients [55].

Musculoskeletal Effects

Children who develop anoxic encephalopathy due to drowning frequently develop musculoskeletal problems [56]. These problems result from spasticity, which appears to be more aggressive in these children than in those with other forms of spastic disorder. The most common of these are lower extremity contractures, hip subluxation or dislocation, and scoliosis [56].

Serum Electrolytes

Experimental studies with animals reveal significant differences in serum electrolytes between fresh- and saltwater drowning [57,58]. In the clinical setting, swallowing large amounts of seawater over an extended period of repeated submersions has been reported to cause significant changes in serum sodium, potassium, chloride, and magnesium [59]. This happens rarely, however, and the body corrects most of the alterations that do occur [60]. Therefore, the actual clinical impact of electrolyte changes is minimal [61,62].

Hematologic Effects

Patients presenting with drowning episodes rarely require medical intervention for anemia. Several studies have demonstrated near-normal hemoglobin values in both sea- and freshwater [57,60]. Disseminated intravascular coagulation

(DIC) has been described as a complicating factor in freshwater drowning [63].

Renal Effects

Acute tubular necrosis, hemoglobinuria, and albuminuria all have been reported as consequences of submersion accidents [50,64,65]. Diuresis has traditionally been considered to be a result of changes in renal tubular function due to hypothermia [66]. However, diuresis is seen in experimental submersions at any temperature [67]. Drowning victims also frequently present with metabolic acidosis as a result of lactate accumulation [68].

Cardiac Effects

Submersion in water causes an increase in left atrial diameter and a decrease in heart rate [69]. Atrial fibrillation and sinus dysrhythmias are common but rarely require therapy [70]. PR, QRS, and QT interval prolongations as well as J point elevation (Osborn wave; see Chapter 65) can be seen as in other causes of hypothermia [71,72]. More severe cases may result in death due to ventricular fibrillation or asystole. Autopsy studies of drowned patients demonstrate focal myocardial necrosis that may be similar to findings in pheochromocytoma and other situations of high adrenergic output [73,74].

The anoxia caused by drowning can also have an effect on hemodynamics. Orlowski and colleagues [75] found transient increases in central venous and pulmonary artery balloon occlusion pressures after experimental drowning. In addition, there was a persistent decrease in cardiac output that lasted more than 4 hours. These findings were independent of the tonicity of the solutions used and no different from those of anoxic controls.

Infectious Complications

Although a variety of infections are reported to be associated with drowning, pneumonia is the predominant infection described. Aspiration of mouth contents, gastric contents, and contaminated water all play a role in the development of pneumonia after drowning. A wide variety of organisms, including aerobic Gram-negative bacteria, aerobic Gram-positive bacteria, and fungi, have been described. Combinations of infections, some with opportunistic organisms, have also been described [76]. Because organisms that can survive in very cold water usually cannot survive and proliferate at human body temperature, most pneumonia cases occur after warm-water drowning [77]. In addition to pneumonia, cases of brain abscess, meningoencephalitis, bacteremia, skin and soft tissue infections, and endophthalmitis are reported to occur.

DIAGNOSIS AND CLINICAL PRESENTATION

History

The minimum background historical information that must be obtained includes the patient's age; underlying cardiac, respiratory, or neurologic diseases; and medications used. It is also important to determine the activities precipitating the submersion, such as boating, diving, or ingestion of drugs or alcohol; the duration of submersion; and the temperature and type of water in which it occurred.

Physical Examination

The initial physical examination is often hurried, with more detailed assessment delayed until resuscitative efforts have been established. Tachypnea is the most frequent finding, and tachycardia is also common [60]. Patients may also be apneic and pulseless. Hypothermia is common and depends on the temperature of the water and duration of submersion. It is important that an appropriate thermometer be used that can accurately measure hypothermic temperatures because the duration of resuscitation may depend on this value. Other findings include fever and signs of pulmonary edema. Any physical findings seen in cases of cerebral anoxia or severe hypothermia also may be seen in drowning. In addition to revealing the consequences of hypoxia/anoxia and hypothermia, the major importance of the physical examination is to uncover coexisting injuries that may have caused or resulted from the submersion.

Victims of nonfatal drowning have traditionally been classified with a simple scale [78]. Category A patients are fully alert within 1 hour of presentation to the emergency department. These patients uniformly do well neurologically. Category B patients are obtunded and stuporous but arousable at the time of evaluation; 89% to 100% of these patients survive, and severe permanent neurologic is not usually seen [79]. Category C patients are comatose with abnormal respirations and abnormal response to pain. Category C may be further subdivided depending on the pain response: C1, decorticate posturing; C2, decerebrate posturing; and C3, flaccid [79]. Category C patients have a much higher mortality, and survivors, particularly children, have a higher rate of neurologic dysfunction.

Laboratory Studies

Hemoglobin, hematocrit, and serum electrolytes are usually normal on arrival in the emergency department whether the submersion occurred in freshwater or saltwater [80]. Arterial blood gas analysis frequently shows metabolic acidosis and hypoxemia. The blood alcohol level, prothrombin time, partial thromboplastin time, serum creatinine, urinalysis, and drug screen should also be obtained to help determine the cause of the accident and assess for complications of drowning. Cervical spine films should be performed whenever there is evidence of trauma. An electrocardiogram should be obtained and continuous monitoring performed whenever there is a significant chance of dysrhythmia.

Up to 20% of initial chest radiographs in drowning victims are normal [60,81–83]. The remaining 80% show evidence of varying degrees of pulmonary edema. Two patterns are commonly seen. Some films display confluent alveolar densities primarily in the perihilar regions, whereas others exhibit a diffuse, almost homogeneous nodular pattern bilaterally. Sand bronchograms have also been reported. These are associated with the aspiration of sand and its deposition in the airways [84].

THERAPY

The treatment of nonfatal drowning should be approached in four phases.

Initial Resuscitation

Resuscitation of apneic or pulseless drowning victims should be initiated immediately and continue as needed throughout the prehospital phase into the emergency department. Mouth-to-mouth resuscitation must be begun in the water and not delayed until the victim is brought to shore [85,86]. The

rescuer should carefully support the victim's neck to prevent exacerbation of undiagnosed vertebral injuries. Full CPR with chest compressions should begin immediately on arrival on shore and proceed according to standard guidelines, and advanced life support should begin as soon as appropriate providers arrive [87]. The use of the Heimlich maneuver in the absence of a foreign body obstruction may exacerbate cervical spine injury and predispose to vomiting and aspiration [88]. Its routine use in resuscitation of drowning victims was strongly recommended against by an Institute of Medicine Report [88].

Resuscitation must be continued in victims of cold-water submersion at least until the patient has been rewarmed. Core temperature should be obtained immediately on arrival at the emergency department and monitored carefully during the first several hours. All drowning victims with cardiopulmonary arrest and hypothermia should be rewarmed rapidly only to a temperature between 32°C and 34°C and then maintained at that level (see following discussion) [89]. In the field, wet clothing should be removed and passive external rewarming plus inhalation of heated oxygen begun [90,91]. In the hospital, cardiopulmonary bypass should be used in cases of severe hypothermia from drowning, especially with circulatory collapse [30,90,92–94]. This method has the advantage of rapidly and directly rewarming the core. It can also correct the metabolic acidosis that commonly occurs. When this technique is not possible, rewarming with warmed peritoneal lavage, hemodialysis, or heated oxygen can be attempted. (See Chapter 65 for an in-depth discussion of rewarming techniques.)

A more difficult question is when and how long to resuscitate victims of warm-water submersion. As previously mentioned, there is no clearly established method of predicting ultimate neurologic recovery in individual patients. Therefore, until more information is available, the decision to terminate resuscitation must be based on a variety of factors particular to the individual case. On the other end of the clinical spectrum, most patients who are asymptomatic at or soon after presentation do very well. Victims who are asymptomatic and have normal oxygenation at 6 to 8 hours after presentation do not deteriorate during the subsequent 18 to 24 hours [95,96].

Therapy of the Underlying Cause

If there is any question of possible head or neck trauma, the neck should be immobilized in a brace until cervical spine films are available. Hypoglycemia and severe electrolyte abnormalities can be detected on routine serum testing and corrected rapidly in the emergency department. Serum alcohol levels and a drug screen can detect potential intoxicants and prompt administration of necessary antidotes or other measures. Anticonvulsant levels can help tailor therapy in known epileptic patients.

Treatment of Respiratory and Other Organ Failure

The initial management of all pulmonary edema states involves monitoring PaO_2 and providing appropriate supplemental oxygen. The use of nasal continuous positive airway pressure has been advocated for use in patients with pulmonary edema after drowning [97]. This technique has the advantage of being noninvasive and potentially less expensive than mechanical ventilation via endotracheal intubation. However, the literature supporting for this intervention is very limited and we cannot recommend its use. Mechanical ventilation with positive end-expiratory pressure should be instituted if refractory hypoxic or hypercapnic respiratory failure develops. The most important advance in the management of ARDS from any cause is the use of low tidal volume, low pressure ventilation [98] (Table 55.1). Use of such a strategy has been shown to have a major effect on survival of ARDS patients.

Other therapies for the respiratory complications of drowning have been proposed, but none of those has demonstrated improvements in outcomes. Examples of these types of therapies include exogenous surfactant in respiratory failure and prophylactic antibiotics. We do not advocate the use of either of these therapies.

Treatment of other end-organ damage must be approached systematically. Serum electrolytes rarely require therapy. The treatment of renal failure focuses on optimizing fluid status and renal blood flow. Severe cases may require temporary dialysis. Lactic acidosis should be corrected by restoration of adequate ventilation and circulation. The only clinically significant hematologic effect is DIC. The treatment of DIC is addressed in Chapter 108.

The cardiac dysrhythmogenic effects of hypothermia are corrected by rewarming. Sinus and atrial dysrhythmias as well as most interval prolongations rarely require additional therapy [70]. For a discussion of the treatment of hypothermia-related malignant ventricular dysrhythmias, see Chapter 65.

Musculoskeletal complications of nonfatal drowning are treated in standard fashion. Contractures are treated with casts or splints; subluxated or dislocated hips can be approached with various operative procedures; and scoliosis is treated with bracing or spinal instrumentation [56]. The relative success of these interventions in this population is unclear.

Neurologic Therapy

The recommendations of the World Congress on Drowning support the following interventions for patients following cardiopulmonary arrest from drowning:

TABLE 55.1

ADVANCES IN THE MANAGEMENT OF DROWNING BASED ON RANDOMIZED CLINICAL TRIALS

Intervention	Outcomes favorably affected	References
Small tidal volume ventilation for ARDS	Mortality, organ failure days, mechanical ventilation days	[98]
Therapeutic hypothermia for comatose survivors of cardiac arrest	Mortality	[100]
	Neurologic status	[99,100]

ARDS, acute respiratory distress syndrome.

- Restoration of spontaneous circulation is the highest priority goal.
- Core temperature should be monitored continuously.
- Therapeutic hypothermia to a core temperature of 32°C to 34°C should be maintained for a period of 12 to 24 hours. Hyperthermia should be prevented at all times in the acute recovery period.
- Seizures should be looked for and treated as necessary.
- Blood glucose concentrations should be monitored frequently and normoglycemia maintained.
- Hypoxemia should be avoided.
- Hypotension should be avoided.

The use of therapeutic hypothermia was substantiated in outpatient cardiac arrest victims in two randomized controlled trials published in 2002. In both studies, mortality and neurologic outcomes were improved by a treatment strategy including hypothermia when compared with conventional care and normothermia [99,100]. These findings are the basis for the strong recommendation given by the World Congress and other organizations.

CONCLUSIONS

The course of nonfatal drowning is variable. Patients who receive prompt CPR, are rapidly restored to a perfusing rhythm, and regain neurological function usually have dramatic and complete recoveries. On the other hand, patients with delayed resuscitation and those who do not rapidly recover neurological function often have a poor outcome. Although fresh- and seawater drownings cause different clinical pictures in experimental animals, they are difficult to distinguish in humans. In general, patients who aspirate water present with hypoxemia and metabolic acidosis. They usually do not aspirate enough fluid to produce changes in blood volume, electrolytes, hemoglobin, and hematocrit sufficient to be life-threatening.

The development of treatments specifically for drowning victims has been very slow. In general, most therapies are general treatments directed at cardiac arrest and ARDS. Treatment varies with the severity of the illness. In severely hypothermic patients, rewarming methods should be instituted immediately. These include removing wet clothing, covering with warm blankets, infusing warm fluids intravenously, and performing gastrointestinal irrigation with warm fluids. If the patient's temperature is less than 32°C, core rewarming may be most easily accomplished by cardiopulmonary bypass or peritoneal dialysis with a potassium-free dialysate warmed to 54°C. The desired core temperature for patients after cardiac arrest is 32°C to 34°C. Therapy for patients with severe hypoxemia includes institution of all the supportive modalities used in ARDS. Abnormalities of multiple organ systems must be addressed systematically. The most important ways for reducing deaths from drowning currently reside in the area of drowning prevention.

CHAPTER 56 ■ PULMONARY HYPERTENSION IN THE INTENSIVE CARE UNIT

KIMBERLY A. FISHER AND HARRISON W. FARBER

INTRODUCTION

Pulmonary hypertension, defined as a mean pulmonary artery pressure (mPAP) greater than 25 mm Hg, is a common finding in critically ill patients. It can be related to the underlying critical illness (respiratory failure, pulmonary embolism, decompensated heart failure), pre-existing conditions (left-sided heart disease, chronic obstructive pulmonary disease (COPD), interstitial lung disease), or may be the primary cause of critical illness, as in the case of decompensated right heart failure due to pulmonary arterial hypertension (PAH). Initiation of appropriate therapy requires differentiating among these possible etiologies.

CLASSIFICATION/ETIOLOGY

Pulmonary hypertension is classified into five groups based on similar pathology and response to treatment, according to the fourth World Symposium on Pulmonary Hypertension (Table 56.1) [1]. In this classification, groupings are based on whether the primary abnormality is in the precapillary arteries and arterioles (Group 1), postcapillary pulmonary veins and venules (Group 2), alveoli and capillary beds (Group 3), or due to chronic thromboemboli (Group 4). Group 5 comprises causes of pulmonary hypertension with multiple or unclear mechanisms.

PAH refers only to Group 1 and is distinct from other forms of pulmonary hypertension. PAH can be idiopathic (IPAH, formerly primary pulmonary hypertension or PPH), heritable (HPAH), or associated with underlying conditions such as collagen vascular disease, congenital heart disease, portal hypertension, HIV infection, and specific drugs (e.g., fenfluramine) or toxins (e.g., rapeseed oil). Pulmonary venous hypertension is the result of elevated pulmonary venous (e.g., sclerosing mediastinitis) or left-sided cardiac filling pressures that lead to passive elevation in pulmonary artery pressures (PAPs). This is typically caused by left ventricular (LV) systolic or diastolic heart failure, or valvular heart disease (mitral or aortic regurgitation or stenosis). Lung disease can cause pulmonary hypertension due to alveolar hypoxemia (hypoxic pulmonary vasoconstriction) and vascular destruction [2]. Chronic thromboembolic pulmonary hypertension (CTEPH) can be due to proximal and/or distal obstruction of the pulmonary vasculature by chronic thromboemboli.

Pulmonary hypertension related to critical illness can occur through multiple mechanisms, and therefore patients may fall into any of the above-described groups (Table 56.2). However, no matter the group, or the reason for admission to the intensive care unit (ICU), right heart failure in this setting is associated with a poor prognosis. Among patients with PAH or inoperable CTEPH admitted to the ICU with decompensated right heart failure, infection is the most commonly identified trigger (23% to 27%), with other causes including drug or dietary noncompliance, arrhythmia, pulmonary embolism, and pregnancy. In approximately 50% of cases of decompensated right heart failure, no precipitating etiology can be identified, suggesting it is due to underlying disease progression. Decompensated right heart failure requiring ICU admission is associated with a high mortality rate (32% to 41%) [3,4].

