FIGURE 58.1. Components of inlet pressure. Model of the respiratory system consisting of a resistive element (straight tube) and an elastic element (balloon) connected to a ventilator (piston). During inflation of the model with constant flow (*bottom*), there is a stepwise increase in inlet pressure (P_i) that equals the loss of pressure across the resistive element (P_{res}) (*top*). Thereafter, P_i increases linearly and reflects the mechanical properties of the elastic element (P_{el}). P_i is the sum of P_{res} and P_{el}. At end inspiration, when flow has ceased (Insp. Pause), P_i decreases by an amount equal to P_{res}; P_i equals P_{el} during Insp. Pause. T_I, inspiratory time; T_E, expiratory time. [From Gay PC, Rodarte JR, Tayyab M, et al: The evaluation of bronchodilator responsiveness in mechanically ventilated patients. *Am Rev Respir Dis* 136:880, 1987, with permission.]

Assuming linear system behavior, the inlet pressure–time profile can be computed for any piston stroke volume (V_{stroke}) and flow ($\dot{V}$) setting, provided the resistive properties of the tube (R) and the elastic properties of the balloon (E) are known:

$$P_{i(t)} = E\,V_{(t)} + R\dot{V}_{(t)}$$

Elastance, E, is a measure of balloon stiffness and is equal to the ratio of P_{el} and V_{stroke} (assuming 0 volume and pressure at the beginning of balloon inflation). Therefore, $P_{el(t)}$ of the first equation can be substituted with $EV_{(t)}$ in the second equation. Applied to the respiratory system, E reflects the elastic properties of lungs and chest wall, whereas R reflects primarily the resistive properties of endotracheal tube and airways. Because Ohm's law states that the resistance R is equal to the ratio of pressure and flow, $P_{res(t)}$ of the first equation can be substituted with the product $R\dot{V}_{(t)}$ in the second equation.

During inflation with constant (square wave) flow, there is an initial step change in driving pressure measured at the inlet (P_i) that equals the pressure loss across the resistive element (P_{res}). Thereafter, P_i increases linearly with time and volume and attains a maximal value (P_{peak}) at the end of inflation. The linear rise in P_i with time (and volume) indicates that elastance of the respiratory system (E_{rs}) is constant over the tidal breathing range and suggests that the mechanical ventilator is the only source of pressure during inflation (i.e., the respiratory muscles are relaxed).

When the airway is occluded at end inspiration, flow ($\dot{V}_{insp}$) falls to zero and the airway pressure drops from P_{peak} to P_{ei} (the end inflation/static/plateau or pause pressure). P_{ei} represents the static elastic recoil pressure of the respiratory system at end-inflation volume (P_{el}). As long as P_{el} at end expiration is zero (absence of hyperinflation), E_{rs} can be calculated from the ratio of P_{ei} and tidal volume (TV).

Contrast the waveforms pertaining to volume preset mechanical ventilation in Figure 58.1 with the simulation of *pressure preset (pressure is the independent variable) mechanical ventilation* in Figure 58.2. When ventilators are programmed to generate a step change in pressure, the resulting inspiratory flow profile contains information about the mechanical properties of the respiratory system. Inspiratory flow rises to an early peak and then declines as the lungs fill with gas. The reason for the decline in flow with volume and time is the increase

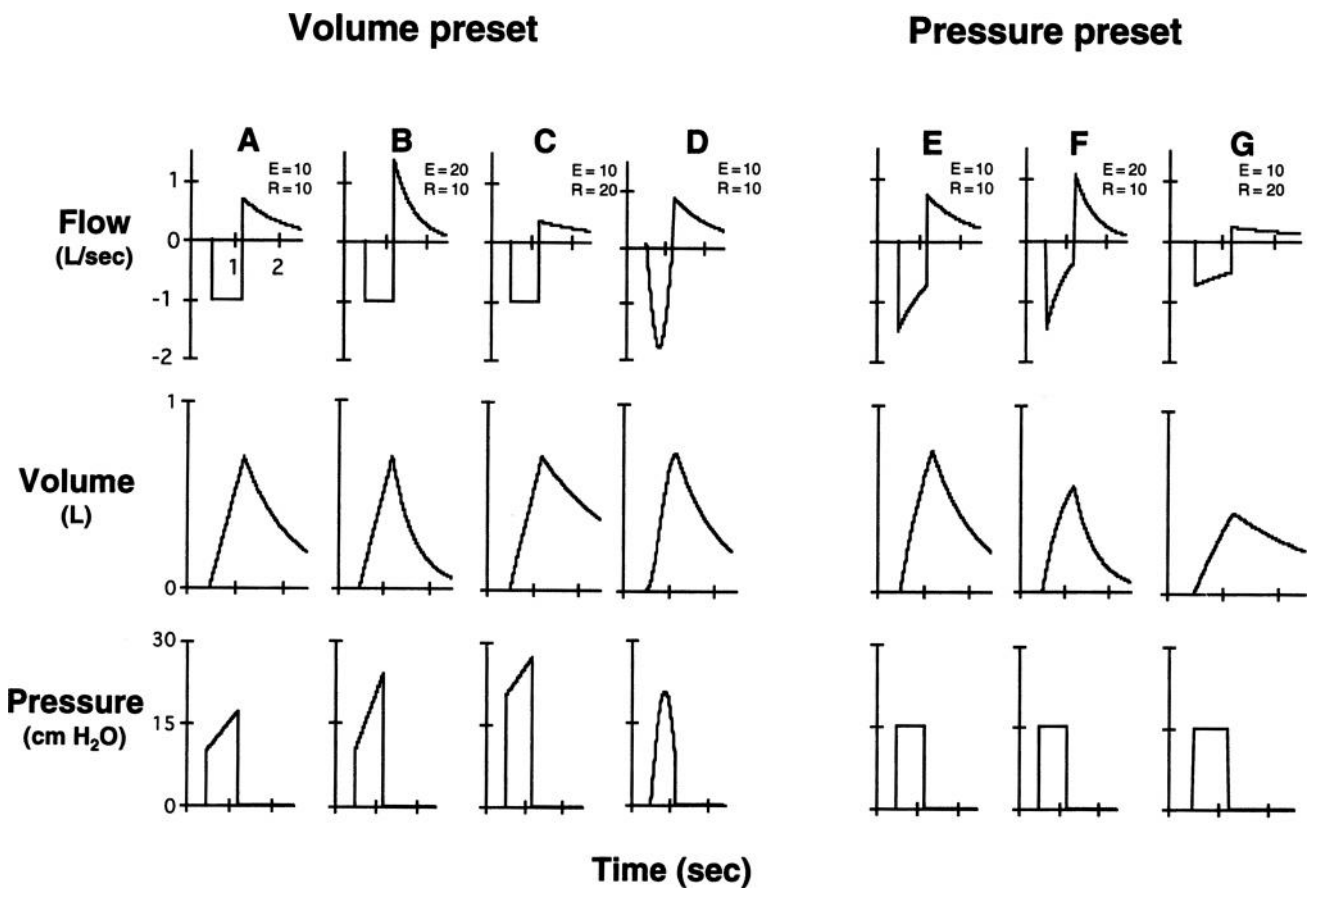

FIGURE 58.2. Schematic representation of the interdependence between pressure, volume, and flow during volume preset ventilation (**A–D**) and pressure preset ventilation (**E–G**). In the volume preset mode, increases in respiratory elastance (**B**) and resistance (**C**) as well as the choice of the inspiratory flow profile (**D**) affect airway pressure. In the pressure preset mode, the same changes in elastance (**F**) and resistance (**G**) compared to control (**E**) affect volume and flow profiles.

in elastic (balloon) pressure (*dashed line*) (see Fig. 58.1) with volume and time. The rise in balloon pressure (surrogate for alveolar pressure, P_{alv}) in the face of a constant P_i accounts for a progressive reduction in net driving pressure [$P_{i(t)} - P_{el(t)}$] during lung inflation. Because P_{res} varies with flow, P_{res} must also decline during lung inflation, reaching a minimum at end inflation. If inspiratory time is long enough to allow P_i and P_{alv} to equilibrate ($P_i = P_{el}$), as is the case in Figure 58.2, then inspiratory flow becomes 0 and E_{rs} may again be calculated from P_{ei} and TV.

The volume and flow profiles during pressure preset lung inflation are determined by the time constant of the respiratory system, which itself is a function of the respiratory system's mechanical properties. The time constant (τ) is a feature of linear systems and defines the time it takes an elastic element to fill to approximately 63% of its capacity or conversely to passively discharge 63% of its capacity when it is exposed to a step change in pressure.

$$\tau = R/E = R \times C$$

Notice from the third equation that τ is determined by the product of resistance and compliance. Because R is expressed in units of pressure × time × volume^{-1} and C in units of volume × pressure^{-1}, their product, τ, has the units of time. In the context of pressure preset mechanical ventilation, a low value for τ predicts that airway and alveolar pressure equilibrate rapidly and that TV depends largely on respiratory compliance. Alternatively, when τ is large, TV becomes sensitive to inspiratory time and to the resistance of the intubated respiratory system ($P_i > P_{alv}$ at t = end inflation).

Expiratory Mechanics of the Relaxed Respiratory System

Passive expiration is driven by the elastic recoil of the respiratory system (P_{el}). Assuming linear pressure–volume and pressure–flow relationships, the instantaneous expiratory flow $\dot{V}_{exp(t)}$ may be expressed as

$$\dot{V}_{exp(t)} = P_{el(t)}/R$$

$P_{el(t)}$ is a function of elastance (E) (1/Compliance) and of the instantaneous volume $V_{(t)}$; substituting for the previous equation:

$$\dot{V}_{exp(t)} = [E \times V_{(t)}]/R = V_{(t)}/[R \times C]$$

The product of R and C characterizes the time constant (τ) of single-compartment linear systems. As previously described, this represents the time at which approximately two thirds (63%) of the volume above relaxation volume (V_{rel}) has emptied passively.

CONVENTIONAL POSITIVE-PRESSURE VENTILATION

Modes

The mode of mechanical ventilation refers to the characteristics of the inspiratory pressure or flow program and determines whether a patient can augment TV or rate through his or her own efforts. Descriptors of ventilation mode are conveniently separated into determinants of amplitude, rate, and relative machine breath timing.

Amplitude of Machine Output

Volume Preset Ventilation

In this mode, the machine delivers a volume set on the control panel and, within limits, delivers that volume irrespective of the pressure generated within the system (Fig. 58.2A–D). Most ventilators offer several inspiratory flow profile options that range in shape from square wave (i.e., flow remains constant throughout the inspiratory cycle) to decreasing ramp and sine wave functions. For many years, physicians have considered volume preset ventilation to be the mode of choice in the treatment of adults with acute respiratory failure because a predefined minute volume delivery is guaranteed (for exceptions, see discussion of pop-off pressures in Inflation Pressure Setting section). Yet, proponents of pressure preset modes point to several drawbacks: (a) changes in the mechanical properties of the lungs from atelectasis, edema, or bronchoconstriction may cause high inflation pressures (perhaps increasing the risk of barotrauma); and (b) changes in inspiratory effort may not result in proportional changes in ventilation. Alternatively, those who consider the avoidance of high TVs imperative for lung protection will favor volume preset over pressure preset modes [20].

Pressure Preset Ventilation

During pressure preset ventilation, the ventilator applies a predefined target pressure to the airway during inspiration (Fig. 58.2E–G). The resulting TV and inspiratory flow profile vary with the impedance of the respiratory system and the strength of the patient's inspiratory efforts. Therefore, when either lungs or chest wall become stiff, when the airway resistance increases, or when the patient's own inspiratory efforts decline, TV decreases. An increase in respiratory system impedance can lead to a fall in minute ventilation ($\dot{V}_e$), hypoxemia, and CO_2 retention, but, in contrast to volume preset modes, pressure preset ventilation reduces the probability of lung injury from overdistention.

Means to Activate (Trigger) a Machine Breath

Controlled Mechanical Ventilation

Controlled mechanical ventilation is a mode during which rate, inspiratory-to-expiratory timing (I/E), and inspiratory flow (or pressure) profile are determined entirely by machine settings. Because there is never a reason to impose a rigidly set rate and breathing pattern, the term *controlled mechanical ventilation* usually refers to instances in which patients make no or ineffective inspiratory efforts.

Assist/Control Ventilation

The ventilator in assist/control (A/C) mode is sensitized to respond to the patient's inspiratory effort, if present; if such efforts are absent, the machine cycles automatically and delivers a controlled breath. Therefore, a patient might conceivably assist at a rate of 12 breaths per minute although the control rate is set at 10 breaths per minute. Because volume preset mechanical ventilation had been the most widely used mode of mechanical ventilation for many years, many providers associate the A/C mode with volume preset mechanical ventilation. Nevertheless, the A/C trigger algorithm is also associated with all pressure preset modes in which pressure amplitude and timing are defined by the provider. This is the case in pressure control ventilation but not pressure support ventilation or assisted pressure release ventilation (see following discussion).

Ventilators operating in A/C mode recognize patient efforts and switch from expiration to inspiration by one of two mechanisms. During pressure triggering, phase switching occurs whenever the airway pressure falls below a predetermined level (usually 1 to 2 cm H_2O below end-expiratory pressure). In this mode, a valve occludes the inspiratory port of the ventilator during expiration. An inspiratory effort against an occluded port lowers the airway opening pressure (P_{ao}), causes the demand valve to open, and initiates a machine breath. The flow-by-trigger mode, which is available on virtually all new-generation intensive care unit ventilators, is an alternative to conventional pressure-based machine trigger algorithms [21].

During flow-by, a continuous flow of gas is presented to the patient and is vented in through the expiratory tubing unless the patient makes an inspiratory effort. This so-called base flow can be set by the operator between limits of 5 to 20 L per minute. When the patient makes an inspiratory effort(s), he or she diverts flow into the lungs, resulting in a discrepancy between base flow and the flow of gas through the expiratory circuit. The minimal difference between inspiratory and expiratory flows, which results in a machine breath, is determined by the flow sensitivity setting and can vary from 1 to 3 L per minute. Most modern ventilators combine pressure and flow-triggering algorithms so that concerns about benefits of one over the other triggering mechanism are no longer relevant.

Short-lived inspiratory efforts that occur during early expiration are often insufficient to be recognized by either pressure or flow triggering algorithms. Careful inspection of airway pressure and flow profiles, of neck and chest wall motion, or intermittent flaring of the alae nasi should alert the physician to this phenomenon, which indicates a dissociation between machine rate and the patient's own intrinsic respiratory rate. Wasted inspiratory efforts are commonly seen in weak, sleeping, or heavily sedated patients and in patients unable to overcome intrinsic (or auto) positive end-expiratory pressure (PEEP) (see following discussion) [22].

The A/C feature has lured many physicians into the erroneous assumption that the machine backup rate setting is unimportant (see discussion on rate settings and troubleshooting in Minute Ventilation section). Although only a modest inspiratory effort is required to trigger the ventilator, many patients perform muscular work throughout the entire assisted breath in direct proportion to their ventilatory drive [23]. If the patient's work of breathing is deemed excessive and potentially fatiguing, the physician should lower the trigger sensitivity setting, consider raising $\dot{V}_i$, evaluate oxygenation and alveolar ventilation, assess the adequacy of machine backup rate and PEEP settings, and address sedation and pain control.

In years past, there had been a great reluctance to use of neuromuscular blocking agents (NMB) to prevent adverse patient–ventilator interactions. However for patients with ALI or the acute respiratory distress syndrome (ARDS), who frequently

double their VT by breath stacking and are therefore at risk for ventilator associated lung injury, this reluctance may no longer be appropriate. In several randomized clinical trials, the group of Papazian has reported that patients with ALI, who were initially managed with NMB, had improved surrogate physiologic endpoints, spent fewer days requiring mechanical ventilation and were more likely to survive than those who were managed with sedatives and narcotics alone [24,25] However, the issue is far from settled, awaits independent confirmation, and importantly, the data do not apply to patient populations without acute lung injury, whose risk for ventilator induced injury is much lower.

Intermittent Mandatory Ventilation

Early versions of the intermittent mandatory ventilation (IMV) mode combined spontaneous breathing and volume preset-assisted ventilation [26]. For example, at an IMV rate of 6 breaths per minute, the ventilator would deliver a volume preset breath every 10 seconds. Between these mechanically controlled breaths, the patient would breathe spontaneously and the ventilator would serve as a source of warmed, humidified, potentially oxygen-enriched gas. During the years, IMV has become more complex. In modern ventilators, mandatory breaths may be volume or pressure preset and it has become commonplace to augment spontaneous breaths with positive airway pressure as well (e.g., by using the pressure support mode).

Virtually all modern ventilators use synchronized IMV algorithms that prevent the patient from getting a double breath with IMV (i.e., a machine breath is delivered at the end of a spontaneous inspiratory effort). At intervals determined by the IMV frequency setting, the machine becomes sensitized to the patient's inspiratory effort and responds by delivering a pressure or volume preset breath. Between these preset cycles, the patient breathes spontaneously (with or without pressure support) at a rate and depth of his or her own choosing. For example, at an IMV rate of 6 breaths per minute, the ventilator allows the patient to breathe spontaneously while the delivery of preset breaths is initially refractory to the patient's efforts. After 10 seconds elapse, the machine is rendered sensitive. When an effort occurs, the ventilator delivers a preset breath and the patient breathes spontaneously until 10 seconds after the end of the previous refractory period. If the patient does not make an inspiratory effort during the sensitive period, the ventilator delivers a controlled breath after sufficient time elapses. This time varies inversely with the IMV backup rate; it is equal to 60 seconds divided by the IMV rate. In the example given here, the period would be 10 seconds (60 divided by 6).

IMV is a very complex mode with numerous degrees of freedom. It was originally introduced as a weaning modality. However, in controlled clinical trials this mode has performed inferior to other weaning techniques (see Chapter 60) [27–29]. Nevertheless, in many institutions IMV remains the default mode for patients who are relatively easy to ventilate. Familiarity with this mode and the high incidence of ventilator-induced apneas in sleeping or comatose patients, who are supported in modes without mandatory backup rates, are likely reasons for the persistent popularity of IMVs [30–32].

Pressure Support Ventilation

Pressure support ventilation (PSV) is a form of pressure preset ventilation. It is intermittent positive-pressure breathing with a sensing device that delivers the breath at the time the patient makes an inspiratory effort. As the lungs inflate, $\dot{V}_i$ begins to decline because airway pressure and the pressure generated by inspiratory muscles are opposed by rising elastic recoil forces. When $\dot{V}_i$ reaches a threshold value (which differs among vendors), the machine switches to expiration. Inspiratory off-switch failure, that is, application of inspiratory pressure after cessation of inspiratory muscle activity, is common during PSV [31,33]. High inspiratory pressure settings, a low respiratory drive, airflow obstruction with dynamic hyperinflation, and air leaks predispose patients to this form of patient–ventilator asynchrony [31,34]. Asynchrony, in turn, is an underappreciated cause of sleep disruption [22,35].

PSV is a popular weaning mode for adults. A review of the weaning literature (see Chapter 60) suggests that this mode is as effective as intermittent T-piece trials of spontaneous breathing in liberating patients from mechanical ventilation [36–38]. It should also be noted that PSV is a useful alternative to volume preset mechanical ventilation, particularly in patients with increased rate demands and respiratory drive [39]. However, the risk of lung injury from sustained increases in TV probably applies to the PSV mode as well, because airway pressure despite being low does not inform about lung stress.

Pressure Control Ventilation

Pressure control ventilation (PCV) is a form of pressure preset ventilation. It differs from PSV in two important respects: The operator sets a machine backup rate and determines inspiratory time (T_i). The A/C feature assures ventilation of the lungs in patients who are prone to apneas. Cessation of inspiratory effort can be a problem in sleeping adults who are ventilated in the pressure support mode [30,40]. On the other hand, PCV does not offer the patient the same control over TV and breathing patterns as PSV. For this reason, PCV with long T_i, is usually reserved for hypoxic heavily sedated or paralyzed patients in whom the need to match ventilator rate and timing with intrinsic respiratory rhythms is not an issue.