Decompensation of left heart disease can cause or worsen pulmonary venous hypertension. Exacerbations of chronic hypoxemic lung disease (chronic obstructive lung disease or interstitial lung disease) can be associated with pulmonary hypertension. Acute pulmonary embolism can cause pulmonary hypertension, depending on the degree of vascular obstruction. In a patient with normal pulmonary vasculature, greater than 50% obstruction of the pulmonary vasculature must occur before pulmonary hypertension occurs. Pulmonary hypertension may also occur following acute pulmonary embolism with lesser degree of pulmonary vascular obstruction in patients with underlying cardiopulmonary disease [5].

Pulmonary hypertension complicates most cases of acute respiratory distress syndrome (ARDS); for example, it has been reported in 93% to 100% of patients with severe ARDS [6,7]. When pulmonary hypertension occurs, it is almost always mild to moderate in severity; only 7% of patients have severe pulmonary hypertension [7]. The magnitude of pulmonary hypertension in ARDS correlates with severity of lung injury [8] and has adverse prognostic significance [9]. More recent data in the era of low tidal volume ventilation have demonstrated a significantly lower prevalence of echocardiographically detected acute cor pulmonale (25% vs. 61%) in patients with ARDS. The lack of direct hemodynamic data and differences in data acquisition in these studies (transesophageal vs. transthoracic echocardiograms) precludes definitive conclusion; however, these studies suggest that the incidence of pulmonary hypertension in ARDS may have decreased with changes in mechanical ventilation strategies [10,11]. Furthermore, a recent study has demonstrated a low rate of right ventricular (RV) failure among patients with ARDS [12].

PHYSIOLOGY OF THE PULMONARY CIRCULATION AND RIGHT VENTRICLE

The pulmonary circulation is the only vascular bed that accommodates the entire cardiac output while maintaining both low pressure and low vascular resistance. Normally, the pulmonary vasculature is able to accommodate increases in cardiac output without increases in pressure or resistance via dilation of pulmonary vessels and recruitment of previously closed vessels [13]. Pulmonary hypertension develops when abnormalities of the pulmonary vasculature lead to increases in pulmonary vascular resistance (PVR) and therefore increased RV afterload.

TABLE 56.1

UPDATED CLINICAL CLASSIFICATION OF PULMONARY HYPERTENSION (DANA POINT, 2008)

Group 1. Pulmonary arterial hypertension (PAH)
Idiopathic PAH
Heritable
Drug and toxin induced
Associated with connective tissues disease, HIV infection, portal hypertension, congenital heart diseases, schistosomiasis, chronic hemolytic anemia
Persistent pulmonary hypertension of the newborn
Pulmonary veno-occlusive disease and/or pulmonary capillary hemangiomatosis
Group 2. Pulmonary hypertension owing to left heart disease
Systolic dysfunction
Diastolic dysfunction
Valvular disease
Group 3. Pulmonary hypertension owing to lung disease and/or hypoxia
Chronic obstructive pulmonary disease
Interstitial lung disease
Other pulmonary diseases with mixed restrictive and obstructive pattern
Sleep-disordered breathing
Alveolar hypoventilation disorders
Chronic exposure to high altitude
Developmental abnormalities
Group 4. Chronic thromboembolic pulmonary hypertension
Group 5. Pulmonary hypertension with unclear multifactorial mechanisms
Hematologic disorders: myeloproliferative disorders, splenectomy
Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, vasculitis
Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

Modified from Simonneau G, Robbins IM, Beghetti M, et al: Updated clinical classification of pulmonary hypertension. *J Am Coll Cardiol* 54:S43–S54, 2009.

TABLE 56.2

COMMON CAUSES OF PULMONARY HYPERTENSION IN THE INTENSIVE CARE UNIT

Hypoxemia/parenchymal lung disease
Acute respiratory distress syndrome
Pulmonary embolism
Interstitial lung disease
Obstructive sleep apnea
Chronic obstructive pulmonary disease
Left heart disease
Acute myocardial infarction
Valvular disease (mitral regurgitation/mitral stenosis)
Severe diastolic dysfunction
Cardiomyopathy
Postoperative states
Coronary artery bypass grafting
Cardiac transplantation
Lung/heart–lung transplantation
Pneumonectomy
Thromboembolic lung disease
Pulmonary embolism
Deterioration of chronic pulmonary arterial hypertension
Infection
Fluid overloaded state
Arrhythmias
Pulmonary embolism
Acute on chronic pulmonary hypertension
Medication withdrawal

Modified from Zamanian RT, Haddad F, Doyle RL, et al: Management strategies for patients with pulmonary hypertension in the intensive care unit. *Crit Care Med* 35:2037–2050, 2007.

Because the RV normally ejects blood against a significantly lower afterload than the LV, it has a thinner wall and is therefore more compliant. This allows it to accommodate large increases in volume (preload). However, increases in afterload result in proportionate decreases in RV stroke volume [14]. Decreased RV stroke volume reduces blood return to the LV, thereby decreasing cardiac output. In addition, RV pressure overload causes "ventricular interdependence," in which elevated right ventricular end-diastolic pressure (RVEDP) causes bowing of the interventricular septum toward the LV during diastole, preventing LV diastolic filling and further reducing cardiac output [15–17]. RV pressure overload can also open the foramen ovale, allowing the shunting of blood from right to left, with resultant hypoxemia [14].

PATHOLOGY AND PATHOGENESIS

Patients with PAH share common pathologic findings including intimal fibrosis, increased medial thickness, pulmonary arteriolar occlusion, and plexiform lesions [18]. Multiple molecular pathways involved in the pathogenesis of IPAH have been identified [19]. Patients with IPAH have an increase in mediators of vasoconstriction and vascular smooth muscle cell proliferation (thromboxane A2, Endothelin-1) [20–22] and a decrease in substances that promote pulmonary vasodilation and inhibition of vascular smooth muscle cell proliferation (prostacyclin, nitric oxide, vasoactive intestinal peptide) [23–25].

Pathologic findings of pulmonary hypertension associated with ARDS vary with the time course of illness. Micro- and macrothrombi have been demonstrated in most patients. Early in disease, there are findings of acute endothelial cell injury. In the intermediate phase, chronic capillary changes, fibrocellular obliteration of arteries, veins, and lymphatics can occur. Vascular remodeling with distorted, tortuous arteries and veins, arterial muscularization, and reduced capillary number are seen in late stages [26]. While hypoxia and hypoxic pulmonary vasoconstriction likely play a role in the pathogenesis of pulmonary hypertension seen in ARDS, both the pathologic findings and the persistence of pulmonary hypertension in ARDS even after correction of severe hypoxemia [27] suggest the presence of additional pathogenic mechanisms. Indeed, intravenous infusion of endotoxin increases PAP in sheep [28], suggesting that disease processes such as sepsis may contribute to the development of pulmonary hypertension associated with ARDS. Patients with ARDS have increased levels of the pulmonary vasoconstrictors thromboxane A2, LTC4, and LTD4 in bronchoalveolar lavage fluid [29,30]. Finally, circulating levels of endothelin-1 are elevated in patients with ARDS [31].

DIAGNOSIS

Signs and Symptoms

Patients with PAH typically present with exertional dyspnea. Other presenting symptoms may include fatigue, syncope or near syncope, palpitations, and chest pain. As the disease progresses, patients may develop symptoms referable to reduced cardiac output and RV failure including fatigue, abdominal bloating and distension, and lower extremity edema. The presence of orthopnea and paroxysmal nocturnal dyspnea is suggestive of pulmonary venous hypertension [32].

Signs of elevated PAP on physical examination include (a) prominent pulmonary component of the second heart sound or P2, (b) RV heave, (c) early systolic ejection click, (d) midsystolic ejection murmur, (e) RV S_4 gallop, and (f) prominent jugular "a" wave. With more advanced disease, patients may develop findings of tricuspid regurgitation, including a holosystolic murmur along the left lower sternal border, and elevated jugular venous pressure. Findings of RV failure include elevated jugular pressure, pulsatile hepatomegaly, peripheral edema, ascites, and hypotension [32,33]. Patients with non–Group 1 causes of pulmonary hypertension may also have findings related to the primary disease, such as wheezing, decreased breath sounds and prolonged expiratory phase in COPD, and crackles in interstitial lung disease. The presence of bruits over the lung fields is specific for CTEPH, although present in only 30% of patients [34].

Diagnostic Testing

Electrocardiography (ECG) findings suggestive of pulmonary hypertension include right axis deviation (RAD), right atrial enlargement (P-wave $\geq$2.5 mm), and right ventricular hypertrophy (RVH) (frontal plane QRS axis $\geq$80°, R-wave/S-wave ratio in lead V1 >1, R-wave in lead V1 >0.5 mV) [32,35]. RVH and RAD are seen in 87% and 79% of patients with IPAH, respectively [33]. In a study of 61 patients with IPAH or PAH related to connective tissue disease, 8 patients (13%) had completely normal ECGs; thus, ECG is not sufficiently sensitive to screen patients suspected of PAH. ECG findings in patients with IPAH have prognostic significance with findings of P-wave amplitude 2.5 MV or more in lead II, qR lead V1, and RVH by WHO criteria associated with significantly increased risk of death, even after controlling for hemodynamic parameters, functional class, and treatment [36].

Radiographic findings of pulmonary hypertension include enlarged main and hilar pulmonary arterial shadows ($\geq$18 mm diameter in men, $\geq$16 mm diameter in women) with peripheral pulmonary vascular attenuation ("pruning") and RV enlargement as evidenced by decreased size of the retrosternal clear space [32,33]. Other radiographic findings may suggest an underlying cause for pulmonary hypertension such as hyperinflation (COPD), prominent interstitial markings and fibrosis (interstitial lung disease), or cephalization and Kerley B lines (left-sided congestive heart failure).

Computerized tomography may be helpful in further delineating underlying parenchymal lung disease. Ventilation/perfusion ($\dot{V}/\dot{Q}$) scanning is the test of choice for identifying CTEPH; however, this cannot be performed on intubated patients and may be difficult to obtain in unstable patients, limiting its utility in critically ill patients. A normal or low probability $\dot{V}/\dot{Q}$ scan virtually excludes the diagnosis of CTEPH. Computerized tomographic angiography can identify acute pulmonary emboli and often CTEPH as well, although the role of computerized tomographic angiography for diagnosing CTEPH remains poorly defined [34].

Laboratory evaluation may reveal underlying diseases associated with an increased risk of pulmonary hypertension, such as connective tissue disease positive anti-nuclear antibody (ANA), or HIV infection. Brain natriuretic peptide (BNP) may have prognostic value in patients with PAH [37]; however, BNP levels may be elevated in critically ill patients with shock, or cardiac dysfunction of any cause and is, therefore, a nonspecific finding of unclear clinical significance [14,38].

Pulmonary hypertension may be suggested in critically ill patients by echocardiography. Echocardiography can provide noninvasive estimates of pulmonary arterial pressures, assessment of right and LV function, and evaluation of valvular disease. Echocardiographic findings of pulmonary hypertension may include RV dilation and hypertrophy, D-shaped LV due to septal bowing in the LV during late systole, RV hypokinesis, tricuspid regurgitation, right atrial enlargement, and a dilated inferior vena cava (IVC) [17]. In patients with IPAH, right atrial enlargement and the presence of a pericardial effusion are associated with poor prognosis [39]. Although echocardiographic estimates of PAP correlate well with invasively measured PAP in patients with left-sided heart disease [40–42], multiple studies have demonstrated that echocardiographic estimates of PAPs in patients with suspected pulmonary hypertension or with underlying lung disease can be inaccurate; the false-positive rate is 30% to 40% under these circumstances [43–46].

Therefore, right heart catheterization remains the gold standard for diagnosis of pulmonary hypertension and must be performed to confirm the diagnosis, determine the appropriate etiology, and determine the treatment. As stated previously, pulmonary hypertension is defined as an mPAP of more than 25 mm Hg, measured by right heart catheterization. The finding of a pulmonary capillary wedge pressure (PCWP) greater than 15 mm Hg is indicative of pulmonary venous hypertension. Right heart catheter findings may include the following hemodynamic profiles: (a) elevated PAP, normal PCWP, elevated PVR, consistent with PAH or PH due to hypoxemic lung disease; (b) elevated PAP, elevated PCWP, normal pulmonary artery diastolic pressure (PAD)–PCWP gradient, consistent with pulmonary venous hypertension; (c) elevated PAP, elevated PCWP, elevated PAD–PCWP gradient, consistent with pulmonary venous hypertension with "active" component. In patients with IPAH, findings at right heart catheterization of mPAP greater than or equal to 85 mm Hg, right atrial pressure greater than or equal to 20 mm Hg, and cardiac index less than 2 L per minute per m^2 are associated with worsened survival [47].

Vasodilator testing may be performed at the time of right heart catheterization. This is done by measuring baseline hemodynamics, administering a short-acting pulmonary vasodilator (adenosine, inhaled nitric oxide [iNO], or prostacyclin), and then repeating the hemodynamic measurements. Vasodilator responsiveness is defined as a decrease in the mPAP by at least 10 mm Hg, to less than 40 mm Hg with no change or an increase in cardiac output [48]. Vasodilator responsiveness in patients with IPAH is predictive of response to treatment with high-dose calcium channel blockers and suggests a better prognosis. Of note, patients with IPAH who are not acutely vasodilator responsive respond to long-term treatment with pulmonary vasodilators [49]; therefore, the finding of vasodilator responsiveness should only be used to decide which patients might be treated with calcium channel blockers, not which patients should be treated in general. The clinical significance of vasodilator responsiveness in forms of pulmonary hypertension other than IPAH is unproven.

TREATMENT

Treatment of pulmonary hypertension is dictated by the underlying cause, according to the revised classification of pulmonary

hypertension (Table 56.1). When treating pulmonary hypertension in the ICU, one must differentiate between patients with pulmonary hypertension associated with underlying critical illness and patients who are critically ill due to PAH with RV failure and hemodynamic compromise.

General Measures

Hypoxic pulmonary vasoconstriction may contribute to pulmonary hypertension in critically ill patients. Supplemental oxygen results in a small, but statistically significant, decrease in PVR and an increase in cardiac output in patients with pulmonary hypertension of diverse etiologies [50]. Therefore, maintaining adequate oxygenation in critically ill patients with pulmonary hypertension is an important therapeutic goal.

Optimal fluid management in critically ill patients with decompensated RV failure can be extremely challenging. Because the RV is preload dependent, hypovolemia can result in decreased preload and therefore decreased cardiac output. However, hypervolemia can exacerbate RV pressure overload and ventricular interdependence, leading to decreased LV filling, also reducing cardiac output. Finding the optimal fluid balance for any given patient may require invasive hemodynamic monitoring.

Patients with RV dysfunction are poorly tolerant of loss of atrioventricular (AV) synchrony as occurs with atrial fibrillation and complete AV block. Therefore, maintenance of sinus rhythm may have salutary hemodynamic effects [51].

Retrospective and nonrandomized prospective studies of anticoagulation in patients with IPAH have demonstrated survival benefit with anticoagulation [52–54]. In the absence of contraindication, anticoagulation is therefore recommended for patients with PAH. However, there are no studies of anticoagulation in critically ill patients with pulmonary hypertension and thus no proven role for anticoagulation in this patient population.

Pulmonary Vasodilators

Significant advances in the outpatient treatment of PAH have been made since 1996 when the first pulmonary specific vasodilator was approved by the Food and Drug Administration (FDA). Patients with PAH (Group 1) benefit from treatment with prostacyclins (epoprostenol, treprostinil, iloprost), endothelin-receptor antagonists (bosentan, ambrisentan), and phosphodiesterase-5 inhibitors (sildenafil, tadalafil). Table 56.3 summarizes the major randomized controlled trials that have demonstrated clinical benefit with each of these medications [55–61]. Choice of initial therapy in stable outpatients with PAH is dictated by patients' risk profile, as assessed by functional class, 6-minute walk distance, BNP level, hemodynamics, and echocardiographic findings [62]. Oral pulmonary vasodilators are reserved for stable outpatients with low-risk profiles.

Patients with PAH and decompensated RV failure requiring admission to an ICU generally require treatment with intravenous prostanoids, although the initiation of pulmonary vasodilators as "rescue therapy" in the setting of decompensated right heart failure has not been well studied. In one small, retrospective study of patients with PAH and decompensated right heart failure, treatment with iloprost (inhaled) or treprostinil (intravenous or subcutaneous) was associated with decreased mortality [3]. However, in another study, treatment with intravenous epoprostenol or continuous iNO did not influence survival in patients with PAH or inoperable CTEPH and acute RV failure [4]. Of note, neither study was designed to study or compare the effects of pulmonary vasodilators on mortality in decompensated RV failure; therefore, no conclusions regarding which treatment may be most efficacious in this setting can be made.

Intravenous epoprostenol is the only medication with proven survival benefit in patients with IPAH [55] and is therefore the drug of choice for patients with severe PAH and a high-risk profile [63]. Epoprostenol therapy is typically initiated in the ICU with a right heart catheter in place. It is started at a dose of 1 to 2 ng per kg per minute and uptitrated by 1 to

TABLE 56.3

RESULTS OF PROSPECTIVE, RANDOMIZED TRIALS OF PHARMACOLOGIC TREATMENTS FOR PAH

Medication	No. of patients	WHO functional class	Results	Reference
Epoprostenol	81	III, IV	Improved survival, 6MWD, hemodynamics, and quality of life	[55]
Treprostinil	470	II, III, IV	Improved 6MWD, signs and symptoms of PAH, hemodynamics; no difference in rates of death, transplantation, or clinical deterioration.	[56]
Iloprost	203	III, IV	Improved combined clinical endpoint of 10% increase in 6MWD, WHO functional class, and the absence of deterioration or death; improved individual endpoints of 6MWD, postinhalation hemodynamics, WHO functional class.	[57]
Bosentan	213	III, IV	Improved 6MWD, Borg dyspnea index, WHO functional class, delayed time to clinical worsening	[58]
Ambrisentan	394	I, II, III, IV	Improved 6MWD, and delayed time to clinical worsening.	[59]
Sildenafil	278	I, II, III, IV	Improved 6MWD, hemodynamics, WHO functional class; no delay in time to clinical worsening.	[60]
Tadalafil	405	I, II, III, IV	Improved 6MWD, delayed time to clinical worsening, decreased incidence of clinical worsening. No significant improvement in WHO functional class.	[61]

6MWD, 6-minute walk distance; clinical worsening defined as combined endpoint of death, lung transplantation, hospitalization for pulmonary hypertension, lack of clinical improvement or worsening leading to need for additional therapy for PAH, or atrial septostomy.

2 ng per kg per minute at intervals of 15 to 30 minutes, with the hemodynamic goal of increased cardiac output and decreased PAP and PVR. Dose escalation is limited by side effects, such as headache, jaw pain, nausea, diarrhea, and systemic hypotension [55].

Treatment with epoprostenol can be complicated by the development of pulmonary edema, due to increased delivery of blood to the left side of the heart with resultant increased left-sided filling pressures. The development of pulmonary edema following the initiation of epoprostenol therapy should prompt consideration of pulmonary venoocclusive disease or pulmonary capillary hemangiomatosis, but this can also be seen in more common conditions such as occult diastolic dysfunction [64,65]. Epoprostenol results in nonselective pulmonary vasodilation. This can worsen $\dot{V}/\dot{Q}$ matching and cause clinically significant oxygen desaturation [66]. For patients chronically treated with epoprostenol, this can cause severe hypoxemia if superimposed focal lung disease such as pneumonia occurs. Abrupt discontinuation of epoprostenol has been demonstrated to lead to severe rebound pulmonary hypertension and death.

Treatment of patients with non–Group 1 pulmonary hypertension is focused on treating the underlying disease. For patients with pulmonary venous hypertension, optimization of afterload reduction and fluid management is the mainstay of therapy. Ensuring adequate oxygenation of patients with pulmonary hypertension due to parenchymal lung disease (Group 3) and treating the underlying disease are the main goals of therapy.

Given the poor prognostic significance of pulmonary hypertension in patients with ARDS, much attention has been focused on treating this aspect of ARDS. Administration of intravenous pulmonary vasodilators (epoprostenol, prostaglandin E_1, diltiazem) to patients with ARDS and pulmonary hypertension increases intrapulmonary shunting with resultant deterioration in oxygenation without improving survival [67–69]. There is therefore no proven role for using these agents in patients with pulmonary hypertension related to ARDS.

Inhaled pulmonary vasodilators are only delivered to ventilated alveoli and therefore improve $\dot{V}/\dot{Q}$ matching and oxygenation in patients with ARDS, while reducing pulmonary pressures. Specifically, iNO improves oxygenation, reduces pulmonary shunting, and reduces PVR in patients with ARDS [68,70]. However, in two large, multicenter, randomized, controlled trials comparing treatment with iNO with conventional therapy in patients with ARDS, no mortality benefit was demonstrated [71,72]. Similarly, nebulized prostaglandin I_2 improves oxygenation and decreases PAPs in patients with ARDS, without improving survival [73,74].

Treatment of pulmonary hypertension in ARDS with oral medications such as endothelin-receptor antagonists and phosphodiesterase-5 inhibitors used for treatment of PAH has not been studied.

Vasopressors

Patients with pulmonary hypertension may develop hemodynamic instability requiring vasopressor support. This may be due to progression of pulmonary hypertension with the development of RV failure or due to the development of a superimposed process, such as sepsis. The main goals of vasopressor therapy in patients with pulmonary hypertension are to reduce PVR, preserve or improve cardiac output, and maintain systemic blood pressure. There are limited data to guide the choice of vasopressors in the setting of pulmonary hypertension and RV failure.

Dobutamine reduces PVR and increases cardiac output in animal models of pulmonary hypertension [14,75,76]. In humans with mild-to-moderate pulmonary hypertension, dobutamine decreased PVR and increased cardiac index; however, increased intrapulmonary shunting with resultant decrease in arterial oxygenation was also noted. Dobutamine administered in combination with iNO resulted in significant decreases in PVR with concomitant increases in cardiac index and improved oxygenation [77]. Of note, these studies were performed in patients with stable cardiopulmonary hemodynamics. The physiologic effects of dobutamine in critically ill patients with pulmonary hypertension have not been well characterized. In a prospective, observational study of patients with PAH or inoperable CTEPH with acute RV failure requiring treatment with catecholamines, increasing dobutamine dose was associated with increased mortality [4]. However, this more likely reflects patients with more severe disease, rather than a deleterious effect of dobutamine on survival.

Norepinephrine administration in patients with pulmonary venous hypertension and systemic hypotension following induction of anaesthesia resulted in increased mPAP and PVR, but with decreased ratio of PAP to SBP (i.e., systolic blood pressure [SBP] increased more than PAP) and no change in cardiac index (CI). By contrast, phenylephrine administration resulted in decreased CI, without a concomitant decrease in the ratio of PAP to SBP [78]. Norepinephrine may be beneficial in restoring systemic blood pressure in patients with persistent hypotension despite treatment with pulmonary vasodilators and dobutamine, but should otherwise be avoided due to its pulmonary vasoconstrictive effects. Similarly, phenylephrine increases mPAP and PVR, with evidence of worsened RV function in patients with chronic pulmonary hypertension [79]. It should therefore be avoided in patients with hemodynamic compromise due to pulmonary hypertension.

Dopamine decreases PVR and increases cardiac output in an animal model of acute pulmonary embolism [80]. Similar effects were noted in patients with pulmonary hypertension due to chronic obstructive lung disease [81]. In humans with pulmonary venous hypertension, dopamine infusions increased mPAP, but this effect was mediated through increased cardiac output, not by pulmonary vasoconstriction [82]. The effects of dopamine in patients with PAH have not been well studied. In a retrospective, single-center study of patients with PAH and decompensated RV failure, higher doses of dopamine were associated with increased mortality. However, patients requiring treatment with dopamine had significantly more severe disease, by both clinical and hemodynamic parameters [3].

The effects of vasopressin on cardiopulmonary hemodynamics have not been characterized in patients with pulmonary hypertension. In an animal model of pulmonary hypertension, high-dose vasopressin increased mPAP and PVR and decreased cardiac output [83]. However, the effects of lower dose vasopressin, as used in treatment of septic shock, have not been studied.

In an animal model of pulmonary hypertension, isoproterenol reduces PVR and improves cardiac output [84]. However, these beneficial effects are largely offset by induction of tachyarrhythmias [85]. Although isoproterenol reduces PVR in patients with IPAH, the chronotropic effects limit its role in patients with PAH [14].

There are no published studies of the hemodynamic effects of epinephrine in patients with pulmonary hypertension.

Mechanical Ventilation

Institution of mechanical ventilation has complex hemodynamic effects that can be of clinical significance, especially in patients with severe PAH and decompensated RV failure.

Mechanical ventilation increases RV afterload and decreases RV preload that can be of particular hemodynamic consequence in patients with pulmonary hypertension. The increased afterload effects appear mediated primarily through increased lung volume [86]. Many of the studies evaluating effects of mechanical ventilation on RV function were performed prior to the era of low tidal volume ventilation for ARDS; therefore, it is unknown whether these effects are as pronounced or clinically important at lower tidal volumes.

Permissive hypercapnia has become common with the widespread institution of low tidal volume ventilation. Hypercapnia increases pulmonary pressures, although it is unclear whether this is due simply to increased cardiac output or by a direct pulmonary vasoconstrictive effect [87–89]. In one study of hemodynamically stable patients following coronary artery bypass grafting, hypercarbia (mean $PaCO_2$ 49.8 mm Hg) increased mPAP, PVR, and RVEDP and decreased right ventricular ejection fraction (RVEF) by 20% [87].

Similarly, elevations in positive end-expiratory pressure (PEEP) also increase pulmonary arterial pressure and PVR [90,91]. In one study of patients with ARDS, a mean increase in PEEP from 4 cm H_2O to 17 cm H_2O elevated mPAP from 27.7 mm Hg to 36.7 mm Hg [91].

Although the net effect of mechanical ventilation is to increase pulmonary arterial pressure, this is typically well tolerated in patients with mild-to-moderate pulmonary hypertension. These effects, however, may be of particular hemodynamic consequence in patients with PAH and RV failure. Mechanical ventilation in these patients should ideally be with low tidal volume and low PEEP, while avoiding permissive hypercapnia.

Surgical Management

Atrial septostomy, or the surgical creation of an atrial septal shunt, decompresses the RV by creating an alternative outflow tract for blood and increases left atrial filling. However, it is associated with very high morbidity and mortality in critically ill patients with RV failure [92–94]. It is complicated by oxygen desaturation through the creation of a right-to-left shunt. It is contraindicated in patients with mean right atrial pressure (RAP) greater than 20 mm Hg, significant hypoxemia, and PVR index greater than 4,400 dyne second per cm^5 per m^2 [93].

CHAPTER 57 ■ PLEURAL DISEASE IN THE CRITICALLY ILL PATIENT

PETER DOELKEN AND STEVEN A. SAHN

Pleural disease is an unusual cause for admission to the intensive care unit (ICU). Exceptions are a large hemothorax for monitoring bleeding rate and hemodynamic status and an unstable secondary spontaneous pneumothorax or large unilateral or bilateral pleural effusions that have caused acute respiratory failure.

Pleural disease can be overlooked in the critically ill patient because it may be overshadowed by the presenting illness that has resulted in ICU admission. Furthermore, it is often a subtle finding on the clinical examination and supine chest radiograph. A pleural effusion may not be seen on the supine chest radiograph because a diffuse alveolar filling process can mask the posterior layering of fluid or because bilateral effusions without parenchymal infiltrates are misinterpreted as an underexposed film or objects outside the chest. Pneumothorax may remain undetected in the supine patient because pleural air tends to be situated anteriorly and does not produce the diagnostic visceral pleural line seen on an upright radiograph. When the patient on mechanical ventilation support is at increased risk for barotrauma because airway pressures are high, the index of suspicion for pneumothorax should be heightened; if there is evidence of pulmonary interstitial gas (see following discussion) or subcutaneous emphysema, appropriate radiologic studies should be obtained.

RADIOLOGIC SIGNS OF PLEURAL DISEASE IN THE INTENSIVE CARE UNIT

Because the distribution of fluid and air in the normal pleural space tends to follow gravitational influences, and because the lung has a tendency to maintain its normal shape as it becomes smaller, fluid initially accumulates between the bottom of the lung and the diaphragm, and air accumulates between the top of the lung and the apex of the thorax in the upright position. When chest radiographs are obtained in other than the erect position, free pleural fluid and air change position and result in a different radiographic appearance.

PLEURAL FLUID

Standard Chest Radiograph

In healthy humans in the supine position, the radiolucency of the lung base is equal to or greater than that in the lung apex [1]. Furthermore, when in the supine position, breast and pectoral tissue tend to fall laterally away from the lung base. Thus, an effusion should be suspected if there is increased homogeneous density over the lower lung fields compared to the upper lung fields. As the pleural effusion increases, the increased radiodensity involves the upper hemithorax as well. However, failure of chest wall tissue to move laterally, cardiomegaly, prominent epicardial fat pad, and lung collapse or consolidation may obscure a pleural effusion on a supine radiograph. Patient rotation or an off-center X-ray beam can mimic a unilateral homogeneous density. An absent pectoral muscle, prior mastectomy, unilateral hyperlucent lung, scoliosis, previous lobectomy, hypoplastic pulmonary artery, or pleural or chest wall mass may lead to unilateral homogeneous increased density and mimic an effusion.

Approximately 175 to 525 mL of pleural fluid results in blunting of the costophrenic angle on an erect radiograph [2]. This quantity of effusion can be detected on a supine radiograph as an increased density over the lower lung zone. Failure to visualize the hemidiaphragm, absence of the costophrenic angle meniscus, and apical capping are less likely to be seen with effusions of less than 500 mL [1]. The major radiographic finding of a pleural effusion in a supine position is increased homogeneous density over the lower lung field that does not obliterate normal bronchovascular markings, does not show air bronchograms, and does not show hilar or mediastinal displacement until the effusion is massive. If a pleural effusion is suspected in the supine patient, ultrasonography (US) should be performed.

Other Radiographic Imaging

Sonography

US provides good characterization for pleural diseases and is a useful diagnostic modality for critically ill patients who cannot be transported for computed tomography (CT). US takes less time and is less expensive than CT, can be done at the bedside, and can be repeated serially. Disadvantages include hindrance of the ultrasonic wave by air, in either the lung or the pleural space, a restricted field of view, inferior evaluation of the lung parenchyma compared with CT, and operator dependence. US was helpful in diagnosis in 27 (66%) of 41 patients and treatment in 37 (90%) of 41 patients, and had an important influence on treatment planning in 17 (41%) of 41 critically ill patients [3].

US has also been demonstrated to be a useful modality to guide bedside thoracentesis in the mechanically ventilated patient, resulting in high success rate and excellent safety of the procedure [4].

Computed Tomography

CT is recognized as providing increased resolution compared with conventional imaging. Although moving a critically ill

patient for CT has potential risks, the diagnostic advantage is justified in the stable patient when the clinical course is not congruent with the proposed diagnosis suggested by the portable chest radiograph. In selected patients with multisystem trauma, chest CT often provides additional diagnostic information and positively affects patient management and outcome.