Assisted Pressure Release Ventilation and Bilevel Support Modes

Although bilevel positive airway pressure ventilation (BiPAP) technically describes any mode in which the pressure applied to the airway cycles between two provider set levels, in practice most associate BiPAP with a PSV like mode that is often used in noninvasively mechanically ventilated patients. It is a pressure/time cycle mode which allows the patient's own breathing to supplement ventilator output. There are subtle differences in the cycling algorithms among devices of different vendors, somewhat clouding the literature on the topic. When bilevel pressure ventilation is delivered with an inverse inspiratory to expiratory time ratio, the mode becomes indistinguishable from assisted pressure release ventilation (APRV). Arguments in favor of bilevel pressure ventilation modes including APRV in patients with injured lungs center on improved gas exchange and maintenance of dependent lung aeration attributable to preserved diaphragm activity [41]. However, superiority of bilevel modes relative to volume preset modes has not been established. Detractors point out that it is more difficult to assure delivery of lung protective tidal volumes in pressure preset modes.

Noninvasive Mechanical Ventilation

Noninvasive mechanical ventilation (NMV) (see Chapter 59) encompasses all modes of ventilatory assistance that can be applied without an endotracheal tube. The realization that certain patients benefit from intermittent positive pressure breathing through a mask has fundamentally changed the initial management of many respiratory failure syndromes. The literature on NMV has grown exponentially, and the following comments focus on the use of NMV in the acute care setting.

Several randomized prospective clinical trials have shown NMV to be an effective initial therapy for patients with

impending or overt respiratory failure [42–47]. The early application of NMV in the emergency department is particularly important in patients with exacerbation of airways obstruction as it may spare them the risks and discomfort associated with intubation and conventional mechanical ventilation. Other conditions in which NMV appears to be an effective initial rescue treatment include ventilatory insufficiency from chest wall disease, neuromuscular weakness, and sleep-related breathing disorders. The use of NMV in hypoxic forms of respiratory failure is increasing, but in comparison to COPD its efficacy is less well established [46,48–53], NMV is relatively contraindicated in patients who cannot protect their airway or who cannot clear their secretions, and in our experience NMV invariably fails in patients with shock or metabolic acidosis [54].

Less Commonly Used Modes of Mechanical Ventilation

Some new-generation mechanical ventilators feature modes with closed-loop feedback control of both pressure and volume [55,56]. Dual-control modes seek to provide a target ventilation while maintaining low inflation pressures. To this end, ventilator output is adjusted based on volume, flow, and pressure feedback within each machine cycle or gradually from one cycle to the next. Modes that adjust output within each cycle execute a predetermined pressure–time program as long as the desired TV is reached. When the TV target is not reached, inspiration continues at a preselected inspiratory flow rate (volume-limited) until the target volume is attained. Volume-assured pressure support and pressure augmentation are examples of such modes. Breath-to-breath dual control modes are pressure-limited and time or flow cycled. Ventilator output is derived from the pressure–volume relationship of the preceding breath and adjusted within predefined pressure limits to maintain the target TV. Pressure-regulated volume control, volume control plus, auto-flow, adaptive pressure ventilation, volume support, and variable pressure support are examples of breath-to-breath control modes.

Neurally adjusted ventilatory assistance (NAVA) and proportional assist ventilation (PAV) are the most complex and arguably the most promising closed-loop ventilation modes [57,58]. At the time of this writing, only PAV is commercially available in the United States. During PAV, the relaxation characteristics of the respiratory system are assessed on a breath-by-breath basis so the ventilator may provide a set fraction of the inspiratory elastic and flow resistive work [57–59]. Its applications in NMV will be discussed in Chapter 60. During NAVA, the diaphragm's electrical activity is recorded with an esophageal probe and the signal is conditioned and transposed into a positive airway pressure output. Preliminary observations on patients suggest that NAVA results in greater patient–ventilator synchrony than conventional modes [60]. Moreover, there is some evidence from animal models that NAVA affords greater lung protection from ventilator associated injury [61] by virtue of preserved coupling between respiratory control and motor output. At the time of this writing however, there is no evidence that either dual- or closed-loop modes are safer or more effective than conventional approaches.

Choice of Ventilation Mode

The therapeutic end points of mechanical ventilation vary considerably among different respiratory failure syndromes. For example, the ventilatory management of patients with ALI has little in common with that of patients suffering from exacerbation of COPD. However, the need for pathophysiology-based treatment objectives should not be confused with a need to find an optimal ventilation mode for each class of respiratory disorders. In general, the therapeutic goals of mechanical ventilation can be achieved with more than one mode [62].

Ventilator Settings

Fraction of Inspired Oxygen

The hazards of indiscriminate administration of oxygen to patients with CO_2 retention and the topic of pulmonary oxygen toxicity are discussed in Chapters 49 and 62. Notwithstanding these very real concerns, oxygen must never be withheld from a mechanically ventilated patient. If there is any suspicion that the patient may require oxygen, it should be given. Certain drugs, such as bleomycin, may sensitize the lungs to reactive oxygen species-mediated injury and it is advisable to minimize the fraction of inspired oxygen (FIO_2) in patients receiving them [63]. Adjustments in FIO_2 are usually guided by pulse oximetry and/or arterial blood gas analyses. Most caregivers dose FIO_2 to an arterial oxygen tension (PaO_2) more than 60 mm Hg and/or an oxygen saturation more than 90%. Although these targets are based on reasonable physiologic assumptions, they are nevertheless empiric. Some accept lower O_2 saturations in young patients with adequate end organ perfusion, when the treatment of hypoxemia seems risky. Ultimately, the risk associated with hypoxemia must be balanced against the risk of oxygen toxicity and the risks associated with raising PEEP and manipulating hemoglobin and cardiac output. It is currently believed that an FIO_2 below 0.6 is not injurious to the lungs even when used for days or weeks. Because the contribution of oxygen to lung injury cannot be separated from that of other insults (e.g., sepsis-related inflammatory mediator release, gastric acid, infectious agents, lung parenchymal stress), oxygen dosing recommendations remain open to debate.

Tidal Volume

When using a volume preset mode, TV is either set directly or follows from the minute volume and rate setting. When a pressure preset mode is used, TV is the consequence of the patient's respiratory effort, the mechanical properties of the respiratory system, the pressure amplitude setting, and the duration over which the inflation pressure is applied. TV is arguably the most important ventilator setting. Historically it had been common practice to scale TV to actual body weight. This practice is no longer acceptable because the high prevalence of obesity biases TV settings toward injurious levels, and because height and gender are much more powerful predictors of lung size than is body weight [64]. Height and gender are also used to estimate ideal or predicted body weight that by virtue of its use in the acute respiratory distress syndrome network (ARDS Net) trials has become the preferred TV scaling factor [65].

Predicted Body Weight (in kg):

$$\text{Men} = 50 + 2.3 \times (\text{height in inches} - 60)$$
$$\text{Women} = 45.5 + 2.3 \times (\text{height in inches} - 60)$$

Most experts suggest to target TV in patients with injured lungs between 6 ± 2 mL per kg predicted body weight. Although the evidence in support of lung protective TV settings in other patient population is less compelling, there is no reason to suspect that TV settings in excess of 8 ml/kg are of benefit. There is overwhelming evidence that inflating the lungs above total lung capacity (TLC) can damage normal lung units, particularly when this occurs in conjunction with large tidal excursions [66–68]. In patients with a normal body habitus (i.e., normal chest wall recoil and compliance), TLC corresponds to a plateau or end-inflation hold pressure between 30 and 35 cm H_2O [69]. For this reason most experts limit respiratory system inflation pressures to 30 cm H_2O or less, However, in light of recent data this guideline may have to be reevaluated (see discussion about inflation pressure setting later). Unless lung function is severely impaired, even large TVs are unlikely

to distend the lungs beyond their structural limit (i.e., TLC). This has caused some experts to reason that reducing TV to values less than 8 mL per kg ideal body weight (as is custom in ARDS Net trials) is neither required nor beneficial in patients with plateau pressures less than 30 cm H_2O. We address this controversy in greater detail in the context of ventilator management of ARDS.

Sighing and Recruitment Maneuvers

Periodic hyperinflation (the "sigh" or "yawn" maneuver) is a spontaneous reflex in conscious humans. Periodic stretching of the lung stimulates surfactant production and release and therefore prevents atelectasis [70,71]. However, the effects of sighing on mechanics and gas exchange tend to be short lived and vary with disease state, posture, and ventilator mode and setting [72,73]. Some experts recommend that the lungs of patients with ARDS should be intermittently held at high volumes and pressures (e.g., 30 to 50 cm H_2O for 20 to 40 seconds) to recruit collapsed and/or flooded units [74–76]. The use of recruitment maneuvers has been associated with improved gas exchange, altered lung mechanics and less inflammation in experimental lung injury models [77–81]. By virtue of volume and time history, such maneuvers tend to potentiate the effects of PEEP on functional residual capacity [82]. Incorporating sighs into a lung-protective mechanical ventilation strategy in patients with early ALI/ARDS improved oxygenation and static compliance, but had no effect on survival [83]. This confirms that periodic lung inflation and recruitment maneuvers exert demonstrable effects on lung function, but are not appropriate surrogate markers of clinical efficacy. In fact, a post hoc analysis of the ARDS-Network low tidal volume trial revealed that patients, who had been randomized to the injurious high tidal volume arm had better oxygenation during the first 24 hours than those, who in hindsight, had received lung protection [65].

"Biologically variable mechanical ventilation" is an experimental mode of mechanical ventilation that seeks to maximize lung recruitment by preserving the normal breath-to-breath variability in TV and rate [84]. Biologically variable mechanical ventilation is superior to evenly timed sighs in improving gas exchange and lung function [85,86]. Moreover, biologically variable mechanical ventilation finds a strong mechanistic underpinning in the principle of stochastic resonance [87]. Stochastic resonance is a feature of nonlinear systems that explains why seemingly minor variability in input (e.g., TV) has major effects on output (e.g., number of recruited alveoli) [88]. At the time of this writing, this mode is not available for commercial use in North America.

Inflation Pressure Setting

Volume Preset Mode. Although pressure is a dependent variable during volume preset ventilation, generally the cycling pressure should not be allowed to increase without limit. Rather, a pressure limit or pop-off pressure should be imposed to guard against inadvertent overinflation and possible lung rupture [89]. This is set directly on the ventilator's control panel, and when and if it is reached, a visual and possibly audible alarm alerts the attendant to the fact that the machine has popped off. That particular cycled breath will have been partially aborted and the patient will have received only part of the volume set on the control panel. A random, infrequent pop-off cycle is most often caused by the patient's coughing or splinting, and need not be cause for concern. However, repeated popping off may be an indication that the patient is in acute respiratory distress and should prompt those in attendance to disconnect the patient from the ventilator to determine the cause of the problem. Although the patient is manually ventilated, a suction catheter should be passed through the endotracheal tube to determine whether it is patent, and the ventilator should be checked to ensure it is functioning properly. Other factors to consider are whether the patient is undersedated or anxious and in pain, whether the patient's airway resistance has increased (e.g., bronchospasm, excessive secretions, mucus plugging), whether the endotracheal tube has migrated beyond the carina, or whether a pneumothorax has developed.

Pop-off pressures should usually be set at a level slightly above P_{peak} observed during normal cycling and should not be higher than 40 cm H_2O, whereas PEEP and TV should generally be set to maintain plateau pressures 30 cm H_2O or less. Although no specific airway pressure is guaranteed to exclude the risk of barotrauma, higher airway pressures appear to impose an increased risk of alveolar overdistention that can lead to permeability pulmonary edema, alveolar hemorrhage, subcutaneous emphysema, pneumomediastinum, and pneumothorax. There is general agreement that the main determinant of alveolar overdistention is the end-inspiratory lung volume [67]. On the basis of this reasoning, Dreyfuss et al. [90] and Dreyfuss and Saumon [91] have coined the term *volutrauma* distinct from barotrauma. The term *barotrauma* refers to injury manifest as extra-alveolar air, whereas volutrauma denotes injury manifest as altered lung barrier function. Regardless, one should appreciate that lung stress (transpulmonary pressure) and lung volume cannot be uncoupled and that neither is routinely measured at the bedside. TV and plateau pressure, the variables that are being measured, inform only indirectly about lung volume and lung stress, and the provider must integrate them with estimates of chest wall compliance (or, more specifically, chest wall recoil) [92]. For these reasons, we believe that plateau pressure limits of 30 cm H_2O should be ignored in patients with obesity, ascites, or abdominal distention [93].

There is evidence that esophageal manometry guided PEEP management is associated with improved lung function compared to a conventional ARDS-Network based approach [94]. In a small clinical trial survival trends favored esophageal manometry guided PEEP management, even though a substantial number of patients were ventilated to plateau pressures in excess of 30 cm H_2O [95]. A subsequent report suggested that the majority of ARDS patients have substantially increased end-expiratory chest wall recoil pressures and that the corresponding implications for PEEP management may not be evident from airway pressure recordings alone [96]. The issue is far from settled, because of concerns for measurement bias in esophageal pressure derived estimates of transpulmonary pressure [97]. Nevertheless, a rigorous adherence to an absolute plateau pressure safety limit of 30 cm H_2O in patients with ALI seems no longer advisable. There is a healthy debate about the appropriate balance between maximizing lung recruitment (through the application of PEEP) and minimizing end-inspiratory parenchymal stress (by avoiding high inflation pressures). In following this debate, we conclude that there is neither a single safe inflation pressure nor safe tidal volume threshold. Rather both surrogates of injurious stress and strain are invariably intertwined. For example, inflating the lungs to near maximal capacity during HFOV seems quite safe provided tidal volumes are kept relatively low. Alternatively, a TV which would likely be injurious during HFOV is well tolerated provided lung inflation pressure is kept relatively low.

Because of the increasing risk of barotrauma with rising airway pressures, it is important to determine not only why peak airway pressures are increasing but also to try to reduce them. For instance, if agitation is responsible, the patient should be sedated and, as addressed earlier, at times even paralyzed [24,25]. Although lower $\dot{V}_I$ rates might help achieve the goal of decreasing peak airway pressure, it is not clear that this prevents susceptible lung units from overdistention injury. Reductions in flow without concomitant reductions in TV may simply reduce the resistive pressure that is dissipated across the endotracheal tube without lowering peak transpulmonary pressure or lung stress.

Pressure Preset Modes. In a pressure preset mode (see the previous discussion of PSV and PCV modes), ventilators require an inflation pressure amplitude setting as opposed to a pop-off pressure setting. The pressure amplitude setting (often referred to as "pressure control" or "pressure support" setting) determines the relative pressure increase during assisted inflation; it should be distinguished from peak airway pressure that is the sum of PEEP and the inflation pressure setting. Inflation pressure is an important determinant of peak lung volume as well as TV. For reasons previously outlined, inflating the respiratory system repeatedly to static (inflation hold) pressures in excess of 30 cm H_2O should be avoided unless concerns about lung recruitment and chest wall mechanics dictate otherwise.

Respiratory Rate, Flow, and Machine Cycle Timing

Volume Preset Mode. The choice of rate setting should be made after considering the patient's actual rate demand in conjunction with the T_i or I/E setting. Most ventilators are not smart enough to vary T_i in proportion to the spontaneous respiratory rate (fS) (as opposed to the set machine rate, fM). At an fM setting of 10 breaths per minute (A/C = 10), the total cycle time (TTOT; inspiration plus expiration) equals 6 seconds. If I/E is 1:2, T_i is 2 seconds and expiratory time (T_e) is 4 seconds. Imagine that the patient actually triggers at 20 breaths per minute (i.e., TTOT declines to 3 seconds). Inspiratory time remains fixed at 2 seconds because it is determined by the preset machine rate and I/E. The T_e must decrease from 4 seconds to 1 second and the actual I/E increases from 1:2 to 2:1. At a rate of 30 breaths per minute (TTOT = 2 seconds), T_e becomes 0 and fighting the ventilator results. For these reasons, the machine backup rate should always be set close to the patient's actual rate. If the actual rate is so high that effective ventilation cannot be achieved, the patient may need sedation alone or with paralysis.

All ventilators provide the option of maintaining lung volume at end inspiration for a predefined time. This time, also called *end inflation hold time* or *inspiratory pause time*, is usually expressed as a percentage of TTOT. For the purpose of defining I/E, the pause time is considered part of the expiratory machine cycle. Long pause times favor the recruitment of previously collapsed or flooded alveoli and offer a means of shortening expiration independent of rate and mean $\dot{V}_i$. Although alveolar recruitment is a desired therapeutic end point in the treatment of patients with edematous lungs, keeping the lungs expanded at high volumes (and pressures) for an extended period may damage relatively normal units [98–100].

Inspiratory Flow. Many ventilators require that $\dot{V}_i$, as opposed to I/E or TTOT, be specified. Because mean $\dot{V}_i$ is equal to the ratio of TV and T_i, flow cannot be changed without affecting at least one of the other timing variables. Under most clinical circumstances, $\dot{V}_i$ is 1 L per second or less during volume preset ventilation. Increasing flow always raises peak P_{ao}, but this need not be of concern if most of the added pressure is dissipated across the endotracheal tube. Although $\dot{V}_i$ is one factor that determines the regional distribution of inspired gas, in disease the effect of flow on pulmonary gas exchange and parenchymal stress is too unpredictable to warrant general guidelines. There is theoretical concern and some experimental evidence that the rate at which lung tissue is being stretched, which is a function of the flow setting, determines the probability of deformation injury [101,102]. It is also important to understand that the flow setting influences a patient's breathing rate and effort [32,103,104] and that the combined effects of flow, volume, and time settings determine the functional residual capacity (FRC) and degree of dynamic hyperinflation (see the following discussion) [105,106].

The $\dot{V}_i$ is rarely specified as part of the physician's orders. Rather, the respiratory therapist usually adjusts the $\dot{V}_i$ pattern and rate by observing patient–ventilator interactions. It has become common practice to deliver volume preset breaths with a decelerating flow pattern; that is, a profile in which flow declines with lung volume and time. In comparison to the traditional square wave flow pattern in which inspiratory flow is held constant throughout inflation, the use of decelerating flow patterns tends to promote alveolar recruitment and may reduce the risk of barotrauma. Although the reasoning seems mechanistically sound, this hypothesis has yet to find experimental support.

Mean Expiratory Flow. Mean expiratory flow is defined by the ratio of TV and T_e. Expiratory time is equal to TTOT minus T_i, and TTOT is equal to 60 per minute (60/f). Because the machine backup rate and actual frequency may differ in the A/C mode, assumed and actual TTOT may also differ. Recall from the discussion on rate and timing that T_i is defined by both the set machine backup rate (fM) and the set I/E, and that T_i remains constant irrespective of the actual rate. In contrast, T_e is affected by the actual breathing rate (fA) (i.e., $T_e = 60/fA - T_i$). Therefore, the choice of volume and timing settings, together with the patient's rate response, determine mean expiratory flow.

It is generally appreciated that end-expiratory alveolar pressure can remain positive during intermittent positive-pressure ventilation even when PEEP is not intentionally applied [107]; this is called auto-PEEP (or intrinsic PEEP [$PEEP_i$]) and is not readily apparent on the ventilator manometer. Mean expiratory flow, TV/T_e, is the principal ventilator setting-related determinant of dynamic hyperinflation. A patient with airways obstruction and a maximal forced expiratory flow of 0.2 L per second in the midvital capacity range ($FEF_{25\%-75\%}$) obviously cannot accommodate a TV/T_e of 0.3 L per second without an increase in end-expired lung volume. Dynamic hyperinflation will result.