PNEUMOTHORAX

When supine, pneumothorax gas migrates along the anterior surface of the lung, making detection on the anteroposterior radiograph problematic. The base, lateral chest wall, and juxtacardiac area should be carefully visualized for evidence of pneumothorax. Accumulation of air along the mediastinal parietal pleura may simulate pneumomediastinum [5]. An erect or decubitus (suspected hemithorax up) radiograph should be obtained to assess for the presence of a pneumothorax. US is sensitive for the detection of pneumothorax by determining the presence or absence of "lung sliding" [6]. In individuals without pneumothorax, the lung–chest wall interface, which represents a to-and-fro movement synchronized with respiration, can be identified. US visualization of lung sliding is correlated with the absence of pneumothorax, and from this sign alone, at least anterior pneumothorax can be excluded rapidly at the bedside of a mechanically ventilated patient. However, absence of lung sliding may be caused by the presence of large bullae or pleural symphysis caused by previous pleurodesis or pleural adhesions due to previous pleural disease. Hence, the absence of lung sliding is not specific for pneumothorax but detection of lung sliding reliably excludes the presence of pleural air in the examined area.

The most common radiographic signs of tension pneumothorax are contralateral mediastinal shift, ipsilateral diaphragmatic depression, and ipsilateral chest wall expansion. Underlying lung disease may prevent total lung collapse, even if tension is present; in patients on mechanical ventilation, little or no midline mediastinal shift may result from the tension [7]. In the latter, a depressed ipsilateral diaphragm is a more reliable sign of tension than mediastinal shift.

In patients with acute respiratory distress syndrome (ARDS), barotrauma can result in a localized tension pneumothorax with a subtle contralateral mediastinal shift, flattening of the cardiac contour, and depression of the ipsilateral hemidiaphragm [8]. Pleural adhesions and relative compressibility and mobility of surrounding structures, in addition to the supine position, probably account for these loculated tension pneumothoraces.

In a study of 88 critically ill patients with 112 pneumothoraces, the anteromedial and subpulmonic recesses were involved in 64% of patients in the supine and semierect position [9]. Furthermore, in 30% of the pneumothoraces in this study that were not initially detected by the clinician or radiologist, half of the patients progressed to tension pneumothorax. Therefore, a high index of suspicion is necessary to avoid catastrophic situations.

Factors that may contribute to an improved ability to diagnose this potentially lethal problem include (a) familiarity with atypical locations of pneumothoraces in critically ill patients, usually due to the supine or semierect position; (b) the consequence of underlying cardiopulmonary disease; and (c) knowledge of other risk factors contributing to misdiagnosis (e.g., mechanical ventilation, altered mental status, prolonged ICU stay, and development of pneumothorax after peak physician staffing hours) [10].

EVALUATIONS OF THE PATIENT WITH A PLEURAL EFFUSION IN THE INTENSIVE CARE UNIT

Diagnostic Thoracentesis

Indications

Patients with a pleural effusion provide the opportunity to diagnose, at least presumptively, the underlying process responsible for pleural fluid accumulation. Pleural effusions are most commonly caused by primary lung disease but may also result from disease in the gastrointestinal tract, liver, kidney, heart, or reticuloendothelial system.

Although disease of any organ system can cause a pleural effusion in critically ill patients, the diagnoses listed in Table 57.1 represent the majority of the causes seen in ICUs. The types of pleural effusions seen in medical and surgical ICUs are similar, but some causes related to surgical (coronary artery bypass grafting, chylothorax, abdominal surgery) and nonsurgical trauma (hemothorax) represent a substantial percentage of surgical ICU effusions.

When a pleural effusion is suspected on physical examination and confirmed radiologically, a diagnostic thoracentesis under ultrasonographic guidance should be performed in an attempt to establish the cause. Exceptions are patients with a secure clinical diagnosis and a small amount of pleural fluid, as in atelectasis, or patients with uncomplicated congestive heart failure (CHF) [11]. Observation may be warranted in these situations, but thoracentesis should be performed if there are adverse changes [12].

The indications for diagnostic thoracentesis do not change simply because the patient is in the ICU or on mechanical ventilation. In fact, establishing the diagnosis quickly in these critically ill patients may be more important and life-saving than in noncritically ill patients. It has been well documented that even in patients on mechanical ventilation, diagnostic thoracentesis is safe if there is strict adherence to the general principles of the procedure and US is used (see Chapter 10) [4,13]. Pneumothorax, the most clinically important complication of thoracentesis [11], is no more likely to occur in the patient on mechanical ventilation than in the patient who is not; however, if a

TABLE 57.1

CAUSES OF PLEURAL EFFUSIONS

In the medical ICU	In the surgical ICU
Atelectasis	Atelectasis
Congestive heart failure	Congestive heart failure
Pneumonia	Pneumonia
Hypoalbuminemia	Pancreatitis
Pancreatitis	Hypoalbuminemia
ARDS	Coronary artery bypass surgery
Pulmonary embolism	ARDS
Hepatic hydrothorax	Pulmonary embolism
Esophageal sclerotherapy	Esophageal rupture
Postmyocardial infarction	Hemothorax
Iatrogenic	Chylothorax
	Abdominal surgery
	Iatrogenic

ARDS, acute respiratory distress syndrome; ICU, intensive care unit.

pneumothorax does develop, the patient on mechanical ventilation is likely to develop a tension pneumothorax.

Contraindications

There are no absolute contraindications to diagnostic thoracentesis. If clinical judgment dictates that the information gained from the pleural fluid analysis may help in diagnosis and therapy, thoracentesis should be performed (see Chapter 10). Diagnostic thoracentesis with a small-bore needle can be performed safely in virtually any patient if meticulous technique is used. The major relative contraindications to thoracentesis are a bleeding diathesis or anticoagulation. A patient with a small amount of pleural fluid and a low benefit-to-risk ratio also represents a relative contraindication. Thoracentesis should not be attempted through an area of active skin infection.

Complications

Complications of diagnostic thoracentesis include pain at the needle insertion site, bleeding (local, intrapleural, or intra-abdominal), pneumothorax, empyema, and spleen or liver puncture (see Chapter 10). Pneumothorax has been reported in prospective studies to occur in 4% to 30% of patients [11,14–16]. However, when ultrasound-guided thoracentesis is performed by experienced physician sonographers, pneumothorax or other injuries due to organ puncture appear to be rare events [4]. Liver or spleen puncture tends to occur when the patient is not sitting absolutely upright because movement toward recumbency causes cephalad migration of the abdominal viscera. The upward displacement of abdominal organs is readily detected by US. However, even if the liver or spleen is punctured with a small-bore needle, generally the outcome is favorable if the patient is not receiving anticoagulants and does not have a bleeding diathesis.

Therapeutic Thoracentesis

Indications and Contraindications

The primary indication for therapeutic thoracentesis is relief of dyspnea. Contraindications to therapeutic thoracentesis are similar to those for diagnostic thoracentesis. However, there appears to be an increased risk of pneumothorax [11], thus making a therapeutic thoracentesis in patients on mechanical ventilation potentially hazardous.

The technique for therapeutic thoracentesis is essentially the same as for diagnostic thoracentesis, except that a blunt-tip needle or plastic catheter, rather than a sharp-tip needle, should be used (see Chapter 10). This reduces the risk of pneumothorax, which may occur as fluid is removed and the lung expands toward the chest wall. Again, the use of sonographic guidance is recommended [17].

The amount of fluid that can be removed safely from the pleural space at one session is controversial. Ideally, monitoring pleural pressure should dictate the amount of fluid that can be removed. As long as intrapleural pressure does not fall to less than -20 cm H_2O, fluid removal can continue [18]. However, intrapleural pressure monitoring is not done routinely. In the patient with contralateral mediastinal shift on chest radiograph who tolerates thoracentesis without chest tightness, cough, or light-headedness, probably several liters of pleural fluid can be removed safely. However, neither the patient nor the operator may be aware of a precipitous drop in pleural pressure. In patients without a contralateral mediastinal shift or with ipsilateral shift (suggesting an endobronchial obstruction), the likelihood of a precipitous drop in intrapleural pressure is increased, and pleural pressure should be monitored during thoracentesis. Alternatively, a small bore catheter connected to a standard thoracostomy pleural drainage system may be temporarily inserted, thus avoiding excessively negative pleural pressure development during drainage. Simple gravity drainage or drainage using any system incorporating a nonreturn valve do not reliably guard against the development of excessively negative pressure.

Physiologic Effects and Complications

Improvement in lung volumes up to 24 hours after therapeutic thoracentesis does not correlate with the amount of fluid removed, despite relief of dyspnea in those patients [19–21]. In some patients, however, maximum spirometric improvement may not occur for several days. Patients with initial negative pleural pressures and those with more precipitous falls in pleural pressure with thoracentesis tend to have the least improvement in pulmonary function after therapeutic thoracentesis because many have a trapped lung or endobronchial obstruction [18]. The mechanism of dyspnea from a large pleural effusion probably is related to the increase in chest wall resting volume resulting in shortening of the respiratory muscles resting length and consequent decrease in contractile efficiency [20]. Drainage of moderately sized pleural effusions (1,495 mL) does not appear to result in predictable changes in respiratory system compliance or resistances although a systematic decrease in work performed by the ventilator as a consequence of thoracentesis has been reported [22].

Complications of therapeutic thoracentesis are the same as those seen with diagnostic thoracentesis (see Chapter 10). Three complications that are unique to therapeutic thoracentesis are hypoxemia, unilateral pulmonary edema, and hypovolemia. After therapeutic thoracentesis, hypoxemia may occur despite relief of dyspnea [23,24] from worsening ventilation–perfusion relationships in the ipsilateral lung or clinically occult unilateral pulmonary edema.

Some investigators have concluded that the change in partial pressure of arterial oxygen (PaO_2) after therapeutic thoracentesis is unpredictable [24]; some have observed a characteristic increase in PaO_2 within minutes to hours [19], and others suggest a systematic decrease in PaO_2 that returns to prethoracentesis values by 24 hours [23] In the largest study, including 33 patients with various causes of unilateral pleural effusions, a significant increase in PaO_2 was found 20 minutes, 2 hours, and 24 hours after therapeutic thoracentesis [25]. This was in conjunction with a decrease in the alveolar–arterial oxygen gradient [$P(A–a)O_2$] and was accompanied by a small but significant decrease in shunt, without a change in V_D/V_T. Data suggest an improved ventilation-perfusion relationship after therapeutic thoracentesis, with an increase in ventilation of parts of the lung that were previously poorly ventilated but well perfused. The relief of dyspnea in these patients cannot be explained by improved arterial oxygen tension. The increases have been modest, and in some cases there has been a fall in PaO_2. Improvement in lung volumes is a constant finding after therapeutic thoracentesis but may take days or even weeks to maximize; immediate changes are usually modest and highly variable. Therefore, the relief of dyspnea cannot be adequately explained by changes in lung volume or in the mechanics of breathing but may be the result of decreased stimulation of lung or chest wall receptors, or both [20].

PLEURAL EFFUSIONS IN THE INTENSIVE CARE UNIT

The types of pleural effusions in critically ill patients are listed in Table 57.2.

TABLE 57.2

DIFFERENTIAL DIAGNOSIS OF PLEURAL EFFUSIONS IN CRITICALLY ILL PATIENTS

	Clinical presentation	Chest radiograph	Pleural fluid analysis	Diagnosis	Comments
Transudates					
Congestive heart failure	Usual signs and symptoms plus I > O, weight gain, worsening $P(A–a)O_2$, ↓ C_{ST}	Bilateral effusions, right > left, cardiomegaly, extravascular lung water	Serous, nucleated cells <1,000/μL, lymphocytes, mesothelial cells, pH 7.45–7.55	Presumptive	Associated with ↑ pulmonary capillary wedge pressure, acute diuresis may result in ↑ protein and LDH
Atelectasis	Asymptomatic or dyspnea, worsening $P(A–a)O_2$	Small unilateral or bilateral effusions, volume loss	Serous, nucleated cells <1,000/μL, lymphocytes, mesothelial cells, pH 7.45–7.55	Presumptive	Common after upper abdominal surgery, also with pulmonary embolism, mucous plug
Hepatic hydrothorax	Stigmata of liver disease, clinical ascites, asymptomatic or dyspnea, worsening $P(A–a)O_2$, poor response to low-flow O_2	Unilateral right or bilateral effusions, small to massive, normal heart size, no other CXR abnormalities	Serous-serosanguineous nucleated cells <1,000/μL, lymphocytes, mesothelial cells, pH 7.40–7.55	Presumptive, PF protein and LDH similar to ascitic fluid	6% of patients with clinical ascites, fluid movement from abdomen to chest via diaphragm defect
Hypoalbuminemia	Asymptomatic or dyspnea, anasarca	Small-to-moderate bilateral effusions, normal heart size, no other CXR abnormalities	Serous, nucleated cells <1,000/μL, lymphocytes, mesothelial cells, pH 7.45–7.55	Presumptive	Serum albumin <1.5 g/dL, never have isolated pleural effusion
Iatrogenic: extravascular migration of central venous catheter	Chest pain, dyspnea	Abnormal position of catheter, widening of mediastinum, small-to-large unilateral effusion	Serous-hemorrhagic or white, may contain PMNs, chemistries similar to infusate, PF/S glucose >1.0	Presumptive	Highest incidence with left external jugular vein placement, aspiration or retrograde flow of blood confirms intravascular placement
Exudates					
Parapneumonic effusions: uncomplicated	Fever, chest pain, ↑ WBC, purulent sputum	New alveolar infiltrate, minimal-to-moderate ipsilateral free-flowing effusion	Turbid, PMNs, glucose >60 mg/dL, LDH <700 IU/L, pH ≥7.30	Presumptive	Effusion resolves without sequelae on antibiotics only
Parapneumonic effusions: complicated	Fever, chest pain, ↑ WBC, purulent sputum	New alveolar infiltrate, moderate-to-large ipsilateral effusion with or without loculation	Pus, positive bacteriology, pH <7.10, glucose <40 mg/dL, LDH >1,000 IU/L	Based on PF acidosis, positive bacteriology, aspiration of pus, loculation	Putrid odor defines anaerobic empyema, requires pleural space drainage for resolution
Pancreatitis	Acute abdominal pain, nausea, vomiting, fever	Small, unilateral, left effusion (60%), atelectasis	Turbid, nucleated cells 10,000–50,000/μL, PMNs, pH 7.30–7.35, PF/S amylase >1.0	PF/S amylase >1.0 or >upper limits of normal for serum	Effusion resolves as pancreatitis resolves without need for pleural space drainage
Pulmonary embolism	Acute dyspnea, tachypnea, chest pain, ↑ $P(A–a)O_2$	Unilateral, small-to-moderate effusion, peripheral infiltrate, atelectasis	Serous-bloody nucleated cells 100–50,000/μL, PMNs or lymphocytes	Presumptive	20% transudates, effusion present on admission, 1/3 of hemithorax, reaches maximum volume by 72 h

(*continued*)

TABLE 57.2

CONTINUED

	Clinical presentation	Chest radiograph	Pleural fluid analysis	Diagnosis	Comments
Postcardiac injury syndrome	Chest pain, pericardial rub, fever, dyspnea 3 d to 3 wk after cardiac injury, ↑ WBC, ↑ erythrocyte sedimentation rate	Left or bilateral small-to-moderate effusion, left lower lobe infiltrates	Serosanguineous-bloody, nucleated cells 500–39,000/μL, PMNs or lymphocytes, pH >7.30	Presumptive	Effusion resolves in 1–3 wk, may require steroids
Esophageal sclerotherapy	Chest pain following sclerotherapy with large sclerosant volume, effusion appears by 48–72 h	Small, unilateral or bilateral effusion	Serosanguineous, nucleated cells 100–38,000/μL, PMNs or mononuclear, pH >7.30	Presumptive	Requires no specific therapy, resolves in days to weeks
ARDS	Depends on cause	Bilateral alveolar infiltrates tend to mask small bilateral effusions	Serous-serosanguineous, PMNs	Presumptive	Requires no specific therapy, effusions resolve as ARDS resolves
Spontaneous esophageal rupture	Severe retching or vomiting followed by thoracoabdominal pain, fever, subcutaneous air	Subcutaneous/mediastinal air; left pneumothorax, followed by left effusion	Early: serous, pH >7.30; later: turbid-purulent effusion, PMNs, pH approaches 6.00, ↑ amylase	Pleural fluid pH <7.00, with ↑ salivary amylase and positive bacteriology	With early diagnosis prognosis good with primary closure and drainage
Hemothorax	Following blunt and penetrating chest trauma, invasive procedures, malignancy, anticoagulation	Small-to-massive unilateral effusion, other abnormalities depending on cause of hemothorax	Gross blood, PF/blood Hct >50%	PF/blood Hct >50%	Often not appreciated on initial radiograph in setting of trauma; should be drained with chest tube
Coronary artery bypass graft	Asymptomatic, dyspnea	Small-to-moderate left effusion without parenchymal infiltrates, left lower lobe atelectasis, elevation of left hemidiaphragm	Hemorrhagic PF/blood Hct <5%, nucleated cells <10,000/μL, lymph predominant, pH >7.40	Presumptive	May require weeks for resolution, rarely results in trapped lung
Abdominal surgery	Asymptomatic 48–72 h after upper abdominal surgery	Small bilateral effusions, atelectasis	Serous nucleated cells <10,000/μL (75%), pH usually >7.40	Presumptive	Larger left effusions following splenectomy, most commonly found with atelectasis and diaphragmatic irritation, resolves spontaneously
Chylothorax (traumatic)	Asymptomatic or dyspnea following intrathoracic surgery, especially coarctation repair and esophagectomy	Small-to-massive left, right, or bilateral effusion	Milky fluid, nucleated cells <7,000/μL almost all lymphocytes, pH 7.40–7.80, ↑ triglycerides	Triglycerides >110 mg/dL, chylomicrons on lipoprotein electrophoresis	Defect in thoracic duct frequently closes spontaneously with tube drainage and minimizing chyle formation

ARDS, acute respiratory distress syndrome; CXR, chest radiograph; ↓, decreased; Hct, hematocrit; ↑, increased; I, input; LDH, lactate dehydrogenase; O, output; PF, pleural fluid; PF/S, pleural fluid/serum; PMN, polymorphonuclear leukocyte; WBC, white blood cell.

Atelectasis

Atelectasis is a common cause of small pleural effusions in comatose, immobile, pain-ridden patients in ICUs [26] and after upper abdominal surgery [27,28]. Other causes include major bronchial obstruction from lung cancer or a mucous plug. Atelectasis causes pleural fluid because of decreased pleural pressure. With alveolar collapse, the lung and chest wall separate further, creating local areas of increased negative pressure. This decrease in pleural pressure favors the movement of fluid into the pleural space, presumably from the parietal pleural surface. The fluid accumulates until the pleural or parietal-pleural interstitial pressure gradient reaches a steady state.

Pleural fluid from atelectasis is a serous transudate with a low number of mononuclear cells, a glucose concentration equivalent to serum, and pH in the range of 7.45 to 7.55. When atelectasis resolves, pleural fluid dissipates during several days.

Congestive Heart Failure

CHF is the most common cause of transudative pleural effusions and a common cause of pleural effusions in ICUs. Pleural effusions due to CHF are associated with increases in pulmonary venous pressure [29]. Most patients with subacute or chronic elevation in pulmonary venous pressure (pulmonary capillary wedge pressure of at least 24 mm Hg) have evidence of pleural effusion on US or lateral decubitus radiograph. Isolated increases in systemic venous pressure tend not to produce pleural effusions. Thus, patients with chronic obstructive pulmonary disease (COPD) and cor pulmonale rarely have pleural effusions, and the presence of pleural fluid implies another cause.

Most patients with pleural effusions secondary to CHF have the classic signs and symptoms. The chest radiograph shows cardiomegaly and bilateral small-to-moderate pleural effusions of similar size (right slightly greater than left). There is usually radiographic evidence of pulmonary congestion, with the severity of pulmonary edema correlating with the presence of pleural effusion [29].

The effusion is a transudate, with mesothelial cells and lymphocytes accounting for the majority of the less than 1,000 cells per μL [13]. Acute diuresis can raise the pleural fluid protein and lactate dehydrogenase into the range of an exudate [30,31]. In the patient with secure clinical diagnosis of CHF, observation is appropriate. Thoracentesis should be performed if the patient is febrile, has pleural effusions of disparate size, has a unilateral pleural effusion, does not have cardiomegaly, has pleuritic chest pain, or has a PaO_2 inappropriate for the degree of pulmonary edema.

Treatment consists of decreasing venous hypertension and improving cardiac output with diuretics, digitalis, and afterload reduction. In successfully managed heart failure, the effusions resolve during days to weeks after the pulmonary edema has cleared.

Hepatic Hydrothorax

Pleural effusions occur in approximately 6% of patients with cirrhosis of the liver and clinical ascites. The effusions result from movement of ascitic fluid through congenital or acquired diaphragmatic defects [32–34].

The patient usually has the classic stigmata of cirrhosis and clinically apparent ascites. The usual chest radiograph shows a normal cardiac silhouette and a right-sided pleural effusion, which can vary from small to massive; effusions are less likely isolated to the left pleural space or are bilateral [32–35]. Rarely, a massive pleural effusion may be found without clinical ascites (demonstrated only by US), implying the presence of a large diaphragmatic defect. The pleural fluid is a serous transudate with a low nucleated cell count and a predominance of mononuclear cells, pH greater than 7.40, and a glucose level similar to that of serum [13]. The fluid can be hemorrhagic due to an underlying coagulopathy or rupture of a diaphragmatic bleb. Demonstrating that pleural and ascitic fluids have similar protein and lactate dehydrogenase concentrations, substantiates the diagnosis [32]. If the diagnosis is problematic, injection of a radionuclide into the ascitic fluid with detection on chest imaging within 1 to 2 hours supports a pleuroperitoneal communication through a diaphragmatic defect [36]; delayed demonstration of the tracer suggests that the pathogenesis of the effusion is via convection through the mesothelium.

Hepatic hydrothorax may be complicated by spontaneous bacterial empyema (SBE), which is analogous to spontaneous bacterial peritonitis. The criteria for diagnosis of SBE are similar to those for the diagnosis of spontaneous bacterial peritonitis. SBE must be considered in the differential diagnosis of the infected cirrhotic patient, even in the absence of clinical ascites [37,38]. The pleural fluid culture and analysis may reveal positive culture, a total neutrophil count of more than 500 cells per μL, and a serum to pleural fluid albumin gradient greater than 1.1. The chest radiograph should not show a pneumonic process. Treatment of SBE is conservative with antibiotics unless purulence is present, in which case tube thoracostomy must be considered.

Treatment of hepatic hydrothorax is directed at resolution of the ascites, using sodium restriction and diuresis. The effusion frequently persists unchanged until all ascites is mobilized. If the patient is acutely dyspneic or in respiratory failure, therapeutic thoracentesis should be done as a temporizing measure. Care should be exercised with paracentesis or thoracentesis because hypovolemia can occur with rapid evacuation of fluid. Chest tube insertion should be avoided as it can cause infection of the fluid, and prolonged drainage can lead to protein and lymphocyte depletion and renal failure. Chemical pleurodesis via a chest tube is often unsuccessful due to rapid movement of ascitic fluid into the pleural space. Treatment options in hepatic hydrothorax refractory to medical management include transjugular intrahepatic portal systemic shunt and video-assisted thoracoscopy to patch the diaphragmatic defect, followed by pleural abrasion or talc poudrage in the properly selected patient [39,40].

Hypoalbuminemia

Many patients admitted to a medical ICU have a chronic illness and associated hypoalbuminemia. When the serum albumin level falls below 1.8 g per dL, pleural effusions may be observed [41]. Because the normal pleural space has an effective lymphatic drainage system, pleural fluid tends to be the last collection of extravascular fluid that occurs in patients with low oncotic pressure. Therefore, it is unusual to find a pleural effusion solely due to hypoalbuminemia in the absence of anasarca. Patients with hypoalbuminemic pleural effusions tend not to have pulmonary symptoms unless there is underlying lung disease, as the effusions are rarely large. Chest radiograph shows small-to-moderate bilateral effusions and a normal heart size. The pleural fluid is a serous transudate with less than 1,000 nucleated cells per μL, predominantly lymphocytes and mesothelial cells. The pleural fluid glucose level is similar to that of serum, and the pH is in the range of 7.45 to 7.55. Diagnosis is presumptive if other causes of transudative effusions can be excluded. The effusions resolve when hypoalbuminemia is corrected.

Iatrogenic

Extravascular migration of a central venous catheter can cause pneumothorax, hemothorax, chylothorax, or a transudative pleural effusion [42–44]. Its incidence is estimated at less than 1% but may be considerably higher. Malposition of the catheter on placement should be suspected if there is absence of blood return or questionable central venous pressure measurements. The immediate postprocedure chest radiograph should be assessed for proper catheter placement; a catheter placed from the right side should not cross the midline. If the catheter is not in the appropriate vessel, phlebitis, perforation of a vein or the heart, or instillation of fluid into the mediastinum or pleural space can occur. In the alert patient, acute infusion of intravenous fluid into the mediastinum usually results in new-onset chest discomfort and dyspnea. Depending on the volume and the rate at which it is introduced into the mediastinum, tachypnea, worsening respiratory status, and cardiac tamponade may ensue. The chest radiograph shows the catheter tip in an abnormal position [45,46], a widened mediastinum, and evidence of unilateral or bilateral pleural effusions. The effusion can have characteristics similar to those of the infusate (milky if lipid is being given) and may be hemorrhagic and neutrophil-predominant due to trauma and inflammation. The pleural fluid to serum glucose ratio is greater than 1.0 if glucose is being infused [43]. The pleural fluid glucose concentration can fall rapidly after glucose infusion into the pleural space, probably explaining the relatively low glucose concentrations in pleural fluid compared to the infusate [47]. Extravascular migration of a central venous catheter appears to be more common with placement in the external jugular vein, particularly on the left side. Left-sided catheters appear to put the patient at increased risk of perforation because of the horizontal orientation of the left compared to the right brachiocephalic vein. When catheters are introduced from the left side, they should be of adequate length for the tip to rest in the superior vena cava.

Free flow of fluid and proper fluctuation in central venous pressure during the respiratory cycle may not be reliable indicators of intravascular placement. This is probably because intrathoracic pressure changes are transmitted to the mediastinum and, thus, the venous pressure catheter. Aspiration of blood or retrograde flow of blood when the catheter is lowered below the patient's heart level should confirm intravascular catheter placement. If blood cannot be aspirated and the effusate is aspirated instead, extravascular migration is assured. The central venous catheter should be removed immediately. If there is a small effusion, observation is warranted. If the effusion is large, causing respiratory distress, or a hemothorax is discovered, thoracentesis or tube thoracostomy should be performed.

Parapneumonic Effusions

Community-acquired or nosocomial pneumonia is common in critically ill patients. The classic presentation is fever, chest pain, leukocytosis, purulent sputum, and a new alveolar infiltrate on chest radiograph. In the elderly, debilitated patient, however, many of these findings may not be present. The chest radiograph commonly shows a small-to-large ipsilateral pleural effusion [48–50]. When the effusion is free-flowing and anechoic on ultrasound, and thoracentesis shows a nonpurulent, polymorphonuclear (PMN) predominant exudate with a pH of 7.30 or greater, it is highly likely that the effusion will resolve during 7 to 14 days without sequelae with antibiotics alone (uncomplicated effusion). If the chest radiograph or CT demonstrates loculation and pus is aspirated, the diagnosis of empyema is established and immediate drainage is needed. In the free-flowing nonpurulent fluid, if Gram's stain or culture is positive or pH is less than 7.30, the likelihood of a poor outcome increases, and the pleural space should be drained.

Although a meta-analysis found that low risk patients with fluid pH between 7.20 and 7.30 may be managed without tube drainage, the patient admitted to the ICU typically cannot be considered low risk, and pH values of less than 7.30 should prompt drainage in most cases [51–53]. Drainage can be accomplished by standard chest tube or small-bore catheter. When loculations occur, pleural space drainage should be accomplished by placement of image-guided tubes or catheters with fibrinolytics or empyectomy and decortication [54,55]. Most thoracic surgeons routinely begin with thoracoscopy and, if not successful, proceed directly to a standard thoracotomy for empyectomy and decortication [56–59].

Pancreatitis

Pleuropulmonary abnormalities are commonly associated with pancreatitis, largely due to the close proximity of the pancreas to the diaphragm. Approximately half of patients with pancreatitis have an abnormal chest radiograph, with pleural effusions in 3% to 17% [60,61]. Mechanisms that may be involved in the pathogenesis of pancreatic pleural effusion include (a) direct contact of pancreatic enzymes with the diaphragm (sympathetic effusion), (b) transfer of ascitic fluid via diaphragmatic defects, (c) communication of a fistulous tract between a pseudocyst and the pleural space, and (d) retroperitoneal movement of fluid into the mediastinum with mediastinitis or rupture into the pleural space [60,62]. Ascitic amylase moves into the pleural space via the previously mentioned mechanisms. The pleural fluid-to-serum amylase ratio is greater than unity in pancreatitis because of slower lymphatic clearance from the pleural space compared with more rapid renal clearance.

The effusion associated with acute pancreatitis is usually small and left-sided (60%), but may be isolated to the right side (30%) or be bilateral (10%) [60]. The patient usually presents with abdominal symptoms of acute pancreatitis. The diagnosis is confirmed by an elevated pleural fluid amylase concentration that is greater than that in serum. A normal pleural fluid amylase may be found early in acute pancreatitis, but increases on serial measurements. The fluid is a PMN-predominant exudate with glucose values approximating those of serum. Leukocyte counts may reach 50,000 cells per μL. The pleural fluid pH is usually 7.30 to 7.35.

No specific treatment is necessary for the pleural effusion of acute pancreatitis; the effusion resolves as the pancreatic inflammation subsides. Drainage of the pleural space does not appear to affect residual pleural damage. If the pleural effusion does not resolve in 2 to 3 weeks, pancreatic abscess or pseudocyst should be excluded.

Pulmonary Embolism

The presence of a unilateral pleural effusion may suggest pulmonary embolism or obscure the diagnosis by directing attention to a primary lung or cardiac process. Pleural effusions occur in approximately 40% of patients with pulmonary embolism [63]. These effusions result from several different mechanisms including increased pleural capillary permeability, imbalance in microvascular and pleural space hydrostatic pressures, and pleuropulmonary hemorrhage [63,64]. Ischemia from pulmonary vascular obstruction, in addition to release of inflammatory mediators from platelet-rich thrombi, can cause capillary leak into the lung and, subsequently, the pleural space, explaining the usual finding of an exudative effusion.

Transudates, described in approximately 20% of patients with pulmonary embolism, result from atelectasis [64].

With pulmonary infarction, necrosis and hemorrhage into the lung and pleural space may result. More than 80% of patients with infarction have bloody pleural effusions, but more than 35% of patients with pulmonary embolism without radiographic infarction also have hemorrhagic fluid [63]. The presence of a pleural effusion does not alter the signs or symptoms in patients with pulmonary embolism. Chest pain, usually pleuritic, occurs in most patients with pleural effusions complicating pulmonary embolism, and is invariably ipsilateral [63]. The chest radiograph virtually always shows a unilateral effusion that occupies less than one third of the hemithorax [63]. An associated pulmonary infiltrate (infarction) is seen in approximately half of patients with pulmonary embolism and effusion.