Although $PEEP_i$ may be present in the majority of ventilated patients in intensive care units [108], it is likely to be worse in patients with COPD [109]. Intrinsic PEEP places the patient at risk for the same pulmonary and cardiovascular consequences as intentional external PEEP ($PEEP_e$). When disregarded, $PEEP_i$ effects can lead to serious errors in management. For instance, failure to recognize that $PEEP_i$ can elevate pulmonary artery balloon occlusion pressure or decrease cardiac output and blood pressure may lead to inappropriate fluid restriction or vasopressor therapy. At the bedside, $PEEP_i$ should be clinically suspected if exhalation has not ended before the next inhalation (Fig. 58.3). Intrinsic PEEP can be measured using

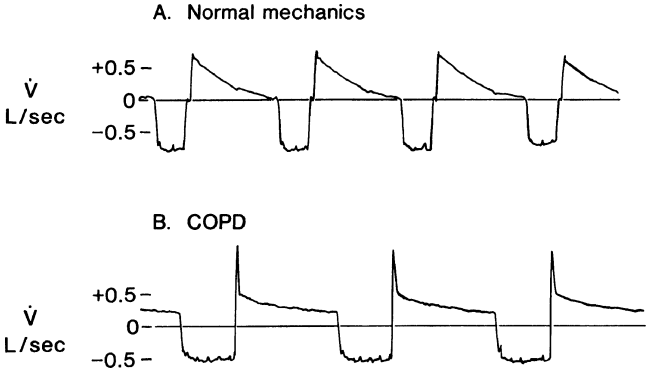

FIGURE 58.3. Comparison of flow profiles during mechanical ventilation in a subject with normal mechanics (**A**) and a subject with chronic obstructive pulmonary disease (COPD) (**B**). The presence of expiratory flow prior to machine inflation of the relaxed respiratory system indicates dynamic hyperinflation and intrinsic positive end-expiratory pressure. [From Hubmayr RD, Rehder K: Respiratory muscle failure in critically ill patients. *Semin Respir Med* 13:14, 1992, with permission.]

the expiratory port occlusion technique [107] or from the measurement of change of P_{ao} at the onset of $\dot{V}_i$ [108]. In many modern ventilators, the $PEEP_i$ measurement is automated, that is, individual machine-breaths can be delayed for appropriately timed airway occlusions. In patients with spontaneous respiratory efforts at end expiration, P_{ao} will not reach a plateau, and in these patients $PEEP_i$ cannot be estimated with this technique. It has been proposed that $PEEP_i$ be estimated from esophageal pressure measurements in spontaneously breathing patients. Because such estimates rely on subtle inflections in the esophageal pressure tracing and because the determinants of $PEEP_i$ in spontaneously breathing subjects are more complex than those during mechanical ventilation and include the contributions of expiratory muscles to intrathoracic pressure, such measurements should be interpreted with caution. Furthermore, the technique is invasive and subject to artifacts in recumbent individuals [110].

Intrinsic PEEP can be minimized by reducing mean expiratory flow requirement or increasing the patient's capacity to generate the required flow near V_{rel}. Examples of the former strategy are reductions in TV, increasing $\dot{V}_i$ and thereby increasing T_e, and reducing the actual ventilator rate through manipulations of the set backup rate, sedation, and pain control, or imposing neuromuscular blockade with sedation. Increasing the $\dot{V}_i$ setting can be counterproductive if it causes an increase in the respiratory rate [32,111]. Strategies for increasing the patient's flow-generating capacity include bronchodilators [105] and occasionally diuretics, when peribronchial edema contributes to obstruction. If subjects with $PEEP_i$ make inspiratory efforts while being ventilated in the A/C mode, it is crucial to use extrinsic PEEP to reduce inspiratory work requirements. As a general rule, PEEP settings approaching 75% of $PEEP_i$ are recommended [112,113].

Pressure Preset Mode. In contrast to volume preset ventilation, inspiratory flow is not a set variable, but is determined by patient mechanics and inspiratory effort as well as the PEEP, pressure amplitude, and T_i settings. During PSV, rate and T_i are largely patient-determined; during PCV, they are programmed. The importance of mean expiratory flow as a determinant of dynamic hyperinflation pertains to pressure as well as volume preset modes of ventilation. However, during pressure preset modes, mean expiratory flow and, hence, end-expiratory lung volumes are not as sensitive to changes in rate. This is because reductions in TTOT and, hence, T_i and T_e bring about reductions in TV.

Minute Ventilation

With the exception of older Siemens servo ventilators, minute ventilation ($\dot{V}_E$) is not a parameter that must be set directly by the operator. It is rather the consequence of the TV (or pressure amplitude) and rate settings. The A/C mode is not a foolproof safeguard for assuring a rate setting independent delivery of an appropriate $\dot{V}_E$. Therefore, a knee-jerk order, such as A/C of 12 and TV of 800, may cause severe alkalemia in a comatose patient with normal lungs, yet lead to profound respiratory acidemia in an individual with ARDS. As a general rule, the $\dot{V}_E$ setting for patients with hypoxic respiratory failure from ARDS should be 10 to 15 L per minute until blood gas analyses, airway pressure responses, and cardiovascular status guide further ventilator adjustments. The high ventilatory requirement of such patients reflects hypermetabolic states with increased CO_2 production as well as an increase in physiologic dead space from high ventilation/perfusion ($\dot{V}$) mismatch. In contrast to patients with ARDS, patients with COPD tend to have a lower ventilatory requirement, usually 8 to 12 L per minute unless their disease is exacerbated by left heart failure, sepsis, or pneumonia. Healthy individuals maintain normocapnia with a resting ventilation of approximately 5 L per minute.

Although normocapnia is a desired therapeutic end point, it is not essential. Increases in respiratory system impedance combined with increased ventilatory requirements and poor pulmonary gas exchange may necessitate a choice between permissive hypercapnia and risking lung injury [114,115]. Hypercapnic acidosis tends to be well tolerated provided patients are sedated and/or paralyzed [116]. Although there are no definitive clinical outcomes data that address the effectiveness of buffer solutions in patients with hypercapnic acidosis, many experts have abandoned their use even when the arterial pH is less than 7.2 [117–119]. Indeed, there is strong evidence that hypercapnia protects the lungs from certain forms of injury, including ventilator-induced lung injury [120,121]. Moreover, a post hoc analysis of patients enrolled in the low TV ARDS Net trial suggests a protective effect of hypercapnia in the usual care arm [122].

Positive End-Expiratory Pressure

The application of positive airway pressure during the expiratory phase of the respiratory cycle is commonly referred to as PEEP, continuous positive airway pressure (CPAP), or expiratory positive airway pressure (EPAP). Although there are subtle distinctions between these terms, they are largely technical and of historic interest. In patients with hypoxic respiratory failure, expiratory pressure is used to raise lung volume to recruit collapsed and flooded alveoli, to prevent cell abrasion in small conducting airways, and to improve oxygenation [123–126]. In contrast, the goal of PEEP/CPAP/EPAP therapy in patients with airways obstruction is to minimize inspiratory work [22,112,127].

Positive End-Expiratory Pressure in Hypoxic Respiratory Failure. PEEP is most useful in the treatment of patients with pulmonary edema resulting from increased alveolocapillary membrane permeability (ARDS) or increased hydrostatic pressure (cardiogenic pulmonary edema) [128,129]. It increases PaO_2 by diminishing intrapulmonary shunting of blood and improving the matching of ventilation and perfusion. Although it may work by redistributing intra-alveolar edema, it need not drive fluid out of the lungs [130].

In the 1970s and 1980s, most physicians considered the "best PEEP" to be the least amount of PEEP necessary to achieve adequate blood gas tensions (ordinarily this means arterial O_2 saturation 90% or more, or PO_2 60 mm Hg or more with FIO_2 values 0.6 or less). The emergence of the open lung approach and concerns about ventilator-induced lung injury have resulted in a revised PEEP management strategy [125,128,131–134]. Although many experts approach PEEP empirically, guided by arterial gas tensions, some advocate PEEP titration based on shape analyses of the respiratory system pressure/volume loop or on image analyses of the thorax [135–141]. Several physiology lessons may be drawn from related experimental literature: (a) the application of PEEP promotes aeration of previously flooded, closed, or atelectatic lung units (i.e., recruitment) and it increases the aeration of previously open or at least partially aerated units [135,136]; (b) in injured lungs there is no single volume or pressure at which all potentially recruitable units appear to be aerated [142]; and (c) even moderate amounts of PEEP may cause overdistension of some lung units [143]. The corresponding clinical lesson is that in the absence of efficacy studies, the pressure/volume curve cannot inform about best PEEP unless one is willing to make additional assumptions about the relative risks of low and high lung volume injury.

One approach that seeks to minimize these risks is the so-called stress–index-guided PEEP management [140,144]. The

stress index is the exponent of the airway pressure–time relationship when it is measured during inflation of the relaxed respiratory system with constant (square wave) inspiratory flow. It is a measure of the linearity of the pressure ramp as shown in the schematic of Figure 58.1. A stress index more than 1 indicates that the tracing is convex to the time axis and that more pressure is required to inflate the lungs in the high as opposed to the low tidal range. This suggests that the lungs are being inflated to volumes near TLC; namely, above the upper inflection point of their inflation pressure/volume loop. At such high volumes, the lungs may be subjected to injurious stress. Conversely, a stress index less than 1 indicates that the pressure ramp is concave to the time axis and that it is easier to inflate the lungs in the high as opposed to the low tidal range. This suggests that the lungs are underrecruited and may be subjected to low volume injury from repeated opening and closure of unstable lung units. Proponents of the stress index concept argue that lungs should be ventilated over a volume range where the stress index is approximately 1, that is, over the linear portion of the inflation pressure/volume loop where the relative risks of high- and low-volume injury are minimal. Although there is some experimental support for this reasoning, the efficacy of this approach has not been tested in the clinical arena.

The volume of partially or nonaerated lung that may be recruited with PEEP varies considerably among patients with ALI and ARDS [142]. In general, patients with the most severe forms of alveolar edema have the largest absolute and relative volumes of recruitable lung. Some studies have suggested that patients with ARDS from extrapulmonary causes such as sepsis are more likely PEEP-responsive than patients with primary pulmonary insults, for example pneumonia [142,145,146]. However, this has not been a universal finding [142,146]. Three relatively large prospective randomized controlled clinical trials specifically designed to compare a high PEEP with a low PEEP management strategy have showed equivalence of the two approaches [147–149]. Those who advocate a high PEEP—open lung—strategy have been hesitant to embrace these results, in part because PEEP management decisions where not driven by patient-specific estimates of recruitable lung [150–152]. A much smaller trial of esophageal pressure guided PEEP management, in which outcomes favored high PEEP has rekindled this debate [95]. Furthermore, recent meta-analyses suggest a benefit from high PEEP strategies in patients with severe forms of ARDS [153,154]. Irrespective of one's interpretation of the PEEP literature adherence to low TVs and "safe" plateau pressures is paramount [65]. At the same time, most experts emphasize that patients with obesity, ascites, and abdominal distention (i.e., patients with high chest wall recoil and/or low chest wall compliance) should be ventilated with PEEP substantially greater than 5 cm H_2O [93].

There are two ways to raise lung volume in the hope of recruiting flooded or partially collapsed alveoli: the judicious use of extrinsic PEEP ($PEEP_e$) and dynamic hyperinflation. Because it is not uncommon for patients with ALI to be tachypneic, a component of dynamic hyperinflation is often present in mechanically ventilated ARDS patients [155]. Despite the short time constant for lung emptying, the use of PEEP values that often represent resistive as well as threshold loads and ventilator settings that require large mean expiratory flows (TV/T_e; see previous discussion) contribute to dynamic hyperinflation. Sedation and neuromuscular blockade are useful adjuncts to PEEP therapy insofar as they help raise lung volume by abolishing expiratory muscle activity. In general, the authors prefer to manipulate end-expired lung volume with extrinsic PEEP. There is at least a theoretical concern that the high respiratory rates required to achieve meaningful hyperinflation are in and of themselves injurious to the lungs [101].

In summary, there is general agreement that PEEP has beneficial effects on the function of injured lungs [91,131,134,156,157] so that in patients with ARDS a knee-jerk setting of 5 cm H_2O is inappropriately low. Unfortunately, this message has been slow to gain acceptance in clinical practice. A 2005 survey of ventilator practice around the world suggests that patients with ARDS are ventilated with a median PEEP setting of 8 cm H_2O (interquartile range, 5 to 10 cm H_2O). This means that 25% of ARDS patients still receive an inappropriately low PEEP setting of 5 cm H_2O or less (O. Gajic, personal communication, 2006).

Effects Of Positive End-Expiratory Pressure On Circulation. The major cardiovascular complication associated with PEEP is reduction in cardiac output. Although the effect of PEEP on cardiac output is complex, the decrease is caused predominantly by decreasing venous return (right ventricular filling) and direct heart-lung interactions [158,159]. It appears that PEEP affects apparent heart compliance rather than contractility. By increasing lung volume and intrathoracic pressure, PEEP (much like recruitment maneuvers) can increase pulmonary vascular resistance and thereby promote hypotension and right ventricular volume overload [160]. Associated changes in the position and shape of the interventricular septum, together with direct compression of the left ventricle by the expanding lungs, account for the fall in left ventricular compliance [161]. A reduction in cardiac output with hypotension should prompt the use of fluid-replacement therapy, vasopressor drugs, and a temporary reduction of PEEP until the former interventions take effect. Also, PEEP may lead to water retention in the lungs [162] by decreasing left atrial volume, thereby stimulating antidiuretic hormone secretion; may alter portal circulatory hemodynamics [163]; and may decrease perfusion to splanchnic organs that may lead to ischemia of the bowel [164]. All of the cardiovascular complications can be avoided or minimized by adhering to proper indications for use of PEEP and by careful monitoring during its use.

Changes in PEEP can introduce uncertainties in the measurement and interpretation of pulmonary artery pressures. Because left ventricular compliance can be affected by PEEP and because PEEP-induced changes in intrathoracic pressure are transmitted to the heart and the pulmonary vasculature, a change in the pulmonary artery occlusion pressure need not reflect a change in left ventricular end-diastolic volume. Indeed, it should be remembered that the pulmonary artery occlusion pressure is a very poor predictor of a patient's cardiac output response to fluid [165]. Although it is unlikely that Swan Ganz catheters will vanish from clinical practice, two prospective randomized controlled clinical trials, one in patients undergoing major cardiovascular surgery and the other in patients with ALI and ARDS, have failed to demonstrate efficacy of pulmonary artery catheter-guided management [166,167].

Positive End-Expiratory Pressure and the Obstructed Patient. Continuous positive airway pressure reduces the inspiratory work of breathing in dynamically hyperinflated patients by two mechanisms: (a) it helps oppose the expiratory action of P_{el} at end expiration (i.e., $PEEP_i$), and (b) it promotes active expiration below the predicted V_{rel} of the respiratory system [168]. As a result, CPAP can inflate the relaxed respiratory system to V_{rel} because of expiratory muscle derecruitment during inspiration even if the inspiratory muscles were to remain inactive. It is crucial to oppose $PEEP_i$ with extrinsic PEEP in ventilator-dependent patients with COPD when they make inspiratory triggering efforts. If this is not done, the patient is forced to generate inspiratory pressures slightly above $PEEP_i$ before the machine can respond. Such efforts are potentially exhausting and could prevent successful weaning from mechanical ventilation.

Physiologic and Prophylactic Positive End-Expiratory Pressure. The term *physiologic PEEP* has been applied to the application

of 5 cm H_2O of PEEP in intubated patients with healthy lungs. The term was coined because laryngeal breaking normally elevates tracheal pressure in the presence of expiratory flow by a few cm H_2O. Bypassing the larynx with an endotracheal tube is frequently associated with a decrease in end-expiratory lung volume [169]. This predisposes intubated patients to gas absorption atelectasis and may be prevented through the application of "physiologic" PEEP [170]. There is no conclusive data to show that prophylactic PEEP reduces the incidence of ARDS in predisposed patients [171] or that it prevents atelectasis after open heart surgery [172]. In fact, it may take more than 20 cm H_2O of pressure to reverse the atelectasis that accompanies inhalational anesthesia and neuromuscular blockade [173], and it takes as little as 6 cm H_2O of PEEP during induction of general anesthesia to prevent it [174,175]. This raises questions about the validity of older studies in which prophylactic PEEP may have been misapplied, mistimed, and underdosed. This is underscored by the demonstrated efficacy of mask CPAP in severely hypoxemic patients after abdominal surgery [176].

Considerations About Mode and Settings During Noninvasive Mechanical Ventilation

In the United States, NMV is most commonly delivered with a bilevel pressure device, that is, a ventilator that operates in a pressure preset mode. This is not to say that volume preset ventilators are inferior or ineffective. Indeed, the European trial that first established efficacy of NMV in the acute care setting used a volume preset mode to assist patients [44]. In addition, there are many patient–ventilator interfaces from which to choose, most notably nasal and full-face masks. This choice should be guided by patient preference. The debate as to the ideal mode for NMV hinges in part on one's bias if it is sufficient to acutely unload fatigued respiratory muscles or if immediate large reductions in arterial CO_2 tension are also required to gain long-term benefit. In practice, TV and pressure amplitude settings are usually limited by patient compliance, and facial pressures in excess of 15 cm H_2O are rarely tolerated. It is customary to set PEEP between 4 and 8 cm H_2O as a means of raising lung volume and promoting upper airway patency. Although most practitioners set the backup frequency between 8 and 12 breaths per minute (they operate the ventilator in a spontaneous/timed, i.e., A/C mode), machine breaths that do not coincide with a patient's inspiratory effort often meet a partially or completely obstructed upper airway. Inspired gas is generally supplemented with low levels of O_2. A need to raise FIO_2 above 0.5 to maintain a pulse oximetry reading above 90% should alert the care provider to the possibility of profound CO_2 retention. (For a more detailed discussion of NMV, see Chapter 59.)

DISEASE-ORIENTED MECHANICAL VENTILATION STRATEGIES

Mechanical Ventilation in Individuals with (Near) Normal Respiratory Mechanics and Pulmonary Gas Exchange

Most patients who require ventilation during anesthesia, neuromuscular blockade, and surgery; most patients with respiratory failure from central nervous system depressant drugs; and many patients with diseases of peripheral nerves and muscles have (near) normal respiratory mechanics and pulmonary gas exchange. The goal in these patients is to maintain or restore adequate alveolar ventilation and oxygenation; therefore, the single most important initial ventilator setting is minute volume ($\dot{V}_E$). Minute volume is the product of fM and TV and is an important determinant of the body's CO_2 stores and consequently of $PaCO_2$:

$$PaCO_2 = \dot{V}_{CO_2} \times k / \dot{V}_E (1 - V_D/TV)$$

$\dot{V}_{CO_2}$ is the volume of CO_2 produced (in liters per minute); V_D/TV is the dead space-to-TV ratio, a variable with which the efficiency of the lung as a CO_2 eliminator can be approximated; k is a constant that equals 0.863 and that scales $\dot{V}_{CO_2}$ and $\dot{V}_E$ to the same temperature and humidity.

In resting patients with healthy lungs and metabolic rates, a $\dot{V}_E$ setting between 80 and 100 mL per kg usually results in normocapnia. Usual TV settings in a volume preset mode range between 6 and 10 mL per kg ideal body weight, with the occasional neuromuscular disease patient preferring higher TVs for comfort. Those who prefer to ventilate patients in a pressure preset mode can deliver similar volumes with pressure amplitudes of 10 to 15 cm H_2O applied for 0.75 to 1 second. If a subsequent blood gas analysis shows hypercapnia despite seemingly adequate $\dot{V}_E$ delivery, a hypermetabolic state (increased $\dot{V}_{CO_2}$) or $\dot{V}$ mismatch (abnormal V_D/TV) should be suspected. It may not be wise to normalize the $PaCO_2$ of patients with chronic CO_2 retention suddenly considering the adverse hemodynamic and metabolic effects of posthypercapnic alkalosis. Therefore, $\dot{V}_E$ settings of approximately 60 mL per kg should be used when the initial $PaCO_2$ and pH targets are approximately 55 mm Hg and 7.35, respectively. It remains unresolved whether patients with chronic CO_2 retention should be mechanically ventilated to normocapnia. Those who argue against this practice assume that a resetting of chemoresponsiveness toward normal elevates ventilatory requirement and prevents weaning. Proponents cite the adverse effects of hypercapnia on respiratory muscle contractility [177].