Pleural fluid analysis is variable and nondiagnostic [64]. The pleural fluid is hemorrhagic in two thirds of patients, but the number of red blood cells exceeds 100,000 per μL in less than 20% [64]. The nucleated cell count ranges from less than 100 (atelectatic transudates) to greater than 50,000 per μL (pulmonary infarction) [64]. There is a predominance of PMNs when a thoracentesis is performed near the time of the acute injury and of lymphocytes with later thoracentesis. The effusion due to pulmonary embolism is usually (92%) apparent on the initial chest radiograph and reaches a maximum volume during the first 72 hours [63]. Patients with pleural effusions that progress with therapy should be evaluated for recurrent embolism, hemothorax secondary to anticoagulation, an infected infarction, or an alternate diagnosis. When consolidation is absent on chest radiograph, effusions usually resolve in 7 to 10 days; with consolidation, the resolution time is 2 to 3 weeks [64].

The association of pleural effusion with pulmonary embolism does not alter therapy. Furthermore, the presence of a bloody effusion is not a contraindication to full-dose anticoagulation because hemothorax is a rare complication of heparin therapy [65]. An enlarging pleural effusion on therapy necessitates thoracentesis to exclude hemothorax, empyema, or another cause. Active pleural space hemorrhage necessitates discontinuation of anticoagulation, tube thoracostomy, and placement of a vena cava filter.

Postcardiac Injury Syndrome

Postcardiac injury syndrome (PCIS) is characterized by fever, pleuropericarditis, and parenchymal infiltrates 3 weeks (2 to 86 days) after injury to the myocardium or pericardium [66–68]. PCIS has been described after myocardial infarction, cardiac surgery, blunt chest trauma, percutaneous left ventricular puncture, and pacemaker implantation. The incidence after myocardial infarction has been estimated at up to 4% of cases [66], but with more extensive myocardial and pericardial involvement, it may be higher. It occurs with greater frequency (up to 30%) after cardiac surgery [69]. The pathogenesis of PCIS remains obscure but is probably on an autoimmune basis in patients with myocardial or pericardial injury and, possibly, concomitant viral illness [70].

The diagnosis of PCIS remains one of exclusion, for no specific criteria exist. It is important to diagnose or exclude PCIS presumptively. Failure to diagnose accurately could lead to iatrogenic complications from inappropriate therapy, such as cardiac tamponade from anticoagulation for presumed pulmonary embolism and adverse effects related to antimicrobial therapy for presumed pneumonia.

Pleuropulmonary manifestations are the hallmark of PCIS. The most common presenting symptoms are pleuritic chest pain, found in virtually all patients, and fever, pericardial rub, dyspnea, and rales, which occur in half of patients [68]. Rarely, hemoptysis occurs, an important differential point when pulmonary embolism with infarction is in the differential diagnosis. Fifty percent of patients have leukocytosis, and almost all have an elevated erythrocyte sedimentation rate (average, 62 mm per hour) [68].

The chest radiograph is abnormal in virtually all patients, with the most common abnormality being left-sided and bilateral pleural effusions; a unilateral right effusion is unusual [68]. Pulmonary infiltrates are present in 75% of patients and are most commonly seen in the left lower lobe [66]. The pleural fluid is a serosanguineous or bloody exudate with a glucose level greater than 60 mg per dL and pleural fluid pH greater than 7.30. Nucleated cell counts range from 500 to 39,000 per μL, with a predominance of PMNs early in the course [68]. Pericardial fluid on echocardiogram is an important finding suggesting PCIS. The pleural fluid characteristics should help differentiate PCIS from a parapneumonic effusion and CHF, but do not exclude pulmonary embolism.

PCIS is usually self-limited and may not require therapy if symptoms are trivial. It usually responds to aspirin or nonsteroidal anti-inflammatory agents, but some patients require corticosteroid therapy for resolution. In those who respond, the pleural effusion resolves within 1 to 3 weeks.

Esophageal Sclerotherapy

Pleural effusions are found in approximately 50% of patients 48 to 72 hours after esophageal sclerotherapy with sodium morrhuate and in 19% of patients after absolute alcohol sclerotherapy [71–73]. Effusions may be unilateral or bilateral, with no predilection for side. Effusion appears more likely with larger total volumes of sclerosant injected and larger volume injected per site [71,72]. The effusions tend to be small, serous exudates with variable nucleated (90 to 38,000 per μL) and red cell counts (126 to 160,000 per μL) and glucose concentration similar to that of serum [71]. These effusions probably result from an intensive inflammatory reaction after extravasation of the sclerosant into the esophageal mucosa, resulting in mediastinal and pleural inflammation. The effusion not associated with fever, chest pain, or evidence of perforation is of little consequence, requires no specific therapy, and resolves during several days to weeks [71,72]. However, late perforation may evolve in patients with apparent innocuous effusions. In patients with symptomatic effusions for 24 to 48 hours, diagnostic thoracentesis should be done and an esophagram considered.

Acute Respiratory Distress Syndrome

The presence of pleural effusions in ARDS has not been well appreciated. In a retrospective study of 25 patients with ARDS, a 36% incidence of pleural effusions was found, a percentage similar to that found with hydrostatic pulmonary edema [74]. All patients had extensive alveolar pulmonary edema and endotracheal tube fluid that was compatible with increased permeability edema. Several experimental models of increased permeability pulmonary edema, including α-naphthyl thiourea, oleic acid, and ethchlorvynol, have been shown to produce pleural effusions. In the oleic acid and ethchlorvynol models, the development of pleural effusions lagged behind interstitial and alveolar edema by several hours. In the oleic acid model, 35% of the excess lung water collected in the pleural spaces. It appears that the pleura act as a reservoir for excess lung water in increased permeability and hydrostatic pulmonary edema. These effusions tend to be underdiagnosed clinically because the patient has bilateral alveolar infiltrates and the radiograph

is taken with the patient in a supine position. Experimentally, the effusion is serous to serosanguineous, with a predominance of PMNs. These effusions usually require no specific therapy and resolve as ARDS resolves. However, in a series of positive end-expiratory pressure (PEEP)-unresponsive patients with ARDS, drainage of pleural effusion via tube thoracostomy has been shown to result in improved oxygenation [75]. The decision to proceed to pleural space drainage in ARDS should be approached on a case-by-case basis and is not generally recommended.

Spontaneous Esophageal Rupture

Esophageal rupture, a potentially life-threatening event, requires immediate diagnosis and therapy. The history in spontaneous esophageal rupture is usually severe retching or vomiting or a conscious effort to resist vomiting. In some patients, the perforation may be silent. Early recognition of spontaneous rupture depends on interpretation of the chest radiograph. Several factors influence chest radiograph findings: the time between perforation and chest radiograph examination, site of perforation, and mediastinal pleural integrity [76]. A chest radiograph taken within minutes of the acute injury is usually unremarkable. Mediastinal emphysema probably requires at least 1 to 2 hours to be demonstrated radiographically and is present in less than half of patients; mediastinal widening may take several hours [77]. Pneumothorax, present in 75% of patients with spontaneous rupture, indicates violation of the mediastinal pleura; 70% of pneumothoraces are on the left, 20% are on the right, and 10% are bilateral [77]. Mediastinal air is seen early if pleural integrity is maintained, whereas pleural effusion secondary to mediastinitis tends to occur later. Pleural fluid, with or without associated pneumothorax, occurs in 75% of patients. A presumptive diagnosis should immediately be confirmed radiographically. Esophagrams are positive in approximately 90% of patients [78]. In the upright patient, rapid passage of the contrast material may not demonstrate a small rent; therefore, the study should be done with the patient in the appropriate lateral decubitus position [79].

Pleural fluid findings depend on the degree of perforation and the timing of thoracentesis from injury. Early thoracentesis without mediastinal perforation shows a sterile, serous exudate with a predominance of PMNs, a pleural fluid amylase less than serum, and pH greater than 7.30 [80]. Once the mediastinal pleura tears, amylase of salivary origin appears in the fluid in high concentration [81]. As the pleural space is seeded with anaerobic organisms from the mouth, the pH falls rapidly and progressively to approach 6.00 [80,82]. Other pleural fluid findings suggestive of esophageal rupture include the presence of squamous epithelial cells and food particles. The diagnosis of spontaneous esophageal rupture dictates immediate operative intervention. If diagnosed and treated appropriately within the first 24 hours with primary closure and drainage, survival is greater than 90% [77]. Delay from the time of initial symptoms to diagnosis results in a reduced survival with any form of therapy.

Hemothorax

Hemothorax (blood in the pleural space) should be differentiated from a hemorrhagic pleural effusion, as the latter can be the result of only a few drops of blood in pleural fluid. An arbitrary, but practical, definition of a hemothorax with regard to therapy is a pleural fluid-to-blood hematocrit ratio greater than 30%. The majority of hemothoraces results from penetrating or blunt chest trauma [83]. Hemothorax can also result from invasive procedures, such as placement of central venous catheters, thoracentesis, and pleural biopsy, and pulmonary infarction, malignancy, or ruptured aortic aneurysm. Bleeding can occur from vessels of the chest wall, lung, diaphragm, or mediastinum. Blood that enters the pleural space clots, rapidly undergoes fibrinolysis, and becomes defibrinogenated; thus, it rarely causes significant pleural fibrosis.

Hemothorax should be suspected in any patient with blunt or penetrating chest trauma. If a pleural effusion is found on the admitting chest radiograph, thoracentesis should be performed immediately and the hematocrit measured on the fluid. The hemothorax may not be apparent on the initial chest radiograph, which may be due to the supine position of the patient. Because bleeding may be slow and not appear for several hours, it is imperative that serial radiographs be obtained in these patients. The incidence of concomitant pneumothorax is high (approximately 60%) [83]. Patients with traumatic hemothorax should be treated with immediate tube thoracostomy [83–85]. Large-diameter chest tube drainage evacuates the pleural space, may tamponade the bleeding (especially if the origin is from a pleural laceration), allows monitoring of the bleeding, and decreases the likelihood of subsequent fibrothorax [85,86]. If bleeding continues without signs of slowing, thoracotomy should be performed, depending on the individual circumstance [85]. Pleural effusions occasionally occur after removal of the chest tube from traumatic hemothoraces [87]. A diagnostic thoracentesis is indicated to exclude empyema. If empyema is excluded, the pleural effusion usually resolves without specific treatment and without residual pleural fibrosis.

Hemothorax is a rare complication of anticoagulation and has been reported in patients receiving heparin and warfarin. Coagulation studies are usually within the therapeutic range. The hemothorax tends to occur on the side of the pulmonary embolism. Anticoagulation should be discontinued immediately, a chest tube inserted to evacuate the blood, and a vena cava filter considered.

Coronary Artery Bypass Surgery

A small, left pleural effusion is virtually always present after coronary artery bypass surgery. This is associated with left lower lobe atelectasis and elevation of the left hemidiaphragm on chest radiograph. Left diaphragm dysfunction is secondary to intraoperative phrenic nerve injury from cold cardioplegia, stretch injury, or surgical trauma [88–90]. The larger and grossly bloody effusions tend to be associated with internal mammary artery grafting, which causes marked exudation from the bed where the internal mammary artery was harvested [91].

The pleural fluid is a hemorrhagic exudate with a low nucleated cell count, a glucose level similar to that of serum, and a pH greater than 7.40. Rarely, a loculated hemothorax may develop with trapped lung, resulting in clinically significant restriction [92]. If there is a large effusion that qualifies as a hemothorax (see previous section), the fluid should be drained by tube thoracostomy. It is also prudent to drain moderately large, bloody effusions to avoid later necessity for decortication.

Abdominal Surgery

Approximately half of the patients who undergo abdominal surgery develop small unilateral or bilateral pleural effusions within 48 to 72 hours of surgery [27,28]. The incidence is higher after upper abdominal surgery, in patients with postoperative atelectasis, and in patients who have free ascitic fluid at the time of surgery [27]. Larger left-sided pleural effusions are common after splenectomy [27]. The effusion is usually an exudate with less than 10,000 nucleated cells per μL. The

glucose level is similar to that of serum, and pH is usually greater than 7.40 [27]. The effusion usually is related to diaphragmatic irritation or atelectasis. Small effusions generally do not require diagnostic thoracentesis, are of no clinical significance, and resolve spontaneously. Pleural effusion from subphrenic abscess or pulmonary embolism is unlikely to occur within 2 to 3 days of surgery. The only indication for diagnostic thoracentesis would be to exclude infection if the effusion is relatively large or loculated.

Chylothorax

Trauma from surgery accounts for approximately 25% of cases of chylothorax, second only to lymphoma. Most series estimate an incidence of chylothorax of less than 1% after thoracic surgery [93], but a 3% incidence has been reported after esophagectomy [94]. Virtually all intrathoracic procedures, including lobectomy, pneumonectomy, and coronary artery bypass grafting, have been reported to cause chylothorax. Other iatrogenic chylothoraces can be caused by complications of prolonged central vein catheterization. Nonsurgical trauma, such as penetrating and nonpenetrating neck, thoracic, and upper abdominal injuries, also has been associated with chylothorax.

When the thoracic duct is torn by stretching during surgery, chyle leaks into the mediastinum and subsequently ruptures through the mediastinal pleura. In the nonsurgical setting, penetrating injuries and fractures may directly tear the thoracic duct. Chylothorax from a central venous catheter usually involves venous thrombosis. Other rare causes of chylothorax include sclerotherapy of esophageal varices and translumbar aortography [95–97].

The patient may be asymptomatic if the effusion is small and unilateral, or may present with dyspnea with a large unilateral effusion or bilateral effusions. The pleural fluid is usually milky, but 12% can be serous or serosanguineous [98], with less than 7,000 nucleated cells per μL, virtually all lymphocytes. The pleural fluid pH is alkaline (7.40 to 7.80), and triglyceride levels are greater than plasma levels. Finding a pleural fluid triglyceride concentration of greater than 110 mg per dL makes the diagnosis of chylothorax highly likely [98]. If the triglyceride level is less than 50 mg per dL, chylothorax is highly unlikely. Triglyceride levels of 50 to 110 mg per dL indicate the need for lipoprotein electrophoresis [98]; the presence of chylomicrons confirms a chylothorax. The thoracic duct defect after trauma usually closes spontaneously within 10 to 14 days, with chest tube drainage as well as bed rest and total parenteral nutrition to minimize chyle formation. A pleuroperitoneal shunt relieves dyspnea, recirculates chyle, and prevents malnutrition and immunocompromise.

Duropleural Fistula

Disruption of the dura and parietal pleura by surgical and nonsurgical trauma may result in a duropleural fistula with subsequent development of a pleural effusion [99–102]. The pleural fluid characteristics depend on the severity of the trauma and the delay between the trauma and the pleural fluid analysis. Pleural fluid due to a chronic duropleural fistula is usually a colorless transudate with low mononuclear cell count; a duropleural fistula associated with recent trauma may be a transudate or an exudate [101,102]. The diagnosis may even be delayed because of a coexisting process such as hemothorax. The diagnosis of duropleural fistula is established by the detection of β_2-transferrin in the pleural fluid [103]. Confirmation of the fistula by conventional or radionuclide myelography is recommended if surgical management is contemplated.

PNEUMOTHORAX

Definition and Classification

Pneumothorax refers to air in the pleural space. Free air may also be found in the adventitial planes of the lung or the mediastinum (pneumomediastinum).