Mechanical Ventilation in Individuals with Airways Obstruction

Because of expiratory airflow limitation, patients with obstructive physiology are at risk of having mechanical ventilation cause or worsen dynamic hyperinflation (i.e., $PEEP_i$). This in turn increases the risk of barotrauma (e.g., pneumothorax), hypotension, and death. Therefore, the goal of therapy is to maintain adequate oxygenation while minimizing the thoracic volume about which the lungs are ventilated. The latter can be accomplished by (a) reducing airway inflammation and alleviating bronchoconstriction, (b) decreasing TV, (c) increasing inspiratory flow rate, and (d) accepting hypercapnia.

Status Asthmaticus

Insights into the determinants of gas trapping, barotrauma, and permissive hypercapnia have changed both indications and ventilator management principles in status asthmaticus [106,114,178,179]. In contrast to patients with chronic airflow obstruction from emphysema or bronchitis, patients with status asthmaticus suffer from airway closure and mucus plugging and have much more severe V/Q mismatch and a higher ventilatory requirement, and are therefore particularly prone to hyperinflation, barotrauma, cardiovascular collapse, and death (see Chapter 48). Intubation and mechanical ventilation should be viewed as measures of last resort and should be reserved for patients who have failed noninvasive mechanical ventilation and who require sedation, neuromuscular blockade, and ventilation with permissive hypercapnia.

Because the primary goal is to prevent overdistention of unobstructed lung units, relatively low initial TV settings (e.g., less than 8 mL per kg predicted body weight) should be used in conjunction with peak inspiratory flows of approximately 60 L per minute and rates of 12 to 16 breaths per minute. Higher rates should be used only if cardiovascular instability is attributed to severe respiratory acidemia rather than dynamic hyperinflation. In practice, it is rarely possible to make this distinction. Because peak airway pressure may not adequately reflect lung parenchymal stress in such patients, Tuxen et al. [178] proposed guiding ventilator adjustments on the basis of measurements of trapped gas volume.

The V_{EI} is the volume of air above FRC that is in the patient's lungs after delivery of TV. Although P_{peak} and P_{plat} are read directly off the ventilator manometer, V_{EI} is measured in a spirometer. For V_{EI} measurement, patients must be sedated, paralyzed, well oxygenated, and disconnected from the ventilator immediately after TV is delivered. Expired air must be collected in a spirometer until no more air escapes. In severely obstructed patients, this collection may take, on average, 40 to 60 seconds. Making ventilator changes aimed at keeping V_{EI} below 20 mL per kg has been shown to protect against barotrauma and hypotension in status asthmaticus [179].

To manage the most severely obstructed patients with status asthmaticus, we recommend making ventilatory changes as needed to stay below the V_{EI} threshold of 20 mL per kg. If V_{EI} is greater than 20 mL per kg after the patient has stabilized on the initial ventilator settings, the TV or rate should be decreased. If V_{EI} is greater than 20 mL per kg but gas exchange is marginal, ventilating the patient with a helium–oxygen mixture may be considered. Breathing helium has been associated with reduced lung inflation pressure, $PEEP_i$, and improved alveolar ventilation and oxygenation [180–183]. However, the use of helium–oxygen mixtures in conjunction with positive pressure ventilation is not a trivial undertaking.

Conventional mechanical ventilators are designed to operate safely with low-density and high-viscosity gas mixtures, so that local experience with this investigational intervention is critical. It must be stressed that there is no single upper $PaCO_2$ or lower pH threshold that has been associated with cardiovascular instability or poor outcome [116]. Therefore, concern for barotrauma must take precedence over maintenance of alveolar ventilation. (See Chapter 48 for the role of bicarbonate infusion.) The measurement of V_{EI} is cumbersome and can be accomplished only in paralyzed patients. We do not believe that it is appropriate to paralyze patients for the sole purpose of making a V_{EI} measurement. We also wish to remind the reader that large portions of the asthmatic lung may be completely obstructed, so that both V_{EI} and $PEEP_i$ often underestimate the degree of trapping [184].

Chronic Obstructive Pulmonary Disease

In general, the management principles for COPD are similar to those for asthmatic patients, except that patients with exacerbations of COPD rarely require neuromuscular blockade or permissive hypercapnia. Patients with COPD are prone to dynamic hyperinflation from expiratory flow limitation rather than airway closure and mucus plugging. The challenge is to minimize hyperinflation and inspiratory work despite limited control over respiratory rate (see Chapter 49). In a patient who is not paralyzed, the machine trigger rate, as opposed to the machine backup rate and I/E settings, determine T_e (see previous discussion). To the extent to which COPD patients remain tachypneic during mechanical ventilation, changing V_i and T_i settings may not be effective in reducing gas trapping. Increasing V_i under the assumption that it would prolong T_e may actually have the opposite effect because higher flows often increase respiratory rate [32,104]. Therefore, we initially choose a TV between 6 and 8 mL per kg predicted body weight, an intermediate inspiratory flow of 40 to 60 L per minute, and a rate close to the patient's spontaneous effort rate. We add up to 10 cm H_2O of CPAP to reduce machine trigger work (see previous discussion).

Because these patients are not paralyzed, it is not feasible to monitor trapped gas volume, as has been proposed for asthmatic patients. Rather, one should assure that end-inflation hold pressure remains below 30 cm H_2O. If the initial ventilator settings fail to reduce dyspnea and patient effort, we raise $PEEP_e$ until peak airway pressure starts to rise [112]. At that point, the difference between $PEEP_e$ and end-expiratory mean alveolar pressure is presumably at a minimum. If adjustments in $PEEP_e$ fail to reduce patient effort, as judged by symptoms or accessory muscle use, sedation must be increased and, rarely, neuromuscular blockade considered.

As pointed out in the section on minute volume settings and CO_2 homeostasis it is better to underestimate the minute volume requirement when initiating support during acute exacerbations. Otherwise one runs the risk of unmasking severe posthypercapnic metabolic alkalosis.

Acute Respiratory Distress Syndrome

Much of our treatment philosophy and its underpinnings for patients with ARDS are presented in the sections that discuss TV and rate settings and the use of PEEP. To summarize, we attempt to increase FRC and mean lung volume through the application of extrinsic PEEP, avoid end-inflation hold pressure in excess of 30 cm H_2O, and reduce TV as we raise PEEP to stay within safe volume boundaries. In practice, this means TV settings are between 4 and 8 mL per kg predicted body weight when we use volume preset modes or P_{peak} settings 30 cm H_2O or less when we use pressure preset modes. The rate is usually 20 to 30 breaths per minute unless the patient has been heavily sedated and paralyzed to tolerate hypercapnia. There is no upper limit to PEEP as long as the peak lung volume and recoil pressure guidelines are adhered to, but in practice it is rarely possible to deliver sufficient alveolar ventilation at cycling pressures between 20 (PEEP setting) and 30 cm H_2O (P_{plat}).

We should emphasize that overdistention is not the only mechanism by which large tidal excursions may injure the lungs. Large intermittent changes in alveolar surface area promote small aggregate conversion of surfactant, and with it lead to impairment in surface tension dynamics [185–187]. This mechanism has been invoked as an explanation for the development of noncardiogenic pulmonary edema in a sheep model with salicylate-induced spontaneous hyperventilation [188]. If this mechanism proves to be important, then the use of pressure-limited ventilation strategies such as bilevel pressure ventilation and assisted pressure release ventilation cannot be assumed protective unless the resulting TV remains between 4 and 8 mL per kg predicted body weight.

There is some suggestion that the use of lung protective ventilation with low TVs is also beneficial for patients without ALI and ARDS. In a retrospective review of patients with respiratory failure from causes other than ALI, Gajic et al. [189] identified TV as a risk factor for the subsequent development of noncardiogenic pulmonary edema. On the basis of this evidence and on mechanistic reasoning, the authors avoid TV in excess of 8 mL per kg predicted body weight in all patients, and in general adhere to the lung-protective ventilator management algorithms of the ARDS Net.

Patients who cannot be oxygenated at lung-protective settings need to be sedated and sometimes paralyzed and may be candidates for unconventional alternatives and investigational support modes. These include turning the patient to the prone posture, supplementing inspired gas with nitric oxide,

and considering the use of high-frequency ventilators, extracorporeal membrane oxygenators, and extracorporeal CO_2 removal devices. To date, however, none of these interventions have proved efficacious in rigorously conducted clinical trials (see Chapter 47).

Despite several inconclusive or negative clinical efficacy trials there continued to be interest in prone positioning [190–192] as a lung protective intervention. However, the recent Prone Supine II study, a large randomized multicenter trial conducted in Spain and Italy, found no survival benefit in either patients with ARDS or in subgroups of patients with moderate and severe hypoxemia [193]. At this time, routine use of the prone position cannot be recommended.

The recent influenza pandemic has generated renewed interest in extracorporeal membrane oxygenation (ECMO) as rescue therapy for refractory hypoxemia [194–196]. Moreover, the recent publication of the CESAR trial [197] in which patients with severe ARDS were randomly assigned to either receive usual on site care or get transferred to a single ECMO center encouraged its use. Patients cared for at the ECMO center had a significantly better 6-month disability-free survival (63% vs. 47%; $p < 0.03$) than patients who were treated on site. Skeptics emphasize that conventional treatment was not standardized across the 103 study sites and that only 75% of patients transferred to the ECMO center actually received ECMO. Clearly ECMO remains a resource-intensive treatment modality reserved for major centers with a dedicated, highly trained, and multidisciplinary staff. At this time routine use of ECMO as rescue therapy is not recommended and the iatrogenic risks related to transport, vascular access and anticoagulation assessed on a case-by-case basis.

Head Trauma

The key to the ventilatory management of patients with head trauma is to avoid excessive intrathoracic pressures and at the same time provide sufficient ventilation to lower $PaCO_2$. It should be emphasized, however, that therapeutic hyperventilation and hypocapnia, when applied for more than 24 hours, have been associated with worse patient outcomes [198,199]. High intrathoracic pressures are transmitted to the subarachnoid space and may thereby reduce the perfusion pressure of a central nervous system that is already compromised by intracranial hypertension from bleeding or edema. However, measurements of PEEP effects on cerebrospinal fluid pressure and, more importantly, cerebral perfusion pressure in patients have generated conflicting results. This is because PEEP-related changes in systemic circulation and blood gas tensions have complex cerebrospinal fluid pressure-independent effects on cerebral blood flow [198]. As a general rule, raising PEEP is unlikely to lower cerebral perfusion pressure unless it is associated with a decrease in systemic blood pressure and cardiac output [200,201]. Because the assumption of the prone posture may also raise intracranial pressure [202], the patient's head must be raised appropriately.

Myocardial Ischemia and Congestive Heart Failure

In addition to the heart–lung interactions already discussed in the context of PEEP therapy, mechanical ventilation reduces systemic as well as myocardial oxygen demands. This may be critical in patients with ischemia and cardiogenic shock and is associated with a redistribution of blood from working respiratory muscles toward vital organs [203].

In principle, the ventilatory management of patients with ischemia and congestive heart failure is similar to that of patients with noncardiogenic forms of pulmonary edema. PEEP should be used to recruit flooded lung units and redistribute edema fluid from the alveolar to the interstitial spaces. When congestive heart failure complicates active ischemia, premature weaning attempts that focus only on maintenance of blood gas tension and ignore work of breathing and associated increases in myocardial oxygen demand are ill advised. Alternatively, it is important to recognize that weaning from mechanical ventilation may trigger congestive heart failure with or without myocardial ischemia [204–206]. Weaning-induced heart failure appears to be more prevalent in COPD (for further discussion, see Chapter 60).

Mechanical Ventilation in the Pregnant Patient

Pregnancy results in a number of physiologic changes that must be considered in the ventilatory management of patients in this condition. Changes include the reduction in chest wall compliance and increases in metabolic rate, minute volume, and respiratory drive. The consequent respiratory alkalosis is thought to aid fetal gas exchange. Alkalemia shifts the fetal oxyhemoglobin dissociation curve to the left, thereby increasing its ability to bind oxygen. Therefore, it stands to reason that in the pregnant mechanically ventilated patient, the minute volume setting should be adjusted to a PCO_2 target between 28 and 32 mm Hg [207]. However, in pregnant patients with ARDS or status asthmaticus, it might not be possible to reconcile this ventilation target with the principles of lung protection from mechanical injury. In the absence of clinical outcome data, it is impossible to offer strict management guidelines. All management decisions must balance benefits to the mother against possible risks to the fetus.

It is well established that gas tensions in maternal blood determine the acid or base status of the fetus. However, the risk of permissive hypercapnia to the unborn child is simply not known. Most experts agree that pregnant women with ARDS should be ventilated with TVs of 6 mL per kg ideal body weight. It is not known whether increasing respiratory rate to promote alkalemia is beneficial or whether associated changes in the rate of lung expansion offset the beneficial effects of low TVs. Because chest wall compliance is reduced, the application of PEEP (usually between 10 and 15 cm H_2O) might raise plateau pressure and predispose the pregnant patient to hypotension and decreased blood flow to the placenta.

Mechanical Ventilation in Individuals with a Bronchopleural Fistula

For discussion of the ventilatory strategy of this entity, see Chapter 57.

COMPLICATIONS ASSOCIATED WITH INTERMITTENT POSITIVE-PRESSURE VENTILATION

The hazards associated with mechanical ventilation can be divided into five major categories: (a) complications attributable to intubation and extubation [208–210], (b) complications associated with endotracheal or tracheostomy tubes [211], (c) complications attributable to operation of the ventilator, (d) medical complications occurring during assisted mechanical ventilation, and (e) psychologic effects.

Complications attributable to intubation and extubation and those associated with endotracheal or tracheostomy tubes include upper airway trauma, inadvertent placement or migration of the endotracheal tube into the right mainstem bronchus, vocal cord edema or granuloma, cuff-related damage to the trachea, accidental intubation of the esophagus, induction of vomiting with resultant aspiration, premature extubation, self-extubation, tube malfunction, nasal necrosis, and sinusitis. For a more complete discussion of these complications, see Chapters 1 and 12. Complications attributable to interfaces used during noninvasive forms of positive-pressure mechanical ventilation include nasal bridge ulcers, nasal congestion, and conjunctivitis from mask leaks directed to the eyes.

Complications attributable to operation of the ventilator include machine failure, alarm failure, alarm inadvertently turned off, inadequate nebulization or humidification, overheating of inspired air, ventilator asynchrony or noncapture, and bacterial contamination of various components of the mechanical ventilator. All of these can be minimized or eliminated if patients on ventilator support are not left unattended and infection-control methods are adhered to strictly. The implementation of ventilator-associated pneumonia (VAP) protection bundles, including head-of-bed elevation, chlorhexidine oral care, and daily sedation holidays have significantly reduced VAP across adult medical [212], surgical/trauma [213] and pediatric [214] ICUs.

Medical complications occurring during assisted ventilation include inadvertent alveolar hypoventilation and hyperventilation, bronchopulmonary dysplasia, hypotension caused by decreased cardiac output from a reduction in venous return, vascular insufficiency in patients with arteriosclerotic vascular disease caused by decreased cardiac output, water retention from increased circulating levels of antidiuretic hormone presumably stimulated when positive-pressure ventilation decreases left atrial volume [162], and lung barotrauma.

The classic manifestations of barotrauma are pulmonary interstitial emphysema with pneumomediastinum, subcutaneous emphysema, pneumoretroperitoneum, pneumoperitoneum, and pneumothorax with or without tension [89]. However, in the last two decades it has become abundantly clear that there are many more subtle manifestations of ventilator-induced lung injury originally attributed to intrinsic disease. These range from capillary leak and noncardiogenic edema to alveolar hemorrhage, inflammation, tissue remodeling, subpleural cyst formations, and fibrosis [67]. The clinical and experimental ventilator-associated lung injury literature has focused on TV and PEEP as major determinants of lung stress. There is no longer any doubt that these ventilator setting-dependent variables are important, but there remains considerable debate whether to apply specific numeric guidelines to individual patients, whether TV guidelines can be relaxed in spontaneously breathing patients who receive partial ventilator support, and what the TV-related injury mechanisms truly are. To understand these controversies, one needs to recall that there are four distinct injury mechanisms, namely (a) regional overexpansion caused by the application of a local stress or pressure that forces cells and tissues to assume shapes and dimensions that they do not assume during unassisted breathing; (b) so-called low-volume injury that is associated with the repeated recruitment and derecruitment of unstable lung units that causes the abrasion of the epithelial airspace lining by interfacial tension; (c) the inactivation of surfactant triggered by large alveolar surface area oscillations that stress surfactant adsorption and desorption kinetics, and that are associated with surfactant aggregate conversion; and (d) interdependence mechanisms that raise cell and tissue shear stress between neighboring structures with differing mechanical properties [215].

The older literature quotes an overall incidence of pneumothorax with intermittent positive-pressure ventilation of 3.5% [216], with values as high as 30% in the status asthmaticus subgroup [217]. It is hoped that an improved understanding of patient/ventilator interactions and lung biology will substantially reduce the incidence of barotrauma. Because 60% to 90% of pneumothoraces in patients on positive-pressure ventilation are under tension [218], and mortality increases from 7% to 31% when there is a delay from 30 minutes to 8 hours in diagnosing and treating pneumothoraces that occur on ventilators [219], there must be a high index of suspicion for this complication and it must be managed swiftly. For management of this problem, see Chapter 57.

Advances in initiation of mechanical ventilation, based on randomized, controlled trials or meta-analyses of such trials, are summarized in Table 58.1.

TABLE 58.1

ADVANCES IN VENTILATOR MANAGEMENT BASED ON RANDOMIZED CONTROLLED CLINICAL TRIALS

- Limiting tidal volume to 6 mL per kg predicted body weight reduces the probability of ventilator-associated lung injury and improves the survival of patients with ALI [20,131].
- For patients with ALI and ARDS who receive mechanical ventilation with a tidal volume goal of 6 mL per kg of predicted body weight and an end-inspiratory plateau-pressure limit of 30 cm of H_2O, clinical outcomes are similar whether lower or higher PEEP levels are used [148].
- Continuous positive airway pressure may decrease the incidence of endotracheal intubation and other severe complications in patients who develop hypoxemia after elective major abdominal surgery [176].
- The routine use of the prone posture in mechanically ventilated patients with ALI is not associated with a survival benefit [193].
- The use of high-frequency oscillatory ventilation should be considered as rescue treatment in patients with severe ARDS [15].
- Noninvasive mechanical ventilation enhances the survival of immunocompromised hosts with hypoxic respiratory failure [46] and is a viable alternative to invasive mechanical ventilation in patients with ALI [48,49].
- Pressure and volume preset modes result in similar outcomes in mechanically ventilated patients with acute respiratory failure [62].

ALI, acute lung injury; ARDS, acute respiratory distress syndrome; PEEP, positive end-expiratory pressure.