Spontaneous pneumothorax occurs without an obvious cause as a consequence of the natural course of a disease process. Primary spontaneous pneumothorax occurs without clinical findings of lung disease. Secondary spontaneous pneumothorax occurs as a consequence of clinically manifest lung disease, the most common being COPD. Traumatic pneumothorax results from penetrating or blunt chest injury. Iatrogenic pneumothorax occurs as an inadvertent consequence of diagnostic or therapeutic procedures.

Pathophysiology

Pressure in the pleural space is subatmospheric throughout the normal respiratory cycle, averaging approximately −9 mm Hg during inspiration and −5 mm Hg during expiration. Because of airways resistance, pressure in the airways is positive during expiration (+3 mm Hg) and negative (−2 mm Hg) during inspiration. Thus, in normal breathing, airway pressure is greater than pleural pressure throughout the respiratory cycle. Airway pressure may be increased markedly with coughing or strenuous exercise; however, pleural pressure rises concomitantly so that the transpulmonary pressure gradient is usually not substantially changed. When there are rapid fluctuations in intrathoracic pressure, however, a large transpulmonary pressure gradient occurs transiently. Bronchial and bronchiolar obstruction, resulting in air trapping, can significantly increase the transpulmonary pressure gradient. The alveolar walls and visceral pleura maintain the pressure gradient between the airways and pleural space. When the pressure gradient is transiently increased, alveolar rupture may occur; air enters the interstitial tissues of the lung and may enter the pleural space, resulting in a pneumothorax. If the visceral pleura remain intact, the interstitial air moves toward the hilum, resulting in pneumomediastinum [104,105]. Because mean pressure within the mediastinum is always less than in the periphery of the lung, air moves proximally along the bronchovascular sheaths to the hilum and mediastinal soft tissues. The development of pneumomediastinum after alveolar rupture requires continual cyclic respiratory efforts, which result in slow movement of air from the ruptured alveolus along a pressure gradient to the mediastinum [105]. Mediastinal air may decompress into the cervical and subcutaneous tissues or the retroperitoneum. With abrupt rise in mediastinal pressure or insufficient decompression to subcutaneous tissue, the mediastinal pleura may rupture, causing pneumothorax. Inadequate decompression of the mediastinum, rather than direct rupture of subpleural blebs into the pleural space, may be the major cause of pneumothorax [104].

When pneumothorax occurs, the elasticity of the lung causes it to collapse. Lung collapse continues until the pleural defect seals or pleural and alveolar pressures equalize. When a ball-valve effect occurs at the site of communication between the pleural space and the alveolus, permitting only egress of air from the lung, there is a progressive accumulation of air within the pleural space, which can result in markedly increased positive pleural pressure, producing a tension pneumothorax. Tension pneumothorax compresses mediastinal structures, resulting in impaired venous return to the heart, decreased cardiac output, and, at times, fatal cardiovascular collapse [106,107]. Rarely, tension along the bronchovascular sheaths

and in the mediastinum can cause collapse of the pulmonary arteries and veins, resulting in cardiovascular collapse [104].

Patients with primary spontaneous pneumothorax have a decrease in vital capacity and an increase in the $P(A–a)O_2$ gradient, and usually present with hypoxemia due predominantly to the development of an intrapulmonary shunt and areas of low ventilation–perfusion in the atelectatic lung [108,109]. Hypercapnia does not occur because there is adequate function in the uninvolved lung to maintain necessary alveolar ventilation. Patients with secondary spontaneous pneumothorax, in contrast, commonly develop hypercapnia because the gas exchange abnormality caused by the pneumothorax is superimposed on lungs with preexisting abnormal pulmonary gas exchange.

Pneumothorax in the Intensive Care Unit

Patients with secondary spontaneous pneumothorax may be admitted to an ICU because they develop severe hypoxemic and, at times, hypercapnic respiratory failure. Patients with primary spontaneous pneumothorax rarely require ICU admission because the contralateral lung can maintain necessary alveolar ventilation and the hypoxemia can be managed with supplemental oxygen. The most common causes of pneumothoraces in ICU patients are invasive procedures and barotrauma.

Iatrogenic Pneumothorax

Central Venous Catheters. Central venous catheters are used routinely in critically ill patients for volume resuscitation, parenteral nutrition, and drug administration. Approximately 3 million central venous catheters are placed annually in the United States, and this procedure continues to be associated with clinically relevant morbidity and some mortality. The morbidity and mortality associated with central venous catheter use are most commonly physician-related [42]. Pleural complications of acquisition of venous access and the indwelling phase of central venous catheters include pneumothorax, hydrothorax, hemothorax, and chylothorax. In a recent study of mechanical complications of central venous catheters, 1.1% of 534 patients had pneumothorax [110]. This translates into approximately 33,000 pneumothoraces per year from central venous catheter insertions in critically ill patients in the United States. In the same study, none of the 405 patients developed pneumothorax when the central venous catheter was replaced over a guidewire.

The subclavian and internal jugular routes have been associated with pneumothorax, hemothorax, chylothorax, and catheter placement into the pleural space. Cannulation of the subclavian vein is associated with a higher risk of pneumothorax (less than 5%) [111] than cannulation of the internal jugular vein (less than 0.2%) [112]; with the external jugular venous approach, pneumothorax is avoided. There is a greater risk of pneumothorax with the infraclavicular compared to the supraclavicular approach to the subclavian vein. All complications of insertion, regardless of approach, can be reduced by appropriate physician training and experience. Operator inexperience appears to increase the number of complications with the internal jugular approach. It probably does not have as much impact on the incidence of pneumothorax with the subclavian vein approach, which accounts for 25% to 50% of all complications [113].

Most pneumothoraces occur at the time of the procedure from direct lung puncture, but delayed pneumothoraces have been noted; therefore, it is prudent to view a chest radiograph 12 to 24 hours after the procedure. Up to half of the patients with needle puncture pneumothorax may be managed expectantly without the need for tube drainage. Bilateral pneumothoraces have been reported to occur from unilateral attempts [113], and death can occur when there is a delay in the diagnosis of pneumothorax. As stated previously, a pneumothorax may be more difficult to detect while the patient is supine. Additional views should be taken, especially if the venous cannulation does not proceed as anticipated. With any newly placed central venous catheter, a postprocedure chest radiograph should be obtained, regardless of the site cannulated, to assure that the catheter tip is properly positioned. If a small pneumothorax is diagnosed by chest radiograph and the patient is asymptomatic and not on mechanical ventilation, the patient can be followed expectantly with repeat chest radiographs to assure that the leak has ceased. If the patient is on mechanical ventilation or the pneumothorax is large or has caused significant symptoms or gas exchange abnormalities, then tube thoracostomy should be performed as soon as possible.

Barotrauma. Pulmonary barotrauma is an important clinical problem because of the widespread use of mechanical ventilation. Barotrauma occurs in approximately 3% to 10% of patients on mechanical ventilation and includes parenchymal interstitial gas, pneumomediastinum, subcutaneous emphysema, pneumoperitoneum, and pneumothorax [7,114–118]. The most clinically important form is pneumothorax, occurring in 1% to 15% of all patients on mechanical ventilation. In patients with ARDS, rates of 6.5% to 87% have been reported [117,118]. The number of ventilation days, underlying disease (ARDS, COPD, necrotizing pneumonia), and use of PEEP have an impact on the incidence of pneumothorax [114–116,119,120]. When a pneumothorax develops in the setting of mechanical ventilation, 30% to 97% of patients develop tension [7,115,119,120]. The reported incidence of barotrauma varies widely between the studies with the lowest incidences reported in the most recent large series [118]. This may be partly explained by the adoption of less aggressive ventilation strategies over time.

The initial radiographic sign of barotrauma is often pulmonary interstitial gas or emphysema [117,121]. In the early stages, however, interstitial gas may be difficult to detect radiographically. This harbinger of pneumothorax may be detected as distinct subpleural air cysts, linear air streaks emanating from the hilum, and perivascular air halos. Subpleural air cysts, most commonly seen in ARDS, tend to appear abruptly on the chest radiograph as single or multiple thin-walled, round lucencies, and are most often visualized at the lung bases, medially or diaphragmatically [122]. The cysts, which may expand rapidly, are usually 3 to 5 cm in diameter. Differentiating between peripheral subpleural air cysts and a localized basilar pneumothorax may be problematic. Pleural air cysts appear to be more common in younger patients, possibly because connective tissue planes of the lung are looser in younger patients than in older patients [123]. The risk of tension pneumothorax is substantial in patients who have developed subpleural lung cysts with continued mechanical ventilation. When mechanical ventilation is discontinued, the cyst may resolve spontaneously or become secondarily infected.

US has emerged as a bedside modality for the detection of pneumothorax. The absence of lung sliding is the finding associated with pneumothorax [6]. False-positive results may occur and are due to bullous lung disease or preexisting pleural symphysis [6,124,125]. The disappearance of lung sliding that was present previously may be more specific for the development of pneumothorax; for example, after line placement. However, this subject awaits further study.

When evidence of barotrauma without pneumothorax is observed in any patient requiring continued mechanical ventilation, immediate attempts should be made to lower the plateau airway pressure. In ARDS, tidal volumes [126,127] and inspiratory flow rates should be lowered, an attempt should be

made to reduce or remove PEEP, and neuromuscular blockers and sedation should be considered [128]. In status asthmaticus, in addition to the aforementioned maneuvers, controlled hypoventilation should be accomplished [129,130]. There is no evidence supporting the use of prophylactic chest tubes. However, the patient should be monitored closely for tension pneumothorax and provisions made for emergency bedside tube thoracostomy.

Tension Pneumothorax

Pneumothorax in the mechanically ventilated patient usually presents as an acute cardiopulmonary emergency, beginning with respiratory distress and, if unrecognized and untreated, progressing to cardiovascular collapse. In one report of 74 patients, the diagnosis of pneumothorax was made clinically in 45 (61%) patients based on hypotension, hyperresonance, diminished breath sounds, and tachycardia [120]. The mortality rate was 7% in these patients diagnosed clinically. In the remaining 29 patients, diagnosis was delayed between 30 minutes and 8 hours, and 31% of these patients died of pneumothorax. Other series of barotrauma in the setting of mechanical ventilation have reported mortality rates from 58% to 77% [7,116].

Tension pneumothorax is lethal if diagnosis and treatment are delayed. The diagnosis should be made clinically at the bedside for the patient on mechanical ventilation who develops a sudden deterioration characterized by apprehension, tachypnea, cyanosis, decreased ipsilateral breath sounds, subcutaneous emphysema, tachycardia, and hypotension. The diagnosis may be problematic in the unconscious patient, the elderly, and the patient with bilateral tension, which may be more protective of the mediastinal structures and lessen the impact on cardiac output.

In the unconscious or critically ill patient, hypoxemia may be one of the earlier signs of tension pneumothorax. In the patient on mechanical ventilation, increasing peak and plateau airway pressure, decreasing compliance, and auto-PEEP should raise the possibility of tension pneumothorax. Difficulty in bagging the patient and delivering adequate tidal volumes may be noted.

When the clinical signs and symptoms are noted in mechanically ventilated patients, treatment should not be delayed to obtain radiographic confirmation. If a chest tube is not immediately available, placement of a large-bore needle into the anterior second intercostal space on the suspected side is lifesaving and confirms the diagnosis, as a rush of air is noted on entering the pleural space. An appropriately large chest tube can then be placed and connected to an adequate drainage system that can accommodate the large air leak that may develop in mechanically ventilated patients [130].

On relief of the tension, there is a rapid improvement in oxygenation, increase in blood pressure, decrease in heart rate, and fall in airway pressures. In experimental tension pneumothorax, it has been observed that the inability to raise cardiac output in response to hypoxemia leads to a reduction in systemic oxygen transport and a decrease in mixed venous partial pressure of oxygen (PO_2), partially explaining the cardiovascular collapse seen in these patients [107]. In mechanically ventilated patients, a decrease in cardiac output is an inevitable consequence of tension pneumothorax.

BRONCHOPLEURAL FISTULA

Definition and Causes

Communication between the bronchial tree and the pleural space is a dreaded complication of mechanical ventilation [131,132]. There are three presentations of bronchopleural fistula (BPF): (a) failure to reinflate the lung despite chest tube drainage or continued air leak after evacuation of the pneumothorax in the setting of chest trauma; (b) complication of a diagnostic or therapeutic procedure, such as thoracic surgery; and (c) complication of mechanical ventilation, usually for ARDS [106]. In ARDS, often a pneumothorax occurs under tension and is later associated with empyema, multiple sites of leakage, and a poor prognosis. A large air leak through a BPF can result in failure of lung reexpansion, loss of a significant amount of each delivered tidal volume, loss of the ability to apply PEEP, inappropriate cycling of the ventilator [133], and inability to maintain alveolar ventilation (Table 57.3).

TABLE 57.3

CONSEQUENCES OF A LARGE BRONCHOPLEURAL FISTULA

Failure of lung reexpansion
Loss of delivered tidal volume
Inability to apply positive end-expiratory pressure
Inappropriate cycling of ventilator
Inability to maintain alveolar ventilation

If there is a continued air leak for longer than 24 hours after the development of pneumothorax, then a BPF exists. The main factors that perpetuate BPF are high airway pressures that increase the leak during inspiration, increased mean intrathoracic pressures throughout the respiratory cycle (PEEP, inflation hold, high inspiratory-to-expiratory ratio) that increase the leak throughout the breath, and high negative suction. In severe ARDS, all of these factors are present because they usually are necessary to support gas exchange and lung inflation.

Management

Given the frequency of barotrauma in BPF in mechanically ventilated patients, intensivists are called to give advice on the management of these difficult patients. Definitive therapy of BPF frequently involves invasive surgical approaches that include thoracoplasty, mobilization of the pectoralis or intercostal muscles, bronchial stump stapling, and decortication [134–139]. Although some of these techniques are still used today, there is a trend toward more conservative management of acute and chronic BPF, using innovations of standard techniques and new modalities that include chest tube management, drainage systems, ventilatory support, and definitive nonoperative therapy (Table 57.4). Even insertion of an endobronchial valve designed for the treatment of emphysema may be considered in selected patients [140]. Nonoperative therapy provides an alternative to the surgical approaches in patients who are poor operative candidates. Each patient with a BPF is unique and requires individual management based on the specific clinical setting. Attention to the basics of medical care of patients with BPF should not be neglected in the face of the potentially dramatic events related to the BPF. Nutritional status must be maintained, appropriate antibiotics used for the infected pleural space, and the space adequately drained.

Chest Tubes

The initial therapy for pneumothorax in a patient on mechanical ventilation is placement of a chest tube in an attempt to reexpand the lung (see Chapter 8). The chest tube is initially necessary, can be detrimental later, and may play a role more

TABLE 57.4

MANAGEMENT OF BRONCHOPLEURAL FISTULA IN PATIENTS REQUIRING MECHANICAL VENTILATION

- Conservative
  - Adequate-size chest tube
  - Use of drainage system with adequate capabilities
  - Mechanical ventilation
    - Conventional (controlled, assist-control, intermittent mandatory ventilation)
    - High frequency
    - Independent lung
  - Flexible bronchoscopy
    - Direct application of sealant
- Invasive
  - Mobilization of intercostal or pectoralis muscles
  - Thoracoplasty
  - Bronchial stump stapling
  - Pleural abrasion and decortication

important than that of a passive conduit. Air leaks in the setting of BPF range from less than 1 to 16 L per minute [141]; therefore, a chest tube that permits prompt and efficient drainage of this level of airflow is required. Gas moves through a tube in a laminar fashion and is governed by Poiseuille's law ($v = [\pi r^4 P/8lV]t$). In the clinical setting, the gas moving through a chest tube is moist; therefore, it is subject to turbulent flow and governed by the Fanning equation ($v = [\pi r^2 r^5 P/fl]$) [141–143]. Therefore, both the length (l) and, even more so, the radius (r) are important when choosing a chest tube and connecting tubing to evacuate a BPF adequately (as flow varies exponentially to the fifth power of the radius of the tube). The smallest internal diameter that allows a maximum flow of 15.1 L per minute at −10 cm H_2O suction is 6 mm [141,142] (a 32-Fr chest tube has an internal diameter of 9 mm). A chest tube with a diameter adequate to convey the potentially large airflow of the BPF must be considered. A chest tube with too small a diameter can lead to lung collapse and tension pneumothorax in the setting of a mobile mediastinum.