CHAPTER 59 ■ MECHANICAL VENTILATION PART II: NON-INVASIVE MECHANICAL VENTILATION FOR THE ADULT HOSPITALIZED PATIENT

SAMY S. SIDHOM AND NICHOLAS HILL

INTRODUCTION

Noninvasive ventilation (NIV) is the provision of mechanical ventilation without the need for an invasive artificial airway. NIV can be subdivided into a number of modalities with different mechanisms of action, including negative pressure ventilation that assists lung expansion by applying an intermittent negative pressure over the chest and abdomen, positive pressure ventilation that applies continuous or intermittent positive pressure to the upper airway, and abdominal displacement ventilators like pneumobelts and rocking beds that assist ventilation at least partly via the force of gravity on the abdominal contents [1–3]. Over the past two decades, noninvasive positive

pressure ventilation (NPPV) [4] via the nose, mouth, or combination has become the predominant mode of NIV in both the outpatient and hospital settings.

In this chapter, we focus on acute applications, comparing and contrasting noninvasive and invasive approaches and describing epidemiologic trends of NIV. Next, we describe the equipment used for NPPV and discuss indications and selection of patients for NPPV in the acute care setting. We then make recommendation regarding the practical and safe application of NPPV, including selecting the proper location, appropriate monitoring, and avoiding complications. Finally, we consider the impact on global patient outcomes as well as health care and hospital quality measures.

TERMINOLOGY

As used in this chapter, NIV is a generic term for a number of different noninvasive approaches to assisting ventilation, whereas NPPV refers specifically to the form that facilitates ventilation by applying a positive pressure to the upper airway. This can be continuous positive airway pressure (CPAP) that can be used to successfully treat certain forms of respiratory failure or intermittent, combining a positive end-expiratory pressure (PEEP) with pressure support (PS), the latter used to actively assist inspiration. Some ventilators are derived from portable positive pressure devices to treat sleep apnea and are commonly referred to as bilevel positive airway pressure (BPAP) devices. With these, the term expiratory positive airway pressure (EPAP) is used rather than PEEP and inspiratory positive airway pressure (IPAP) refers to the total inspiratory pressure. Thus, the difference between IPAP and EPAP equals the level of pressure support.

WHY NONINVASIVE MECHANICAL VENTILATION

NIV has seen increasing popularity in acute care settings throughout Europe and the United States over the past two decades [5,6]. This trend is related to a number of advantages of NPPV over invasive mechanical ventilation, but only in select patients. By averting invasion of the upper airway, NIV avoids a number of well-known complications of intubation, including aspiration of gastric contents, dental trauma, trauma to the hypopharynx, larynx, and trachea including tracheal rupture [7], hypoglossal nerve paralysis, autonomic stimulation leading to arrhythmias, and hypotension [8].

Ongoing use of invasive ventilation increases the risk of ventilator-associated pneumonia (VAP) related to disruption of airway protective mechanisms, pooling of secretions above the tube cuff that leak into the lower airways, and formation of a bacterial biofilm within the tube that is distributed peripherally with suctioning. In addition, irritation from the tube stimulates mucus secretion and interferes with normal ciliary function. The need for repeated suctioning further traumatizes the airway and promotes bleeding and mucus secretion. Following extubation, immediate complications include upper airway obstruction due to glottic swelling, negative pressure pulmonary edema, tracheal hemorrhage, and laryngospasm [9,10]. Complications of prolonged invasive ventilation (in association with tracheostomy) include a spectrum of repeated airway and parenchymal infections, vocal cord dysfunction, and tracheal stenosis and malacia [4,11–14].

In addition, NPPV is usually better tolerated than invasive ventilation, requiring less or no sedation. It usually permits short breaks that help to enhance tolerance. The avoidance of intubation-associated complications and sedation promotes more rapid weaning compared to invasive ventilation, shortening ICU stays and potentially reducing resource utilization and costs.

On the other hand, NPPV should not be considered as a replacement for invasive mechanical ventilation. When used appropriately, NPPV serves as a way to avoid intubation and its attendant complications, but it must be used selectively, avoiding patients who have contraindications (see "Selection Guidelines for NPPV in Acute Respiratory Failure" section). Appropriate candidates must be able to protect their airways and cooperate. Sometimes, NPPV is initiated in inappropriate or marginal candidates who fail to respond favorably. In this situation, it is important to intubate promptly, avoiding delays that can lead to cardiopulmonary arrest, necessitating emergency intubation and increased morbidity and mortality [15].

UTILIZATION AND EPIDEMIOLOGY

Rates of NPPV utilization in acute care settings are increasing in Europe and North America [16,17]. An observational study of NIV utilization for chronic obstructive pulmonary disease (COPD) and cardiogenic pulmonary edema (CPE) patients in acute respiratory failure (ARF) in a single 26-bed French intensive care unit (ICU) revealed an increase from 20% of ventilator starts in 1994 to nearly 90% in 2001 [17]. In association with this increase, the occurrence of healthcare-acquired pneumonias and ICU mortality fell from 20% and 21% to 8% and 7%, respectively. The authors speculated that increasing experience and skill with NPPV in their units contributed to the improved outcomes. In an Italian study examining outcomes of NPPV in two different time periods during the 1990s, success rates remained steady despite an increase in acuity of illness scores, suggesting sicker patients in the later time period were being managed as successfully as less ill patients in the earlier period, a trend the authors attributed to increased skill of the caregivers [16].

Sequential surveys of European (mainly French) ICUs demonstrated an increase in the use of NIV as a percentage of total ventilator starts from 16% to 23% in 1997 and 2002, respectively, with utilization in patients with COPD and CPE increasing from 50% to 66% and from 38% to 47%, respectively [6]. Esteban et al. conducted a worldwide survey in more than 20 countries that compared the trends of mechanical ventilation use and demographics between 1998 and 2004, enrolling more than 1,600 patients and showing an overall increase of about 6% (11.1% from 4.4%) in NIV use [15]. In Italy, Confalonieri et al. reported high utilization rates of NIV in specialized respiratory intensive care units (RICUs) which are similar to "intermediate" or "step-down" units in the United States, where a large proportion of patients have COPD either as an etiology of ARF or as a comorbidity. In that setting, 425 out of 586 (72.5%) patients requiring mechanical ventilation were treated initially with NIV (374 using NPPV and 51 using an "iron lung") [18].

However, in a 2003 national audit of COPD exacerbations in the United Kingdom, NIV was unavailable in 19 of 233 hospitals and 39% of ICUs, 36% of "high-dependency units," and 34% of hospital wards [19]. Similar results were seen in a North American survey of NIV use in 71 hospitals in Massachusetts and Rhode Island [20]. Overall use of NPPV was estimated to be 20% of all ventilator starts, but 30% of hospitals had estimated rates <15%. Reasons for low utilization were mostly attributed to lack of physician knowledge of NPPV, inadequate equipment, and lack of staff training. Most disturbingly, estimated use of NIV for COPD exacerbations and CPE was only 29% and 39% of ventilator starts, respectively

[20]. A follow-up study in Massachusetts using data collected prospectively from 2005 to 2007 revealed an overall 38.7% NIV utilization rate, with 80% and 69% of COPD and CPE patients, respectively, receiving NIV as the initial mode [21].

A national survey of U.S. Department of Veterans Affairs hospitals showed that despite wide availability of NIV, its perceived use was low. Almost two-thirds of respiratory therapists responding to the survey felt that NIV was used less than half the time when it was indicated. The survey also revealed wide variations in the perception of NIV use depending on the size of the ICUs, larger ones reporting more frequent use [22]. Along these lines, a Canadian study reported that between 1998 and 2003, only 66% of patients meeting criteria for NPPV actually received it [23].

Suboptimal utilization has been reported in non-Western countries as well. A Korean survey reported that NIV was used in just 2 of 24 university hospitals and comprised only 4% of ventilator starts. A majority of the physician staff (62%) and 42% of the nurses expressed a desire for additional educational programs on NIV [24]. In an Indian survey of 648 physicians, perceived NIV use was mostly limited to the ICU (68.4%) while COPD was the most common indication for its use [25]. Findings of this survey were similar to those of the Korean, European, and North American surveys in that rates of NIV use varied widely between centers, with a substantial portion reporting low rates. These findings underline the need for NIV educational programs at individual hospitals that permit caregivers to develop the requisite expertise in administering NIV.

INDICATIONS FOR ACUTE APPLICATIONS OF NPPV

Indications for NPPV depend on the etiology of ARF and specific settings in which ARF occurs [i.e., do-not-intubate (DNI) patients]. As much as possible, our analysis is based on available evidence. We recommend application of NPPV for those diagnoses that are those supported by multiple randomized trials. We consider NPPV as an "option" when the application is supported by a single randomized trial, multiple historically controlled or cohort series, or sometimes conflicting evidence. Successful application of NPPV has been reported for all of these indications if applied in appropriately selected and monitored patients (Table 59.1).

TABLE 59.1

INDICATIONS FOR NONINVASIVE POSITIVE PRESSURE VENTILATION AS DETERMINED BY STRENGTH OF EVIDENCE

Recommended (supported by strong evidence[a])
COPD exacerbations
COPD—failure to wean from invasive mechanical ventilation
Acute cardiogenic pulmonary edema
Immunosuppressed patients with acute respiratory failure
Option (supported by weaker evidence[b])
Other obstructive airway diseases with acute respiratory failure
Asthma exacerbation
Cystic fibrosis
Hypoxemic respiratory failure[c]
ALI/ARDS
Community-acquired pneumonia
Trauma
Extubation failure
Mainly patients with COPD or congestive heart failure (CHF)
Postoperative respiratory failure
Prophylactic use of CPAP or "bilevel" after high-risk surgeries
Treatment of acute respiratory failure—mainly COPD or CHF
Do-not-intubate patients
To treat acute respiratory failure (COPD or CHF)
To palliate for relief of dyspnea or extend survival to settle affairs
Obesity hypoventilation
Neuromuscular disease
Partial upper airway obstruction (postextubation)
Not recommended
ALI/ARDS with multiorgan system dysfunction or hypotensive shock
End-stage pulmonary fibrosis with exacerbation
Total or near total upper airway obstruction

[a]Strong evidence refers to multiple randomized controlled trials and meta-analyses.
[b]Weaker evidence refers to mainly case series, case-matched series, single randomized trials, or some conflicting data.
[c]Must be monitored very carefully—not a routine indication.
ALI/ARDS, acute lung injury/acute respiratory distress syndrome.

Recommended Indications

Chronic Obstructive Pulmonary Disease

COPD Exacerbations. The best established acute indication for NPPV is to treat ARF due to COPD exacerbations. This is supported by a strong physiologic rationale. Studies demonstrate that the combinations of extrinsic PEEP and PS alone reduce diaphragmatic work of breathing more than either modality alone, because the expiratory pressure counterbalances intrinsic PEEP and the higher inspiratory pressure (pressure support) actively assists the inspiratory muscles [26]. In the setting of COPD exacerbations, NPPV thereby serves as a "crutch" to assist ventilation while medical therapy is given time to work.

Multiple randomized controlled trials (RCTs) and meta-analyses on COPD patients with ARF have established that NIV more rapidly reduces respiratory rate, improves dyspnea and gas exchange, reduces intubations from an average rate of 50% to 20%, and lowers mortality compared to standard therapy [5,27–32]. This evidence justifies the early use of NPPV for COPD exacerbations as a standard of care unless there are contraindications. COPD exacerbations also respond well to NPPV when complicated by pneumonia [33] or occurring in the setting of a DNI status [34–36], or postoperative or postextubation respiratory failure [37,38].

Facilitation of Weaning in COPD Patients. Some patients with COPD exacerbations require intubation because they are not candidates for NPPV initially or fail a trial of NPPV. Multiple controlled trials have demonstrated that NIV permits earlier extubation in such patients, even if they have failed multiple "T" piece weaning trials [39–41]. Early extubation to NIV increases eventual weaning rates, shortens the duration of ventilator use and hospital length of stay (LOS), reduces the occurrence of nosocomial pneumonia, and reduces mortality. This approach should be considered whenever intubated COPD patients are failing spontaneous breathing trials, but it should be used with caution—only in a patient who is otherwise an excellent candidate for NIV, can breathe without any assistance for at least 5 minutes, can tolerate levels of pressure support deliverable

by mask (i.e., inspiratory pressure <20 cm H_2O), and is not a "difficult intubation."

Cardiogenic Pulmonary Edema

Positive airway pressure has well-known therapeutic effects in patients with acute pulmonary edema. The increased functional residual capacity opens collapsed alveoli and rapidly improves compliance and oxygenation. The increased intrathoracic pressure reduces transmyocardial pressure and has preload and afterload reducing effects, thus enhancing cardiac function in patients with left ventricular dysfunction who are afterload-dependent.

Multiple RCTs have demonstrated that noninvasive CPAP (10 to 12.5 cm H_2O) alone dramatically improves dyspnea and oxygenation and lowers intubation rates in patients with acute pulmonary edema compared with standard O_2 therapy [17,42,43]. Subsequent studies evaluating the efficacy of NPPV (i.e., pressure support plus PEEP or BPAP) either compared with O_2 therapy or CPAP alone [44–46] have shown benefits similar to those previously demonstrated for CPAP. In one large RCT [47], CPAP and NPPV performed similarly, both improving dyspnea scores and pH more rapidly than oxygen alone, but neither lowered intubation nor mortality rate (the major outcome variable) compared to controls. However, the intubation rate in this study was slightly below 3% in all of the groups, including controls, suggesting that the enrolled patients were too mildly ill to manifest a significant mortality benefit.

Meta-analyses of the RCTs on CPAP or NPPV compared with O_2 therapy alone have confirmed the benefits described above, even showing a significant reduction in mortality with CPAP [48,49]. Meta-analyses comparing the two modalities show equivalency of NPPV and CPAP with regard to reduction of intubation, lengths of stay, and mortality, and with no increase in the myocardial infarction rate attributable to NPPV use [50]. However, some studies have found that NPPV reduces dyspnea and improves gas exchange more rapidly than CPAP alone [44,51]. Therefore, by virtue of its greater simplicity and potentially lower cost, CPAP alone is generally regarded as the initial noninvasive modality of choice for cardiogenic edema patients, but NPPV is substituted if patients treated initially with CPAP remain dyspneic or hypercapnic. The strong evidence favoring the use of CPAP or NPPV to treat CPE establishes either one as standard therapy for initial ventilatory assistance of appropriately selected CPE patients.

The success of noninvasive positive pressure to treat CPE has encouraged its extension into the prehospital setting. An emerging trend is to provide CPAP devices on ambulances for initial therapy of CPE. The experience thus far with this practice has been favorable. Plaisance et al. [52] observed a strong trend for reduced intubation and mortality rates among 124 CPE patients randomized to "early" (started immediately on site) versus "late" (delayed by 15 minutes) CPAP (7.5 cm H_2O). In another RCT, Thompson et al. observed an absolute reduction of 30% in intubation rate (17 out of 34 patients, or 50% vs. 7/35 or 20%, unadjusted OR = 0.25 and CI = 0.09 to 0.73) and 21% in mortality (OR 0.3; 95% CI 0.09 to 0.99) among CPE patients treated with CPAP compared to usual therapy with oxygen, including intubation and bag-valve-mask-ventilation if needed [53].

A pilot study by Duchateau et al. reported an improved respiratory status in 12 "do not intubate" (DNI) patients when offered NPPV out-of-hospital by emergency medical services (EMS). Respiratory rate decreased from 34 to 27 per minute, $p = 0.009$, and pulse oximetry improved from 86% to 94%, $p < 0.01$, with only one intolerant patient [54]. These studies suggest that outcomes of CPE patients can be improved by very early initiation of noninvasive positive pressure therapy in the field and adoption of this as a routine practice for EMS seems likely.

Immunodeficient Patients with Acute Respiratory Failure

Patients developing ARF with underlying immunodeficiency states such as human immunodeficiency virus and Pneumocystis pneumonia or following solid organ or bone marrow transplantation have poor outcomes when treated with invasive mechanical ventilation [55]. Nosocomial infections and fatal septicemia are common complications, and those with hematologic malignancies may encounter fatal airway hemorrhages due to upper airway trauma occurring with intubation in patients with thrombocytopenia and platelet dysfunction. NIV offers a way to avoid such complications and improve outcomes.

Randomized trials of NIV in patients with ARF who have undergone solid organ transplantation or bone marrow transplant for hematologic malignancy have demonstrated reduced intubation and mortality rates compared with controls [56–59]. NIV was begun in these patients before respiratory failure became severe, and even then the mortality rate in the NIV group in one study was 50% compared with 80% in the conventionally treated group [58]. Thus, NIV should be considered early during the development of respiratory failure in immunodeficient patients as a way to avoid intubation and its attendant morbidity and mortality [57].

WEAKER INDICATIONS—NPPV IS AN OPTION

NPPV can be used to treat ARF of other etiologies and in other settings, but the evidence to support these applications is weaker and use is optional but not necessarily recommended (Table 59.1).

Other Obstructive Diseases

Asthma Exacerbations

Retrospective cohort studies suggest that NPPV improves gas exchange and avoids intubation in patients with respiratory failure caused by asthma exacerbations [60,61]. However, there are only two randomized trials supporting the use of NPPV for this indication. In one RCT, NPPV improved FEV_1 more rapidly and reduced the hospitalization rate compared with sham controls [62]. The second study [63] reported similar findings with "high" inflation pressures compared to lower pressures (IPAP and EPAP 8 and 6 cm H_2O and 6 and 4 cm H_2O, respectively—all lower than most other studies) or standard medical therapy. Neither study was powered to examine intubation rates or mortality.

Pollack et al. demonstrated that NPPV is an acceptable way to deliver bronchodilator aerosol, showing a greater improvement in peak expiratory flow 1 hour after administration via a "bilevel" device than a standard nebulizer [64]. These studies suggest that when NPPV is used as an early treatment for asthma exacerbations, it can potentiate the bronchodilator effect of beta-agonists. However, in most clinical situations, NPPV is reserved for patients with "status asthmaticus," that is, those with severe airway obstruction who are not responding adequately to initial bronchodilator therapy, an application that is not yet supported by RCTs.

Cystic Fibrosis

Ideally, NPPV is initiated in patients with cystic fibrosis when they develop chronic respiratory failure before an acute crisis arises. For patients with acute exacerbations of cystic fibrosis, NPPV has been used mainly as a bridge to transplantation [65].

These patients may remain severely hypercapnic and require aggressive management of secretion retention, but NPPV permits avoidance of intubation and can sustain them for months while they await availability of donor organs.

Hypoxemic Respiratory Failure

Hypoxemic respiratory failure consists of severe hypoxemia (PaO_2/FIO_2 <200), severe respiratory distress, tachypnea (>30 per minute), and a non-COPD cause of ARF such as ARDS, acute pneumonia, trauma, or acute pulmonary edema [66]. Some RCTs on hypoxemic respiratory failure have observed reductions in the need for intubation, shortened ICU lengths of stay, and even mortality in the NIV group as opposed to controls [66,67], but it is difficult to draw firm conclusions about individual diagnostic groups within this very broad category. One concern is that favorable responses in one subgroup, such as those with CPE, could obscure unfavorable responses in another, such as ARDS or pneumonia patients.

Among studies examining subcategories specifically, Jolliet et al. found very high NPPV failure rates (>60%) in a cohort series of patients with severe community-acquired pneumonia [68]. Confalonieri et al. [33] found that NPPV reduced the need for intubation, shortened ICU LOS, and improved 90-day mortality in a RCT of patients with severe community-acquired pneumonia. However, these benefits were seen only in the COPD subgroup—not in non-COPD patients. Thus, no convincing evidence supports the use of NPPV over invasive ventilation in patients with severe community-acquired pneumonia lacking COPD, and although NPPV remains an option in such patients, it should be used only in carefully selected and monitored patients, with preparedness to intubate promptly if they are not responding well within an hour of NPPV initiation.