Not only can the chest tube be used to drain pleural air, it can also be used to limit the air leak in certain situations. One modality is the application of intrapleural pressure equivalent to the level of PEEP during the expiratory phase of ventilation [144–146]. With positive intrapleural pressure applied through the chest tube, the air leak persists during the inspiratory phase of ventilation but decreases during expiration, allowing maintenance of PEEP in patients in whom it is necessary for adequate oxygenation. Synchronized closure of the chest tube during the inspiratory phase has also been used to control the air leak [147,148]. A combination of these techniques has been suggested for patients with significant BPF air leaks during both the inspiratory and expiratory phases of mechanical ventilation [131,148]. These techniques pose potential hazards, including increased pneumothorax and tension pneumothorax [131,147], necessitating extremely close patient monitoring when such manipulations are used.

Instillation of chemical agents through the chest tube may potentially help close the BPF if the anatomic defect is small and single, but it is unlikely to be successful if the fistula is large or if there are multiple fistulas. Various agents have been successful in preventing recurrent pneumothoraces in patients who are not on mechanical ventilation [149–152] but BPF in the setting of mechanical ventilation is a different situation. One study compared the recurrence of pneumothorax in 39 patients with BPF randomized to intrapleural tetracycline or placebo groups [153]. There was no evidence that intrapleural tetracycline facilitated closure of the BPF. No adverse effects were encountered from the instillation of tetracycline in patients with persistent air leaks.

The chest tube may be associated with adverse effects in patients with BPF. The gas escaping through the chest tube represents part of the minute ventilation delivered to the patient and makes maintenance of an effective tidal volume problematic [154,155] Maintenance of a specific level of ventilation is not only affected by the amount of gas escaping through the fistula. The escaping gas does not passively flow from the airways into the BPF but is involved in physiologic gas exchange [154,155]. Approximately 25% of the minute ventilation has been found to escape via the BPF in patients with ARDS, with more than 20% of CO_2 excretion occurring by this route in half of the patients [155]. The role of the BPF in active CO_2 exchange is complex: Proposed mechanisms include drainage of gas from alveoli in the area of the BPF and removal of gas from remote alveolar areas by pressure gradients created by the BPF [156].

Carbon dioxide excretion and a reduction in minute ventilation occur to a lesser extent in BPF trauma victims [154]. In these patients, variable CO_2 excretion and loss of minute ventilation were dynamic and dependent on the level of chest tube suction. The difference between trauma and ARDS patients may have been due to the variability of lung compliance and the use of different ventilators [155]. Also, BPF may affect oxygen use, which generally decreases the use of inspired oxygen before it escapes through the fistula [154]. This relationship is variable but requires consideration in patients with oxygenation problems.

Negative pressure applied to the chest tube may be transmitted beyond the pleural space and into the airways, creating inappropriate cycling of the ventilator [133,156]. The increased flow through a BPF can occur with increased negative pleural pressure and may interfere with closure and healing of the fistulous site [131]. Therefore, the least amount of chest tube suction that keeps the lung inflated should be maintained in patients with BPF. The chest tube is a potential source of infection, both at the insertion site and within the pleural space.

Drainage Systems

As with the chest tube, the resistance of flow of gases is a consideration in the choice of the drainage system for the patient with a BPF [141]. The size of the air leak and the flow that the drainage system can accommodate are necessary considerations. In an experimental model of BPF that simulated the type of air leak seen clinically (mean maximal flow, 5 L per minute), four pleural drainage units (PDU) (Emerson Post-Operative Pump, Emerson; Pleur-Evac, Teleflex Medical; Sentinel Seal, Tyco; and Thora-Klex, Avilor) were tested at water seal, −20 cm H_2O, and −40 cm H_2O suction [141]. Compared with the water seal, −20 cm H_2O suction significantly increased the ability of all four PDUs to evacuate air via the chest tube, but an increase in suction to −40 cm H_2O did not significantly alter flow. When the air leak reached 4 to 5 L per minute, use of the Thora-Klex or Sentinel Seal became clinically impractical. The Pleur-Evac can handle flow rates up to 34 L per minute, but its use with rates greater than 28 L per minute is impractical due to intense bubbling in the suction control chamber [112]. Air leaks of this magnitude are infrequent clinically in BPF and are likely to be seen only with major airway disruption or diffuse parenchymal leak secondary to ARDS with severe barotraumas [156]. In the latter situations, the low-pressure, high-volume Emerson suction pump remains the only PDU capable of handling the air leak [141]. The choice of PDU should be influenced by its physiologic capabilities and the type of BPF air leak that is encountered.

Mechanical Ventilation

Conventional Ventilation. The dilemma with a BPF in a mechanically ventilated patient is achieving adequate ventilation and oxygenation while allowing repair of the BPF to occur. Because air flow escaping through a BPF theoretically delays healing of the fistulous site, reducing flow through the fistula has been a major goal in promoting repair. The BPF provides an area of low resistance to flow and acts as a conduit for the escape of a variable percentage of delivered tidal volume during conventional positive-pressure mechanical ventilation. Thus, the goal of management is to maintain adequate ventilation and oxygenation while reducing the fistula flow [131]. Using the lowest possible tidal volume, fewest mechanical breaths per minute, lowest level of PEEP, and shortest inspiratory time (see Chapter 58) can do this. Avoidance of expiratory retard also reduces airway pressures. Using the greatest number of spontaneous breaths per minute, thereby reducing use of positive pressure, may also be advantageous. Intermittent mandatory ventilation may have an advantage over assist-control ventilation in BPF.

In a retrospective study of 39 patients with BPF who were maintained on conventional ventilation, only two patients developed a pH less than 7.30 despite air leaks of up to 900 mL per breath [156]. Overall, mortality was higher when the BPF developed late in the illness and was higher with larger leaks (more than 500 mL per breath).

High-Frequency Ventilation. Despite anecdotal reports, experimental data, and clinical studies involving high-frequency ventilation (HFV) in the setting of BPF, controversy exists. However, there appear to be subgroups of patients with BPF in whom HFV may be beneficial. Both animal [157] and human [158] studies suggest that HFV is superior to conventional ventilation in controlling PO_2 and partial pressure of carbon dioxide (PCO_2) when there is a proximal (tracheal or bronchial) unilateral or bilateral fistula in the presence of normal lung parenchyma.

The use of HFV in BPF in patients with parenchymal lung disease, such as ARDS, is more controversial. Although some studies have shown that HFV improves or stabilizes gas exchange in patients with extensive parenchymal lung disease, others have not shown a beneficial effect on gas exchange or a reduction in fistula outflow [159,160]. A trial of HFV appears reasonable in the patient with a proximal BPF and normal lung parenchyma; however, it is unclear whether HFV should be considered the primary mode of ventilation in this setting. Despite discrepancies in clinical results, a trial of HFV in a critically ill patient with a BPF and diffuse parenchymal disease who fails conventional ventilation appears justified. Caution must be exercised, however, with close monitoring of gas exchange parameters and fistula flow whenever HFV is used.

Other Modes of Ventilation. Other maneuvers during both conventional ventilation and HFV can be potentially helpful in patients with BPF. Selective intubation and conventional ventilation of the unaffected lung in patients with unilateral BPF may be useful but predisposes to the collapse of the nonintubated lung [161–163]. The use of differential lung ventilation with conventional ventilation may be of benefit in some patients [159]. Positioning of the patient such that the BPF is dependent has been shown to decrease fistula flow [163].

Case reports and animal studies suggest other potential applications of HFV in BPF, including the use of independent lung ventilation with HFV applied to the BPF lung and conventional ventilation to the normal lung [164]. Another mode of HFV, ultra high-frequency jet ventilation, is being explored and has been used with some success in reducing BPF in humans [165] and animal models [166]. Independent lung ventilation with ultra high-frequency lung ventilation applied to the BPF lung and conventional ventilation to the normal lung led to rapid BPF closure in two of three patients [165].

Flexible Bronchoscopy

The flexible bronchoscope can be valuable in the diagnosis of BPF [167–169] Bronchoscopic therapy of BPF has several potential advantages, including low cost, shortened hospital stay, and relative noninvasiveness, particularly in poor operative candidates [167–169] (see Chapter 9). Proximal fistulas, such as those associated with lobectomy or pneumonectomy or stump breakdown, can be directly visualized through the bronchoscope. Distal fistulas cannot be visualized directly and require bronchoscopic passage of an occluding balloon to localize the bronchial segment leading to the fistula [170–172]. A balloon is systematically passed through the working channel of the bronchoscope and into each bronchial segment in question and then inflated; a reduction in air leak indicates localization of a bronchial segment communicating with the BPF. Once the fistula has been localized, various materials can be passed through a catheter in the working channel of the bronchoscope and into the area of the fistula [167–176]. Direct application of a sealant through the working-channel catheter onto the fistula site is the method generally used for directly visualized proximal fistulas. For distal fistulas, a multiple-lumen Swan–Ganz catheter has been used to localize the BPF and pass the occluding material of choice [170].

Several agents have been used through the bronchoscope in an attempt to occlude BPF. These include fibrin agents [169,170] cyanoacrylate-based agents [167], absorbable gelatin sponge (Gelfoam, Pfizer), blood-tetracycline [171], and lead shot [172]. The reports on all of these agents are limited to only a few patients. The cyanoacrylate-based and fibrin agents have received the most attention but still have had less than 20 total cases reported. These patients have had at least a 50% reduction of fistula flow, and most had closure of the fistula subsequent to sealant application, although multiple applications were necessary in some patients. These agents appear to work in two phases, with the agent initially sealing the leak by acting as a plug and subsequently inducing an inflammatory process with fibrosis and mucosal proliferation permanently sealing the area [167]. They are not useful with large proximal tracheal or bronchial ruptures or multiple distal parenchymal defects [170].

CHAPTER 58 ■ MECHANICAL VENTILATION PART I: INVASIVE

RICHARD A. OECKLER, ROLF D. HUBMAYR AND RICHARD S. IRWIN

Mechanical ventilation refers to any method of breathing in which a mechanical apparatus is used to augment or satisfy the bulk flow requirements of a patient's breathing. Mechanical ventilation is indicated when the patient's spontaneous ventilation is not adequate to sustain life or when it is necessary to take control of the patient's ventilation to prevent impending collapse of other organ functions. At present, it is not known if mechanical ventilation should also be instituted to enable lung protection and prevent the potentially deleterious effects of hyperpnea in a spontaneously breathing patient with injured lungs. This chapter discusses the institution and maintenance of mechanical ventilation.

PRINCIPLES OF OPERATION

Negative-Pressure Ventilation

Until the mid-1950s, mechanical ventilators used for continuous ventilation were predominantly of the negative-pressure variety. The iron lung, or tank ventilator, was the most familiar of these. Bulk flow was mobilized into the patient's lungs by cyclically creating a subatmospheric pressure around the chest; actually, only the patient's head was not enclosed in the negative-pressure chamber. Subsequent ventilators applied negative external pressures to the rib cage only to induce inspiratory flow ($\dot{V}_I$) [1]. The original chest-enclosing ventilators of this type, called *cuirass ventilators*, incorporated a rigid shell that was applied to the chest. Later versions employed a much more flexible housing for the chest that was better tolerated by patients. The logistic problems encountered in providing routine nursing care for unstable patients resulted in an abandonment of negative-pressure ventilators in the acute care setting some 40 years ago. Interest in intermittent nocturnal mechanical ventilation as home therapy for chronic respiratory failure led to a minor resurgence in their use in the 1980s. However, because negative-pressure ventilators tend to be bulky, are poorly tolerated, may cause obstructive sleep apnea, and have not proved effective in the rehabilitation of patients with end-stage chronic obstructive pulmonary diseases (COPD), they have been largely replaced by positive-pressure ventilators for home use as well [2].

A recent experimental study in rabbits with injured lungs has rekindled interest in the use of negative pressure ventilators in the intensive care setting [3]. Rabbits ventilated with negative-body surface pressure had improved oxygenation and better lung recruitment than animals ventilated with equivalent amounts of positive pressure applied to the airway. The study was met with skepticism, because the results are not compatible with long established physical principles. Since the structures contained within the thorax are in essence incompressible, the findings suggest mode and instrumentation specific differences in respiratory impedance rather than inherent advantages of negative over positive pressure ventilation.

Positive-Pressure Ventilation

Positive-pressure ventilation is operative when a superatmospheric pressure is cyclically created at the upper airway. The resultant pressure gradient between the upper airway and the lungs pushes gases through the airways. In the acute care setting, positive-pressure ventilation is usually delivered through an endotracheal or tracheostomy tube. However, an increasing awareness of tube-related complications has contributed greatly to the emergence of noninvasive mechanical ventilation through a face mask, nasal mask, helmet, or mouth seal as a viable treatment option for some patients with respiratory failure (see Chapter 59 for a more complete discussion of noninvasive mechanical ventilation).

Conventional positive-pressure ventilation has come to be identified with respiratory rates up to 60 breaths per minute, even though rates above 30 breaths per minute are rarely used. Any mode of ventilation administered at higher respiratory rates is considered high-frequency positive-pressure ventilation. High-frequency oscillatory ventilation (HFOV) supports pulmonary gas exchange by entraining gas from a bias flow circuit and delivering subnormal tidal volumes (TVs) to the lungs at rates between 3 and 15 cycles per second (Hz) [4,5]. The technique was patented in the late 1950s, came to the attention of pulmonary physiologists in the 1970s, was then touted as promising treatment for babies with immature lungs, but was rejected after a large clinical trial (the HIFI study) found it to be inferior to conventional mechanical ventilation [6]. With the emergence of the "open lung concept" in the 1990s and the realization that ventilation with large TVs can injure susceptible lungs, HFOV attracted renewed interest in recent years [7,8]. In some centers, HFOV has emerged as a first-line treatment option in neonates with respiratory distress [9–14], and the MOAT trial showed a trend in favor of HFOV in adults with acute lung injury (ALI) [15]. A recent expert panel report provides detailed recommendations for HFOV [16]. Moreover, the panel identified areas for further study, such as the role of HFOV as first line treatment in adults with ALI and the choice of initial frequency settings [17]. The latter touches on unresolved issues of fundamental biologic significance: Is rate or the amplitude of lung deformation the more important risk factor for injury, and how does hypercapnia modify this risk?

Before discussing different categories and modes of positive-pressure ventilation, it is useful to review the basic mechanical determinants of patient–ventilator interactions.

Mechanical Determinants of Patient–Ventilator Interactions

Despite gross oversimplifications, linear models of the respiratory system have proved useful for the understanding of patient–ventilator interactions [18,19]. Figure 58.1 shows a simulation of volume preset (volume is the independent variable) mechanical ventilation in a linear respiratory system analogue. When ventilators are programmed to deliver a specific flow, the resulting inspiratory pressure profile contains information about the mechanical properties of the respiratory system. The pressure applied at time (t) to the tube inlet ($P_{i(t)}$, near the attachment to the ventilator) is equal to the sum of two pressures, an elastic pressure ($P_{el(t)}$) and a resistive pressure ($P_{res(t)}$).

$$P_{i(t)} = P_{el(t)} + P_{res(t)}$$

The tube outlet pressure at the junction with the balloon is equal to the pressure inside the balloon (P_{el}). P_{res} is the difference in pressure between the tube inlet and the tube outlet.