The situation with ARDS (which overlaps with severe community-acquired pneumonia) is quite similar, but no RCTs have been performed on the use of NPPV for ARDS per se. Small case series have suggested benefit [69], and in one interesting study that used NPPV as a "first-line" therapy for ARDS, the successful use of NPPV was associated with much lower ventilator-associated pneumonia and mortality rates than in NPPV failures [70]. The authors suggested that an initial simplified acute physiology score (SAPS) II of 34 or less and an improvement of PaO_2/FIO_2 to greater than 176 during the first hour of NPPV therapy could be used to identify patients likely to succeed. However, it is good to remember that this was not an RCT and that only 15% of the patients with ARDS admitted to the ICU (two thirds were intubated prior to ICU admission) actually succeeded with NPPV. Also, in a previous study on risk factors for NPPV failure in patients with hypoxemic respiratory failure, Antonelli et al. observed an odds ratio of 3.75 for ARDS and severe pneumonia [71]. Thus, as with severe pneumonia, NPPV should be used very selectively and cautiously in ARDS patients—only for those with lower acute physiology scores, hemodynamic stability, and good initial improvements in their oxygenation.

Posttrauma Respiratory Failure

Flail chest or mild acute lung injury (ALI) are conditions that are posited to respond favorably to NPPV after traumatic chest wall injuries. Support for this view comes from retrospective studies such as that by Beltrame et al. [72], in which 46 trauma patients with respiratory insufficiency were treated with NPPV and experienced rapid improvements in gas exchange and a 72% success rate, but burn patients responded poorly. More recently, a study that randomized thoracic trauma patients with PAO_2/FIO_2 <200 to NPPV or high flow oxygen was stopped early after enrollment of 50 patients because of significant reductions in intubation rate (12% vs. 40%) and hospital LOS (14 vs. 21 days) in the NPPV group [73]. These results support the use of NPPV for hypoxemic respiratory failure in posttho-racic trauma cases, but it is good to remember that these were carefully selected patients.

Extubation Failure

The recurrence of respiratory failure after extubation of patients initially intubated for a bout of ARF is referred to as *extubation failure* and is associated with a high risk of morbidity and mortality (rates exceeding 40% in some studies [74,75]). NPPV has been proposed as a way to avoid extubation failure if begun early in patients at risk for extubation failure, reducing the need for reintubation and improving outcomes. However, some earlier randomized studies [76] comparing NPPV to standard O_2 therapy found no reduction in reintubation attributable to NPPV. In fact, Esteban et al. even found a significantly increased ICU mortality in the NIV group [77]. These studies were limited by low enrollment of COPD patients (only about 10% of patients), and the increased mortality was thought to be related to a 10-hour delay in reintubations in the NIV group compared with controls.

Two subsequent randomized trials [78,79] on patients deemed to be at "high risk" for extubation failure found that NIV reduced the need for reintubation and ICU mortality. Forty to fifty percent of patients in these trials had COPD or CHF and in one of the trials [78], most of the benefit was attributable to the COPD subgroup. Another recent trial focusing on patients with postextubation hypercapnia showed a significant reduction in the occurrence of postextubation respiratory failure as well as 90-day mortality in the group randomized to NPPV compared to oxygen-treated controls [80]. These studies support the use of NIV in patients at *high risk* of extubation failure, particularly if they have COPD, CHF, and/or hypercapnia. However, based on the Esteban study, NPPV to prevent extubation failure should be used very cautiously in at-risk patients who do not have these favorable characteristics because of the higher risk of NPPV failure and its attendant morbidity and mortality. Patients failing to improve promptly with NPPV should be reintubated without delay.

Postoperative Respiratory Failure/Insufficiency

Noninvasive positive pressure techniques, both CPAP and NPPV, have been used in postoperative patients in either of two ways: to prevent complications after high-risk surgeries or to treat frank postoperative respiratory failure. When used prophylactically after major abdominal surgery [81–83] or thoracoabdominal aneurysm repair [84], CPAP (10 cm H_2O) reduces the incidence of hypoxemia, pneumonia, atelectasis, and intubations compared with standard treatment. In the only randomized study of NPPV in patients with postoperative respiratory failure, post–lung resection patients had reduced intubation and mortality rates if treated with NPPV compared with standard management [85]. These studies strongly support the idea that both CPAP and NPPV should be considered to prevent and treat postoperative respiratory complications and failure, but because of the variety of surgeries and positive pressure techniques evaluated, more specific recommendations cannot be made.

Patients with a Do Not Intubate Status

NIV to treat DNI and palliative care patients has been controversial. Some argue that when patients are dying of respiratory failure, there is little to lose by trying NIV. Contrariwise, others counter that this is apt to add to patient discomfort and prolong suffering in a patient's final hours. Prospective cohort series demonstrate that many DNI patients treated with NIV actually survive the hospitalization, depending on the diagnosis [36,86]. In one series, 43% of 114 such patients survived to hospital discharge, 75% of CHF patients, and 53% of COPD patients, whereas hospital survivals for patients with pneumonia

or an underlying malignancy had hospital survivals in the range of 25% [36]. The presence of cough, awake mental status, and hypercapnia also imparted a favorable prognosis.

Thus, it is possible to identify, on the basis of the diagnosis and some simple clinical observations, patients with a better than even chance of surviving the hospitalization, and NIV could be used in these patients as a form of life support with the hope of "bridging" them through their acute illness. NIV can also be used for palliation of patients with a poor prognosis for survival of the hospitalization, with the possible aims of alleviating dyspnea or to prolong survival slightly so that the patient has time to settle affairs or say goodbye to loved ones. As recommended by a consensus statement by a Society of Critical Care Medicine task force on NIV, it is necessary for the patient, family, and caregivers to agree on these goals and to cease promptly if NPPV seems to be adding to suffering (via mask discomfort, for example) rather than alleviating it [87].

Other Acute Applications of NPPV

Endoscopic Procedures

In separate randomized trials, CPAP alone (up to 7.5 cm H_2O) or NPPV both improved oxygenation and reduced postprocedure respiratory failure in patients with severe hypoxemia undergoing bronchoscopy compared with those receiving conventional O_2 supplementation [88,89]. The evidence supports the use of NIV to improve gas exchange and reduce potential complications during fiber-optic bronchoscopy, especially when the risk of intubation is deemed high such as in immunocompromised patients or in those with bleeding diatheses. However, patients must be monitored closely and the caregiver team must try to minimize the risk of aspiration and be prepared for the possible need for emergent intubation.

NPPV is also being used for other endoscopic procedures, such as placement of percutaneous gastrostomy tubes in patients with respiratory compromise due to neuromuscular disease and performance of transesophageal echocardiography [90,91].

Preoxygenation Before Intubation

A randomized trial in critically ill patients with hypoxemic respiratory failure showed that preoxygenation with NIV before intubation improved O_2 saturation during and after intubation and decreased the incidence of O_2 desaturations below 80% during intubation [92]. This approach is promising but needs further evaluation before routine use can be recommended. This also begs the question whether, if NIV improves oxygenation substantially, intubation could be avoided in some of these patients.

SELECTION GUIDELINES FOR NPPV IN ACUTE RESPIRATORY FAILURE

Determinants of Success/Failure

Selection of appropriate patients for NPPV is critical for optimizing success and providing benefit. Knowledge of factors that predict success or failure is helpful in selecting good candidates for NPPV. Such factors, compiled from previous studies, are shown in Table 59.2. In effect, the predictors indicate that patients who are most likely to succeed with NIV have incipient, milder respiratory failure than those who fail. This suggests that there is a "window of opportunity" for implementation of NIV when success is most likely. NIV should be started when patients have evidence of acute respiratory distress and increased acute physiology and chronic health evaluation II (APACHE II) scores, but not when patients are approaching respiratory arrest, have severe acidemia, high APACHE II scores, or are unable to cooperate.

TABLE 59.2

PREDICTORS OF NIV FAILURE

Inability to cooperate with therapy or GCS <12
RR >30 and hypoxemia
Severe dyspnea
Excessive accessory muscle or paradoxical breathing
Paradoxical breathing
Hypercapnic respiratory failure with acidemia, pH <7.10
Acute hypoxemic respiratory failure with PaO_2/FIO_2 <100
SAPS II score ≥34 or APACHE II score >29
Age >40 but <70 y
Serum HCO_3 <22
Multiorgan dysfunction
ARDS, pneumonia
Lack of improvement in respiratory rate within 1–2 h
Lack of increase in PaO_2/FIO_2 to >175 within 1 h

Predictors of success differ slightly between patients with hypercapnic and hypoxemic forms of respiratory failure. A chart to predict NPPV failure of COPD patients identified pH <7.25, respiratory rate ≥35, APACHE II score >29, and Glasgow Coma score ≤11 as independent predictors of NPPV failure [93], whereas a recent prospective multicenter study on NIV to treat patients with ARDS identified a SAPS II score of ≥34 and a PaO_2/FIO_2 ratio <175 after the first hour as independent predictors of NPPV failure [70]. In both analyses, the response to NPPV after the first hour or two had more predictive value than baseline values.

In hypercapnic respiratory failure, a rise in pH and improving mental status within an hour or two of initiating NPPV (presumably reflecting a drop in $PaCO_2$) predict success, whereas, not surprisingly, a substantial early improvement in oxygenation bodes well in patients with hypoxemic respiratory failure. These observations highlight the importance of a "1- to 2-hour checkpoint" after which if the patient is not improving sufficiently, prompt intubation should be contemplated rather than risk further deterioration and the need for a riskier emergent intubation.

Selection Process

The selection of patients with ARF to receive NPPV is based on criteria used in RCTs, and these are listed in Table 59.3. This is a simple three-step process, the first of which is to establish that the patient has a favorable diagnosis, ideally a condition like CPE or COPD, which is likely to respond to medical therapy fairly rapidly (a few days or less). Patients with weaker indications (i.e., acute asthma or pneumonia) can be tried on NPPV but must be monitored very closely in an ICU, especially if they have risk factors for NPV failure. Patients at very high risk for NPPV failure, such as those with sepsis and evolving multiorgan dysfunction, are generally best managed invasively rather than to delay needed intubation.

Step two is to identify patients who need ventilatory assistance so that the modality is not wasted on patients who are too mildly ill to warrant ventilatory assistance. This is done on the basis of simple bedside observations of dyspnea, vital signs, and evidence of increased work of breathing (such

TABLE 59.3

CRITERIA TO SELECT PATIENTS TO RECEIVE NPPV FOR ACUTE RESPIRATORY FAILURE[a]

Hypercapnic respiratory failure	Hypoxemic respiratory failure
Subjective	
Moderate to severe dyspnea	Moderate to severe dyspnea
Physiologic	
Respiratory rate >24/min	Respiratory rate >30/min
Increased accessory muscle use	Increased accessory muscle use
Abdominal paradox	Abdominal paradox

$PaCO_2$ >45 mm Hg, <98 mm Hg	PaO_2/FIO_2 >100, <300

[a]From a composite of initiation criteria for randomized controlled trials.

as vigorous accessory muscle use). Arterial blood gas results showing acute-on-chronic CO_2 retention may be helpful, but needed ventilatory assistance should not be delayed pending availability of blood gas results.

The third step is to exclude patients who have contraindications to NPPV and should be managed invasively (Table 59.4). Most of the contraindications are relative and judgment must be exercised when deciding whether patients have excessive secretions, medical instability, or uncooperativeness. Coma and severe obtundation are no longer considered absolute contraindications as long as they are related to hypercapnia. Patients with hypercapnic coma (Glasgow Coma Scale <8) have success and survival rates with NPPV that are equivalent to those of similar noncomatose patients [94].

TECHNIQUES AND EQUIPMENT FOR NPPV

Interfaces

Nasal Masks

Nasal masks are the most commonly used interfaces for outpatients with chronic respiratory failure because they are more comfortable than nasal prongs or oronasal masks, even if they are less efficient than oronasal masks at eliminating CO_2 [95]. In addition, they permit speech and expectoration and, with some practice, eating during use. Manufacturers offer numerous modifications of the nasal mask that fit into several basic categories.

TABLE 59.4

CONTRAINDICATIONS TO NPPV IN ACUTE RESPIRATORY FAILURE

Cardiac/respiratory arrest
Medically unstable (hypotensive shock, uncontrolled cardiac ischemia, or arrhythmias)
Severe upper gastrointestinal bleeding
Unable to protect airway (impaired cough or swallowing)
Excessive secretions
Unable to apply mask due to facial surgery, trauma, burns, or facial deformity
Agitated or uncooperative
Undrained pneumothorax
Multiorgan system failure

Standard Nasal Masks

Standard nasal masks were first designed during the early 1980s to provide CPAP for obstructive sleep apnea (OSA) and consist of triangular clear plastic domes that fit over the nose (Fig. 59.1A). A soft, usually silicon cuff makes contact with the skin around the perimeter of the nose to form an air seal. These masks must be fit properly to minimize pressure over the bridge of the nose, which may induce redness, skin irritation, and occasionally ulceration. Forehead "spacers" or an adjustable joint are also often used to minimize pressure on the bridge of the nose. Strap systems that hold the masks in place are important for patient comfort. Various approaches have been used to enhance patient comfort, including an additional thin plastic flap or a baffle system to further reduce the strap tension necessary to maintain an air seal. Gel-containing seals, some that have heat-molding capabilities, may help to evenly distribute the pressure of the seal on the face.

Nasal Pillows

Nasal "pillows" consist of small rubber cones that are inserted directly into the nostrils. By removing the sealing surface from the eyes, these reduce claustrophobia and permit use of eyeglasses. They also eliminate contact with the nasal bridge and are helpful for patients with nasal bridge irritation or ulceration caused by standard nasal masks. However, they can cause irritation of the nostrils, and some patients alternate between different types of masks as a way of minimizing discomfort. These are less often used in the acute care setting.

Oronasal or Full-Face Masks

The main advantage of oronasal over nasal masks is that they reduce air leaking through the mouth because they cover both the nose and mouth. Mainly because of this advantage, Kwok et al. found that the oronasal was significantly better tolerated than the nasal mask in the acute setting [96]. Air seals of oronasal masks are similar to those of nasal masks, using a thin membrane of soft silicon to enhance comfort and minimize air leaks. Oronasal masks have built-in valves to prevent rebreathing or asphyxiation in the event of ventilator malfunction, especially for "bilevel"-type ventilators. Because of concerns that vomiting into an oronasal mask could cause aspiration, these masks have straps that allow rapid removal. Some oronasal masks incorporate a "shelf" that fits under the chin to stabilize it, aiming to minimize air leaking under the seal (Fig. 59.1B). Compared with nasal masks, oronasal masks interfere more with speech and eating, have more dead space, and are less comfortable. However, because of their better initial tolerability and more efficient CO_2 removal than nasal masks, they are usually preferred to treat ARF.

The Total Face Mask (Respironics, Inc.) is a larger version of an oronasal mask that seals around the perimeter of the face [97]. It relocates the sealing surface from the nose and mouth to the perimeter of the face. It easily accommodates most facial shapes and sizes and can be rapidly applied by fastening just two Velcro straps behind the head. Although some patients find it frightening and refuse to try it, most find it comfortable and no more claustrophobic than standard oronasal masks. A more recently introduced version of an oronasal mask is smaller than the Total Face Mask, resembling a snorkeling mask (Fig. 59.1C) and serves as an alternative if patients are intolerant of standard masks.

FIGURE 59.1. Examples of interfaces used in the acute care setting. **A:** Standard disposable nasal mask for use with "bilevel" ventilator. The single circuit of these ventilators necessitates an in-line exhaust valve shown by arrow (Mirage Quattro mask, ResMed, San Diego, CA). **B:** Disposable full-face mask with chin "shelf" to keep mandible in position and reduce air leaking under the seal (Model RT040, Fischer Paykel, Wellington, NZ). **C:** Larger full-face mask that resembles snorkel mask and removes mask seal farther from nose and mouth (Performax, Respironics, Inc. Murrysville, PA). **D:** "Helmet" interface that consists of clear plastic cylinder that fits over entire head and fits with strap under axillae.

Helmet

The helmet (Fig. 59.1D) has been used primarily in Italy and has not yet been approved for use with NIV in the United States. It consists of an inflatable plastic cylinder that fits over the head and seals around the neck and shoulders with straps under the axillae. Studies evaluating its use in COPD patients [98,99] show that it is more comfortable and reduces facial ulcerations compared with an oronasal mask. However, it is less efficient at CO_2 removal and can cause problems with triggering and cycling during pressure support ventilation [100]. It appears to be best suited for applying CPAP in patients with acute cardiogenic edema. To prevent rebreathing, high airflow rates are necessary, which render the helmet much noisier than oronasal masks (100 dB vs. 70 dB, respectively) [101]. Although the helmet has some advantages over the full-face mask, it is limited by less-efficient CO_2 removal, excessive noisiness, higher cost, and is unavailable in many countries.

Oral Interfaces

Oral interfaces consisting of a mouthpiece inserted into a lip seal that is strapped tautly around the head to minimize air leakage have been used to treat patients with chronic neuromuscular conditions for many decades. A commercially available oral interface was introduced more recently for the treatment of occasional patients with sleep apnea. These interfaces are not often used in the acute care setting, although some studies have had patients hold interfaces in their mouths to enhance their sense of control when initiating NIV [102].

Headgear

The straps used to hold interfaces in place are important for interface comfort and stability as well as for control of air leaks. The number of strap connections varies from two to five, depending on the mask. In general, the more connections, the more stable the interface, but discomfort and claustrophobia become concerns. Most straps use soft, elastic material fastened with Velcro, but abrasions can occur if the edges are too rough. Minimizing strap tension just to the point of controlling air leaks is important to optimize comfort.

Ventilators for NPPV

The specific ventilator chosen is probably not as important to NPPV success as the settings selected or the skill of the

FIGURE 59.2. Examples of ventilators commonly used to deliver NPPV. **A**: "Critical care" ventilator that offers an "NIV" mode that permits multiple adjustments. May have trouble adapting to large leaks (Puritan Bennett 840, Covidien, Mansfield, MA). **B**: Typical "bilevel" ventilator designed mainly for home use but is capable of assisting ventilation in patients with acute respiratory failure (VPAP III STA, ResMed, Inc). **C**: Ventilator designed specifically for acute applications of NIV. Has oxygen blender and graphic monitoring screen (BiPAP Vision, Respironics, Inc). **D**: Updated version of ventilator in (**C**). Offers internal battery for portability and improved graphic screen (V60, Philips Respironics, Inc, Andover, MA).

care team. Many ventilator options are available, including critical care ventilators (designed mainly for invasive ventilation in the acute setting), ventilators designed especially for acute applications of NIV in the acute care setting, or portable positive-pressure ventilators designed mainly for use in the home. The choice of ventilator depends mainly on availability, patient needs, and practitioner preferences. For example, patients with hypoxemic respiratory failure may be very difficult to manage noninvasively and the sophisticated monitoring and oxygen delivery capabilities of a critical care ventilator may be preferred, whereas a patient with an exacerbation of COPD who is oxygenating adequately might do just as well with a small, portable, inexpensive bilevel device.

Critical Care Ventilators

The microprocessor-controlled ventilators currently used mainly for invasive mechanical ventilation in critical care units can be adapted for NPPV. These offer an array of volume-limited or pressure-limited modes and sophisticated monitoring and alarm capabilities. Advantages over "bilevel" positive pressure devices include the universal presence of O_2 blenders, accurate tracking of tidal and minute volumes, and a dual-limb circuit with an active exhalation valve that minimizes rebreathing (Fig. 59.2A). Most practitioners use the pressure support mode for NPPV with these ventilators because of enhanced comfort, combining it with PEEP [103,104]. Shortcomings of these ventilators when used to deliver NPPV include intolerance of air leaks that inevitably occur with NPPV, causing difficulty with triggering and cycling which sets off annoying alarms.

Many critical care ventilators now incorporate NIV modes that automatically improve leak tolerance and compensating abilities, disable nuisance alarms, and permit multiple adjustments including those to limit inspiratory time, thus enabling improved expiratory synchrony. These modes have undergone little evaluation in clinical settings, but a recent bench study demonstrated that most NIV modes on critical care ventilators work well to deliver set pressures or volumes unless there are large air leaks, in which case most of them require additional adjustments to maintain delivery [105]. Masks and circuitry for the application of NIV via critical care ventilators should not have the built-in exhalation valves designed for use with bilevel devices because these will increase air leaking and interfere with proper function. Some mask manufacturers use blue coloration for plastic parts of masks meant for use with critical ventilators so that they can be easily identified.

Bilevel Pressure-Limited Ventilators

These devices were first conceived to enhance comfort in patients requiring high CPAP to treat sleep apnea [106], but it rapidly became apparent that they function as pressure support ventilators as well [107]. Portable bilevel ventilators that deliver pressure assist or pressure support ventilation have seen increasing use in recent years. The prototype bilevel device was the "BiPAP S/T" (Respironics, Inc., Murrysville, PA), introduced during the late 1980s, but numerous versions of this technique are now available from many manufacturers (Fig. 59.2B).

Bilevel devices deliver two levels of positive pressure; preset inspiratory and expiratory positive airway pressures (IPAP and EPAP, respectively). The difference between the two is the level of inspiratory assistance, or pressure support. Pressure support modes provide sensitive inspiratory triggering and expiratory cycling mechanisms (usually by sensing changes in flow), permitting excellent patient–ventilator synchrony, reducing diaphragmatic work, and improving patient comfort [108]. Because these devices are lighter (5 to 10 kg), more compact (<0.025 m^3), and have fewer alarms than critical care or portable volume-limited ventilators, they are preferred for patients requiring only nocturnal use in the home. Most have limited IPAP (up to 20 to 35 cm H_2O, depending on the ventilator) and oxygenation capabilities and lack alarms or battery backup systems. Also, unlike volume-limited ventilators, bilevel pressure-limited devices are able to increase inspiratory airflow to compensate for air leaks, thereby potentially providing better support of gas exchange during leakage. O_2 supplementation is provided via a T-connector in the ventilator tubing or connector directly in the mask, the latter providing a slightly higher FIO_2. Even at flow rates of 15 liters per minute, though, the maximum recommended by the manufacturer, the FIO_2 is still only 45% to 50% [109], insufficient for many patients with hypoxemic respiratory failure.

The BiPAP Vision (Respironics, Inc.) (Fig. 59.2C) was designed for both invasive and noninvasive acute care applications, although it is used mainly for noninvasive. Equipped with an O_2 blender, it provides high FIO_2s and has more sophisticated alarm and monitoring systems than the traditional bilevels (including a graphic screen). It also features an adjustable rise time (the time taken to reach target inspiratory pressure) and inspiratory time limits that can help with comfort and synchrony during NIV. Because of these features, the Vision has been well-received as a device for the administration of NIV in acute care hospitals. Two new versions of the BiPAP are now available for acute applications of NIV: the V60 (Fig. 59.2D), which incorporates a battery backup, improved graphics, and some additional modes; and the Focus, a less expensive version that lacks a backup battery or oxygen blender.

Because they have a single ventilator circuit, rebreathing can occur during use of bilevel ventilators and can interfere with the ability to enhance CO_2 elimination [110]. The rebreathing can be minimized by using masks with in-mask exhalation ports, which are associated with less rebreathing than in-circuit valves [111], use of nonrebreathing valves, or EPAP pressures of 4 cm H_2O or greater, which ensure higher bias flows during exhalation [110]. In one study of patients receiving long-term nasal ventilation, a valve designed to minimize rebreathing (Plateau valve, Respironics, Inc.) did not lower nocturnal transcutaneous PCO_2 or daytime $PaCO_2$ compared with a standard in-tubing exhalation valve, probably because of CO_2 elimination during air leaking through the mouth which occurred frequently with both valves [112].

Adjuncts to NPPV

Humidification may enhance comfort during NPPV and is advised if NPPV is to be used for more than a few hours. For the acute care setting, a heated humidifier is preferred over a heat and moisture exchanger because the latter adds to work of breathing [113] and may interfere with triggering and cycling. Also, with excessive air leaking, a heated humidifier lowers nasal resistance [114]. Nasogastric tubes are not routinely recommended as adjuncts to NPPV, even when oronasal masks are used, but small bore flexible nasogastric tubes can be used for feeding if necessary and do not interfere much with mask sealing.

Ventilator Modes

Although pressure support (or bilevel) is the most commonly chosen mode to deliver NIV, others might be considered. Average volume-assured pressure support (AVAPS) is available on the V60 bilevel device (Respironics, Inc). It tracks delivered tidal volumes during the previous several minutes and automatically adjusts inspiratory pressure to achieve a target minute volume. This can be advantageous in hypoventilating patients as has been shown in obesity-hypoventilation patients [115], but no efficacy advantages over standard BiPAP have been shown in acute care settings.

Proportional assist ventilation, a mode that uses the inspiratory flow signal and its integral, volume, to determine how much flow and volume assistance to provide to the patient, functions well as a NPPV mode. It offers the potential advantages of enhanced comfort and synchrony [116]. Once again, studies have not been able to demonstrate improvements in efficacy over standard bilevel or pressure support modes in terms of reducing intubation or mortality rates.

Initiation of NPPV

NPPV is most often begun in the emergency department (ED) or ICU in acutely dyspneic patients who become panicky when masks are strapped to their faces. Thus, unlike initiation of invasive ventilation that consists of a sedated or even paralyzed patient, initiation of NPPV requires skill on the part of the caregiver to rapidly gain the confidence of the patient and help them cooperate so that they can benefit from the technique. Explaining clearly what is happening and what to expect, using verbal cues like "try to let the ventilator breathe for you" and giving patients control by allowing them to hold the mask on their face can be quite helpful.

Proper mask fit should be assured and the mask attached to the ventilator via tubing. Most practitioners start with relatively low ventilator pressures (i.e., 8 to 10 cm H_2O for IPAP and 4 to 5 cm H_2O for EPAP) for at least several minutes to allow the patient to become familiar with the mask and airflow. It is then extremely important to increase the inspiratory pressure (and thereby the level of pressure support) to reduce respiratory distress and effort, targeting a reduction of respiratory rate into the low 20 seconds per minute and an increase in tidal volume to 6 to 7 mL per kg. Patients are often intolerant of higher pressures, especially initially, because of the sensation of burning in the sinuses or pressure in the ears, or because of the perceived effort of breathing against an elevated pressure during expiration. Thus, the adjustment of inspiratory pressure becomes a titration, tailored for individual patients, balancing relief of respiratory distress and achievement of ventilatory targets against intolerance due to excessive pressures.

Expiratory pressure is usually kept at 4 to 5 cm H_2O, but can be adjusted upward if patients are having difficulty triggering due to intrinsic PEEP, upper airway obstructions due to sleep apnea, or are hypoxemic despite increases in FIO_2 to above 50% to 60%. L'Her et al. demonstrated in patients with ALI that increases in PEEP during NPPV were quite effective at improving oxygenation and pressure support in relieving dyspnea [117]. However, it is well to recall that if EPAP is increased

during NPPV, IPAP must also be increased by the same amount to maintain the level of pressure support.

MONITORING

Location for NPPV

Because of the importance of prompt initiation to avoid further patient deterioration that could necessitate intubation, NPPV should be started wherever the patient comes to medical attention, as long as appropriate equipment and personnel are available. Once initiated, transfer to an appropriately monitored location becomes important. This depends on the patient's need for monitoring as well as the unit's monitoring capabilities and skills of the staff in managing NPPV. Assessment of a patient's need for monitoring includes consideration of the severity of the respiratory failure as well as any comorbidities. If in doubt, a brief trial of NPPV withdrawal may be helpful. In one study of patients treated with NPPV in the ED for acute pulmonary edema or COPD, patients who remained stable during a 15-minute discontinuation trial were transferred to a regular ward and none subsequently required intubation [118].

NPPV is used on regular wards in many hospitals because of the scarcity of ICU beds, but some guidelines have recommended that NPPV be applied only in the ICU because of concerns about patient safety [119]. Farha et al. [120] reported on their experience with 76 patients treated on a regular ward with NPPV. Of the 62 patients without a DNI status, 31% required intubation and were transferred to the ICU. The authors considered this comparable to the experience with patients treated in more closely monitored settings, concluding that NPPV can be administered safely on regular floors. But unless the ward has considerable experience administering NPPV, only stable patients should be treated there.

What to Monitor

Monitoring of NPPV shares similarities with that of invasive mechanical ventilation but also fundamental differences. Most importantly, subjective responses are critical to the success of NIV (Table 59.5). Alleviation of respiratory distress and good tolerance of the technique must be achieved without using large doses of analgesia and sedation as is commonly done with invasive ventilation. Thus, caregivers must observe patients closely for these responses and be prepared to make prompt adjustments as needed to maintain patient cooperation.

Physical signs of increased respiratory effort should also respond promptly when NPPV is administered properly, including reductions in accessory muscle use and respiratory rate. Air leaks should be sought. These are universal with NPPV, and with bilevel devices, the continuous leak through the exhalation device is intentional, of course. But leaks under the seal of the mask can be large and interfere with synchronization and efficacy and should be sought.

Poor synchrony between the patient and ventilator, sometimes caused by excessive air leaking, patient agitation, ventilator maladjustment, or other factors, is another factor contributing to failure and must be monitored. Oximetry should be monitored continuously until the patient has stabilized and arterial blood gases should be drawn at baseline and after 1 to 2 hours of therapy to assure the desired gas exchange response. One important aspect of NPPV monitoring is to determine early when patients are responding poorly to NPPV so that the reasons can be reversed or failing that, the patient can be intubated promptly, avoiding undue delay and possible respiratory arrest with the emergent intubation and attendant morbidity and mortality that may entail.

TABLE 59.5

WHAT TO MONITOR DURING NPPV

- Subjective responses
  - Comfort
    - Mask related
    - Air pressure and flow related
  - Dyspnea
  - Claustrophobia
  - Agitation
  - Delirium
- Vital signs
  - Respiratory rate
  - Heart rate
  - Blood pressure
- Breathing effort
  - Accessory muscle use
  - Paradoxical breathing
- Gas exchange
  - Continuous oximetry
  - Baseline and 1–2 h arterial blood gases, then as indicated
- Synchrony
  - Triggering
  - Expiratory asynchrony
- Air leaks
  - Mask seal
  - Through mouth with nasal masks
- Secretion clearance
  - Cough effectiveness
  - Quantity of secretions
- Development of complications (see Table 59.6)

Complications and Side Effects of NPPV and Possible Remedies

NPPV is successful in most patients and most adverse side effects are minor, but failure rates in studies representing "real-life" applications of NIV still approach 40% [6,75,121] and a knowledge of potential complications and ways of managing them can be helpful in minimizing NPPV failure rates. There are many possible adverse effects and complications, a variety of possible ways of categorizing them, and inevitable areas of overlap between the categories. For practical purposes, we distinguish between side effects related to the interface and those attributable to ventilator airflow and pressure, caregiver inexperience, and patient factors (Table 59.6).

Adverse Effects and Complications Associated with the Interface

Mask Discomfort

Mask discomfort is one of the most common reasons cited for NPPV failure. It may reflect a poorly fit mask, a patient's difficulty accepting the interface chosen, excessively tight headstraps, a dyspneic patient's discomfort at having foreign material strapped to their face, or other factors. The clinician faced with a patient tolerating NPPV poorly because of mask discomfort should quickly attempt to decipher the specific problem and correct it if possible. Often, inexperienced practitioners select masks that are too large and a trial with a smaller mask or a different mask type may help. If it does not lead to excessive air leaking, reseating the mask or loosening the straps often helps.

TABLE 59.6

ADVERSE EFFECTS AND COMPLICATIONS OF NPPV AND POSSIBLE REMEDIES

Adverse effect	Possible remedy
Interface related	
Mask discomfort	Check size and fit. Readjust headgear. Try different type.
Skin ulceration, irritation	Readjust mask. Loosen straps. Artificial skin prophylactically.
Air pressure and flow related	
Nasal, sinus pain, dryness	Lower pressure temporarily. Humidify gas. Nasal saline.
Conjunctivitis	Reseat mask. Check seal on nasal bridge. Artificial skin. Consider new mask type.
Gastric distension	Lower pressure if possible. Simethicone. Observe or distension, consider nasogastric drainage.
Patient–ventilator asynchrony	Eliminate leaks, treat agitation, assess for discomfort. Try lowering pressure support or limiting inspiratory time.
Rebreathing	Use mask with in-mask exhalation valve. Use adequate EPAP ($\geq$4 cm H_2O). Use ventilator with active exhalation valve.
Air leaks	Reseat, readjust strap. Try different mask type. Chin strap if nasal mask. Lower pressure if possible.
Caregiver related	
Inadequate or excessive pressures	Monitor more carefully. Adjust upward as tolerated. Assure adequate training.
Inadequate equipment	Initiate NPPV program, with full selection of masks.
Patient related	
Agitation, anxiety	Assure proper mask fit, ventilator settings. Reassure, consider sedation.
Major complications	
NPPV failure	Optimal monitoring to detect and address problems before they lead to failure. If failure not responding to appropriate measures, intubate promptly to avoid delay.
Respiratory arrest	Monitor at-risk patients in ICU or closely in stepdown unit. Intubate before arrest occurs to avoid attendant morbidity and mortality.

As discussed earlier, an oronasal mask is usually the best initial mask choice, but some patients who are claustrophobic or expectorating frequently fare better with a nasal mask. Masks used in the acute setting are usually disposable after one use but some are reusable. They are relatively inexpensive compared to masks used for long-term applications of NPPV, but it is still desirable to check that the mask selected is likely to fit (using a fitting gauge, for example) to minimize the need to dispose of multiple masks for each patient application. Noisiness can contribute to intolerance with some mask types such as the helmet, with measured levels reaching upward of 90 dB in the CPAP mode [122].

Skin Irritation and Ulceration

Skin irritation and ulceration, mainly over the nasal bridge, is a common complication of NIV. Contributors to NIV-related skin breakdown include excessive strap tension, mask type, poor mask fit, prolonged ventilation, high inspiratory pressure necessitating more strap tension to control leaks, hypersensitivity to mask material, and patient factors such as age and comorbidities such as congestive heart failure that limit skin perfusion [123–126]. Facial structure and anatomical variation between patients also play a role. Skin complication rates vary considerably between studies ranging from less than 5% to as high as 43% [126–128]. A recent study by Dellweg et al. showed that a larger mask cushion size distributes contact pressure to the skin over a larger contact area [123], but the study did not show that cutaneous complications were lowered as a consequence.

Prevention rather than treatment of skin breakdown is the best management strategy. This can be accomplished by optimizing mask fit while using the lowest effective positive pressures and strap tension and applying artificial skin to the affected area at the first sign of redness. Also, newer mask model types have softer, larger silicon sealing surfaces that minimize trauma to the facial skin. With these interventions, a significant nasal bridge ulcer should now be a rare event during NPPV therapy.

Adverse Effects and Complications Associated with Airflow and Pressure

Nasal, Sinus and Ear Pain and Burning

Initiation of NPPV is commonly associated with the sensation of nasal, sinus and ear pain and burning. This is related to the patient's lack of familiarity with the sensation of air pressure and flow and usually subsides as the patient accommodates to the sensations. Using lower initial pressures and raising them gradually can help to minimize this problem as can making sure that leak is minimized. Use of routine humidification can help with these side effects too.

Conjunctivitis

Conjunctivitis is another common adverse consequence of airflow during NPPV. In this case, air leaks into the eye due to a combination of high inspiratory pressure and incomplete mask sealing along the steep sides of the nose related to suboptimal mask fit and, possibly, patient anatomic variations. This causes dryness, irritation, erythema, and discomfort after a period of hours and may respond to lowered inspiratory pressure (if possible), reseating the mask or tightening the straps, or trying a new mask type.

Gastric Distension

Gastric distension in patients receiving NPPV is common but is usually well tolerated. However, some recent cases were reported of extreme complications such as gastric perforation and abdominal compartment syndrome [129,130]. A study on obese patients found that those receiving NPPV with an inspiratory pressure of 16 cm H_2O had more gastric distension than those breathing spontaneously [131]. The authors cautioned that the increased gastric air might raise the risk of aspiration. As stated earlier, the amount of gastric distension during NPPV is usually clinically insignificant, but if it causes excessive abdominal distension, discomfort, nausea, bowel distension on a KUB exam, or a compartment syndrome, then drainage with a naso- or orogastric tube is the next logical step. Gas dispersing agents like simethicone can be tried but are usually unsuccessful. Lowering the inspiratory pressure as much as possible may also help. But if there is a high risk of vomiting and aspiration or if nasogastric suctioning is unsuccessful, then intubation and other methods to decompress the bowel should be considered.

Patient–Ventilator Asynchrony

Patient–ventilator asynchrony is the lack of coordination between a patient's own respiratory effort and the ventilator's output. The consequences of this phenomenon can include inefficient gas exchange, muscle fatigue, and ultimately, failure of NPPV [132]. Asynchrony occurs frequently during NIV, mostly because of air leaks, rendering it difficult for the ventilator to sense the onset of patient inspiration and expiration, altered patient respiratory drive or agitation, ventilator mode, and inappropriately high inspiratory pressure in patients with COPD, contributing to ineffective triggering and cycling [133–135]. An observational study in three teaching hospital ICUs used an asynchrony index [the number of asynchrony events/ventilator cycles + wasted respiratory effort) × 100] [132]. This study found that discomfort and air leaks were independent risk factors for asynchrony indices >10%. The study, however, was limited because it used only critical care ventilators.

The type of interface also is important considering that when used to deliver pressure support, helmets have high rates of asynchrony compared to other NIV interfaces, mostly due to their high structural compliance [136,137]. Strategies to deal with asynchrony include minimizing air leaks, changing to timed modes (such as pressure control) to reduce the persistence of ventilator inspiration into patient expiration that occurs with bilevel modes [134], lowering pressure support if tidal volumes are large and breathing efforts fail to trigger, and giving sedation to control agitation.

Rebreathing

Rebreathing of CO_2 is a concern with bilevel ventilators because of their single circuit design. Earlier bench and clinical studies demonstrated rebreathing during use of NPPV [138]. However, more recent studies have not demonstrated CO_2 rebreathing at levels deemed detrimental to patients, and rebreathing during NPPV has not been implicated in adverse patient outcomes [139–143]. The routine use of expiratory pressures of 4 cm H_2O or greater was shown in earlier studies to minimize rebreathing along with modifications in ventilator circuitry, and the placement of exhaust vents in masks themselves has also been shown to curb rebreathing [110,139,144,145]. Helmet masks are associated with high levels of rebreathing, especially in the CPAP mode, necessitating use of high flow rates to flush out the CO_2 and thereby generating high noise levels [98,146,147]. However, newer helmet designs with expiratory ports, as well as use in conjunction with open-circuit ventilators, have been shown to decrease rebreathing [136,147,148]. Thus, although concerns regarding rebreathing during NPPV continue to draw attention in the medical literature, the modifications to ventilators and interfaces over the past decade have largely eliminated the concern.

Air Leaks

Air leaks are universal during NPPV because of its open circuit design. Some leaks are intentional as with bilevel ventilators, but air also leaks under the mask seal through the mouth and even into the gastrointestinal tract. Small leaks (<30 to 40 L per minute) are generally well tolerated as most ventilators compensate quite easily for them. However, large leaks (>60 L per minute) can have deleterious effects by interfering with ventilator assistance and synchrony, leading to increased work of breathing, fatigue, oxygen desaturations, and NIV failure. Leaks also contribute to patient discomfort, contributing to conjunctivitis, sleep disruption, and dry mouth [144,149–152].

Air leaks are associated with improperly sized or sealed masks, loose or excessively tightened headstraps, the presence of facial hair, unusual facial anatomy variability, high inspiratory pressure settings, and the presence of surgical dressings or catheters that disrupt the seal. Nasal masks are commonly associated with mouth leaks, reported to occur in as many as 94% of patients receiving NPPV for hypercapnic ARF and contributing to the majority of mask failures [153]. In a comparison study of four different NPPV interfaces in patients with ARF, the mouthpiece had the largest leak, while there was no significant difference between the Total Face Mask, oronasal mask, or nasal mask [154].

Measures that can be undertaken by the clinician to minimize leaks include careful mask selection and fitting, proper strapping to the face, removal of facial hair, use of chin straps with nasal masks, and chin supports (built into certain mask types) for patients using oronasal masks. Reduction of inspiratory pressure usually helps, as well, if feasible. Leak-compensating ability of the ventilator is another consideration in patients having frequent large leaks. Most bilevel ventilators compensate quite well, but older critical care ventilators in the pressure support mode may have difficulty dealing with intermittent variable leaks. Many newer critical care ventilators have NIV modes that enhance leak-compensating abilities, but most need additional adjustments in the face of large leaks [105].

Caregiver-Related Factors

Complications of NPPV are sometimes related to caregiver decisions that inadvertently predispose to NPPV failure. Most commonly, these include selection of inappropriate candidates with excessively high risk of failure, such as ALI/ARDS patients who are septic and developing multiorgan failure or elderly pneumonia patients with poor cough and excessive secretions. Inadequate attention to detail during initiation predisposes to failure, including neglecting to spend time with the patient to instruct and win confidence or to properly fit or attach the mask.

Failure to increase the inspiratory pressure after initiation is a common cause of NPPV failure because the patient never receives adequate ventilator assistance. Inadequate monitoring, either because an unstable patient is never sent from a regular ward to the ICU or because caregivers neglect the early signs of deterioration, permitting a respiratory crisis to occur, are other common reasons for NPPV failure. Caregivers need to know when to intubate patients who are not responding adequately to NPPV before an emergency or respiratory arrest occurs, avoiding delays of needed intubation.

There is no substitute for having a skilled and experienced multidisciplinary team if NPPV success rates are to be

optimized. Evidence from several studies indicates that as caregivers gain experience with NPPV, patient outcomes improve, or they can sustain the same favorable outcomes in sicker patients [16].

Multidisciplinary Approach

NPPV works best if administered as part of a team effort. Ideally, this is achieved in a specialized unit such as an ICU or step-down unit where members can gain experience by working together over time. Although team members may have different roles depending on the country they work in, the roles must be adopted by one team member or another in order for optimization of NPPV delivery. In North America, physicians must be skilled at selecting appropriate patients for NPPV and writing proper orders for its initiation. The respiratory therapist then fits and applies the interface and makes initial ventilator adjustments. Nurses then monitor the patient, notifying the physician and therapist if problems arise.

Physicians and therapists should also participate in monitoring so that they can intervene with timely adjustments to the mask or ventilator settings or with intubation, if needed. Pharmacologists assist in choosing the type and dose of sedation or analgesia if deemed indicated, and nutritionists assist in assuring that nutritional needs are met. Physical therapists may also become involved to help with secretion removal or early mobilization. In other countries such as in the United Kingdom, physiotherapists assume many of the roles of the respiratory therapist, and in many countries in the developing world, physicians are responsible for initiation and application of equipment in addition to their other duties. Regardless of how the responsibilities are distributed, most programs favor using protocols and having periodic training in-services for their team members.

Patient-Related Factors

Patients vary enormously in their ability to tolerate NPPV, and this is reflected in success rates. Patients who are cognitively impaired due to congenital or acquired processes, such as strokes, dementia, or delirium, are unlikely to tolerate NPPV because they cannot comprehend the purpose and become agitated. Other patients panic when a mask is strapped to their face, either because of claustrophobia or because of their already heightened anxiety and distress due to their respiratory condition. These factors must be kept in mind when selecting patients or when deciding that the modality has failed. Some anxious patients respond to reassurance and being given control of the mask and others require sedation. Patients with dementia or delirium can sometimes be managed successfully with anti-psychotics like haloperidol or risperidone.

Sedation and Analgesia During NPPV

Judicious use of sedation may help to calm patients having difficulty cooperating with NPPV, but most clinicians are very cautious, using smaller doses, mainly by intermittent bolus, than they use in invasively ventilated patients. Most respondents to a survey of critical care physicians from North America and Europe indicated that they used sedation or analgesia in less than 25% of patients [155]. They registered concerns about blunting the drive to breathe in spontaneously breathing patients. North Americans were more apt to use benzodiazepines alone and Europeans opioids alone as their preferred initial choice. More information from clinical studies is needed before specific recommendations on specific medications and doses can be made, but use of sedation or analgesia should be considered in patients at risk of failing NPPV because of agitation, apprehension, or discomfort.

Impact of NPPV on Quality Measures

The aging population in developed countries will place increasing stress on healthcare resources over the next couple of decades, so efficient utilization of resources while enhancing quality of care will become paramount goals [156]. Projections in the United States are an annual 2 million increase in prolonged (>96 hours) mechanical ventilation days through the year 2020 compared to the year 2000 and an annual increase of 3 million ICU days during the same time period [157]. In this context, appropriate use of NIV becomes even more necessary as it has the capability of improving outcomes as well as the efficiency of resource utilization.

Effects of NPPV on ICU and Hospital Lengths of Stay

A number of studies have demonstrated reduced ICU and hospital lengths of stay in association with NPPV use in COPD patients with respiratory failure. In a systematic analysis, Keenan et al. [158] derived an absolute reduction in hospital LOS of 4.49 days (CI 3.66–7.52 days). A meta-analysis of randomized trials in 2003 confirmed the positive effect of early NPPV use on hospital LOS for COPD patients [159]. When used to treat COPD patients with an infectious exacerbation or severe hypercapnic neurological dysfunction in the emergency room, Briones et al., in a case control study, found a significant reduction in hospital LOS with NPPV (11.1 ± 4.7 days for IMV vs. 6.5 ± 1.9 for NPPV, $p = 0.001$) [160]. Thus, the preponderance of evidence indicates that NPPV reduces ICU and hospital LOS compared to standard therapy in COPD patients with ARF.

The effects are not as robust in patients with other diagnoses, though. Although one recent study suggests that NPPV reduces ICU LOS as well as in-hospital mortality in patients with ARF due to a host of etiologies other than COPD [161], a Cochrane analysis of 21 studies comparing NPPV plus standard therapy to standard therapy alone in the treatment of ARF due to CPE found that NPPV reduced ICU LOS by 1 day but did not significantly reduce hospital LOS [162].

In patients with acute hypoxemic respiratory failure and ALI/ARDS, Agarwal et al. found no difference in ICU or hospital LOS between those treated with NPPV versus invasive mechanical ventilation [163,164]. A Swiss observational case-control study with a small number of subjects reported a reduction in ICU LOS along with an improvement in oxygenation in ARDS patients treated with NPPV compared to matched controls treated invasively. The study, however, showed a trend for a higher ICU mortality rate for the NIV patients [5].

The use of NIV for treatment of postoperative respiratory failure has also been shown to be advantageous in reducing ICU LOS. Michelet et al. reported an average reduction in ICU LOS of 8 days ($p = 0.034$) in patients who were treated with NPPV compared to conventional treatment for postoperative ARF after esophagectomy [165]. The impact of NIV on ICU LOS was also shown with great success in patients with persistent weaning failure who were immediately tried on NIV post extubation and were found to have shorter ICU LOS compared to those undergoing conventional weaning (14.1 ± 9.2 vs. 25.0 ± 12.5 days, $p = 0.002$) [38].

In summary, NPPV reduces resource consumption in COPD patients with ARF as well as in COPD patients with weaning and postsurgical respiratory failure. Most of the studies have been performed in Europe where average hospital and ICU LOS tend to be longer than in North America. The LOS shortening effect appears to be less potent for patients with other diagnoses such as CPE or ALI/ARDS. Nonetheless, NPPV is a modality that will likely have an expanding role in the therapy

of ARF in the future, not only to improve patient outcomes, but also to improve efficiency of resource utilization, and thereby contribute to a reduction in healthcare costs.

SUMMARY AND RECOMMENDATIONS

NPPV has assumed an important role in the management of patients with ARF in critical care settings. Epidemiologic studies indicate that use of NPPV has increased substantially over the past decade throughout the world. Current evidence indicates that NPPV is well supported for therapy of ARF associated with COPD exacerbations, acute pulmonary edema, and immunocompromised states. Use is sensible in a number of other settings, including facilitation of weaning in intubated COPD patients and COPD or acute pulmonary edema patients in other settings, such as postoperative, postextubation, and patients with a DNI status. Less evidence supports use in acute asthma, obesity hypoventilation with an exacerbation, cystic fibrosis, or neuromuscular disease, but NPPV would be a consideration to treat these.

Most patients with ARDS or severe community-acquired pneumonia should not be treated with NPPV, but exceptions include those with minimal secretions, stable otherwise and with only one or at most two organ failures, and in a closely monitored setting. Initiation of NPPV requires a properly fit and tolerable interface and a ventilator that is appropriately set. Patients should be placed in a location that permits adequate monitoring for their state of acuity, and monitoring should pay particular attention to subjective adaptation including mask tolerance and adaptation to the ventilator. Administration should be by a skilled and experienced multidisciplinary team. Achievement of these goals should lead to appropriate and safe administration of NPPV with better overall patient outcomes and more efficient utilization of scarce ICU resources.

Summary of Major Recommendations

- NPPV should be considered the ventilator mode of first choice for respiratory failure associated with COPD exacerbations [31,159], acute CPE [50], and immunocompromised states [37].
- NPPV can be considered to treat other patients with ARF such as those with asthma, exacerbations of cystic fibrosis, or obesity hypoventilation [13].
- In patients with a DNI order, NPPV can be used as a form of life support or to palliate, but should be discontinued if goals are not being achieved [87].
- NPPV should not be used routinely but very selectively and with close monitoring in patients with ARDS or pneumonia [70].
- NPPV should be administered in an ICU or stepdown unit under close and continuous monitoring until stabilization has occurred [118].
- The full-face mask is the preferred initial interface for acute applications of NPPV [96].
- Increases in expiratory pressure can be used to treat hypoxemia and increases in pressure support reduce work of breathing [117].
- Patient/ventilator asynchrony and air leaks can contribute to NPPV failure and should be minimized [133].
- When NPPV is failing, intubation should not be delayed [77].

CHAPTER 60 ■ MECHANICAL VENTILATION PART III: DISCONTINUATION

RICHARD S. IRWIN, NICHOLAS A. SMYRNIOS AND ROLF D. HUBMAYR

A great deal of effort has been devoted to developing scientifically based strategies to more consistently achieve successful discontinuation of mechanical ventilation (MV). This chapter reviews the advances made in four general areas: (a) understanding the problem, (b) the value of criteria for reliably predicting discontinuation success, (c) identifying the most useful modes, and (d) managing discontinuation failure.

UNDERSTANDING THE DISCONTINUATION PROBLEM

Who Are the Patients and What Are Their Outcomes?

Patients with, or likely to develop, respiratory failure are the individuals who require MV support. Although there is overlap, respiratory failure can be generally categorized into lung failure and pump failure. *Lung failure* is pure gas-exchange failure and is manifested by hypoxemia. It is commonly due to the acute respiratory distress syndrome or cardiogenic pulmonary edema. *Pump failure* is synonymous with ventilatory failure and is manifested by hypercapnia and hypoxemia. It is commonly due to central nervous system depression (e.g., overdose, anesthesia) or respiratory muscle fatigue or weakness.

For those who recover from the insult that necessitated MV, most (80% to 90%) [1–4] can have MV easily discontinued and be extubated. In this group, MV can be discontinued in 77% of patients within 72 hours of the initiation of MV [4]. This group is composed predominantly of postoperative patients, patients with overdoses, and patients whose conditions cause pure lung failure that reverses rapidly. In the minority of patients, probably 10% to 20% overall, MV is more difficult to discontinue. Data suggest that duration of MV does not necessarily have an impact on long-term survival. For example, 1-year survival for patients on MV for more than 21 days can

TABLE 60.1

POTENTIALLY REVERSIBLE REASONS FOR PROLONGED MECHANICAL VENTILATION

Inadequate respiratory drive
Inability of the lungs to carry out gas exchange effectively
Inspiratory respiratory muscle fatigue/weakness
Psychological dependency
Combinations of these items

be as high as 93% [5]. Although it may take 3 months or longer to be able to discontinue MV in these patients in long-term facilities, the ultimate quality of life of the survivors ranges from being minimally to moderately impaired [6,7].

What Is Wrong with Patients on Prolonged Ventilator Support?

There are potentially four separate and reversible reasons for prolonged MV [8] (Table 60.1).

1. *Inadequate respiratory drive* may be due to nutritional deficiencies [9], sedatives, central nervous system abnormality, or sleep deprivation [10].
2. *Inability of the lungs to carry out gas exchange effectively* may continue if the underlying cause of respiratory failure has not sufficiently improved.
3. There may be profound *inspiratory respiratory muscle weakness* and possibly *fatigue*.
4. *Psychological dependency* may be an additional factor [11].

Although no studies have been performed to determine systematically the relative importance of these factors, and combinations of these factors may be responsible for prolonged MV, the literature suggests that pump failure due to inspiratory respiratory muscle fatigue/weakness [12] is primarily responsible for failure of discontinuation of MV in these patients [3,13,14]. *Muscle fatigue* is "a condition in which there is loss in the capacity for developing force and/or velocity of a muscle, resulting from muscle activity under load and which is reversible by rest" [15,16]. *Muscle weakness* is "a condition in which the capacity of a rested muscle to generate force is impaired" [15,16]. Although fatigue and weakness can be experimentally distinguished, this is not usually possible in the clinical setting. Therefore, the term muscle fatigue, when used clinically and by us in this chapter, may actually encompass fatigue or weakness, or both. Contributors to respiratory *muscle fatigue* may be (a) central nervous system depression, (b) mechanical defects (e.g., flail chest and kyphoscoliosis) that increase the work of breathing, (c) lung disease that increases the work of breathing, and (d) mediators of ongoing active diseases (e.g., sepsis, ventilator-induced diaphragmatic dysfunction) that adversely affect the respiratory muscles.

What Factors Impact upon Respiratory Muscle Fatigue and Weakness?

The cause of inspiratory respiratory muscle fatigue is likely to be multifactorial [17–36]. The major factors that compromise muscle strength and endurance are listed in Table 60.2. A few items deserve additional explanation.

TABLE 60.2

POSSIBLE CAUSES OF INSPIRATORY RESPIRATORY MUSCLE FATIGUE

Nutritional and metabolic deficiencies [18]
Hypokalemia [19]
Hypomagnesemia [20]
Hypocalcemia [21]
Hypophosphatemia [22]
Hypothyroidism [23]
Corticosteroids [24]
Chronic renal failure [25]
Systemic diseases
Decreased protein synthesis and increased degradation [26]
Decreased glycogen stores [27]
Hypoxemia and hypercapnia [28,29]
Persistently increased work of breathing (e.g., underlying disease, mechanical ventilator, airway humidification devices) [30–32]
Failure of the cardiovascular system (e.g., disease, ventilator) [33,34]
Neuromuscular dysfunction/disease
Drugs [35]
Critical illness polyneuropathy/myopathy [36]
Combinations of the items in this table

Mechanical Ventilation

Although it is assumed that one of the benefits of MV is that it rests the respiratory muscles, this may not actually occur [37]. The response of mechanical ventilators to rapid changes in patient effort is often inadequate. This is particularly true for older-generation ventilators. Positive pressure MV may increase minute volume without decreasing respiratory muscle work. In part, this is because ventilators used in either the assist control or synchronized intermittent mandatory ventilation (SIMV) mode do not synchronize their output with that of the patient's respiratory system. In extreme cases, the lack of synchronization causes patient effort to exceed that observed during unassisted breathing. Both SIMV and assist ventilation modes may cause problems in this regard. Also, SIMV systems expose patients to increases in airway resistance during spontaneous efforts that occur between machine breaths.

Continuous flow and demand valve systems have the potential for increasing the work of breathing. For instance, the continuous flow may not satisfy the patient's inspiratory flow demands. Demand valve SIMV systems may increase the work of breathing because they require substantial effort by the patient to breathe spontaneously. Moreover, in assist mode, the patient's inspiratory muscles might work throughout the entire inspiratory cycle if tidal volume and inspiratory flow rate do not meet the patient's inspiratory requirements. If auto–positive end-expiratory pressure (auto-PEEP) is present (see Chapter 58), the patient may not be able to trigger the ventilator or may be able to capture it only intermittently while performing a prohibitively large amount of work during assist ventilation, because he or she must drop airway pressure below the amount of auto-PEEP before triggering the ventilator. If there is an increased work of breathing due to the patient's ventilator that provokes respiratory distress, the patient's diaphragm may develop an inflammatory injury that may not appear clinically for days afterward [31,37–39]. Although it is important to minimize the work of strenuous muscle activity while patients are receiving MV, it is also important to avoid prolonged muscle unloading because neuromuscular inactivity ("rest") can lead to ventilator-induced diaphragmatic dysfunction [30].

Cardiovascular Disease

Failure of the cardiovascular system may prolong MV for a variety of reasons. Gas exchange may be impaired by passive congestion of the lungs, and this may contribute to an increased work of breathing during spontaneous breaths. Poor cardiac performance may contribute to an inadequate supply of oxygen to the respiratory muscles, while an increased work of breathing conversely may provoke myocardial ischemia [33]. Although MV may adversely affect cardiac output by increasing intrathoracic pressure, thereby decreasing venous return and cardiac output, it is also possible that some cardiovascular patients cannot have MV discontinued because the ventilator exerts a beneficial influence on cardiac function (i.e., unloading the left ventricle in left ventricular failure) [40]. Prematurely withdrawing MV from these patients may lead to deterioration in cardiac function.

Nutritional Factors

Nutritional deficiencies may prolong the discontinuation process from MV by leading to myocardial as well as respiratory muscle dysfunction [41]. Older studies have suggested that an appropriate amount of nutritional support may improve the success rate of discontinuation of MV [42,43], but these were not definitive. More recent randomized controlled trials comparing high-fat/low-carbohydrate feeds versus conventional feeds and growth hormone versus placebo showed no change in duration of MV or discontinuation success. These trials have been summarized elsewhere [44].

CRITERIA FOR PREDICTING SUCCESSFUL DISCONTINUATION

When Is It Appropriate to Begin the Discontinuation Process?

Because there are no objective, rigorously generated data to determine the appropriate time to initiate weaning, physicians must rely on their clinical judgment. Therefore, the authors recommend that clinicians consider a carefully monitored spontaneous breathing trial (SBT) of discontinuation when the following criteria, set forth in a national clinical practice guideline, have been met: (a) The underlying reason(s) for MV has been stabilized and the patient is improving, (b) the patient is hemodynamically stable on minimal-to-no pressors, (c) oxygenation is adequate (e.g., PaO_2/FIO_2 greater than 200, PEEP no more than 7.5 cm H_2O, FIO_2 less than 0.5), and (d) the patient is able to initiate spontaneous inspiratory efforts [45]. Because potentially harmful effects of suddenly having to take on the work of breathing occur early (albeit infrequently) during SBTs [46], patients should be closely monitored during the first 5 minutes. Basing weaning decisions on the rapid shallow breathing index (RSBI) in effect enforces this (see section Predictive Indices for Total Discontinuation of Mechanical Ventilation). SBTs, variably performed with a T-piece, with low-level pressure support ventilation, or with just a predetermined amount of continuous positive airway pressure (CPAP) in ventilators equipped with "flow-by" internal circuits, should be timed to coincide with the daily sedation holiday to maximize the opportunity for success and to allow assessment of patient comfort and behavioral effects on breathing.

If the patient deteriorates or becomes distressed during this brief period of observation, MV should be reinstituted. The authors caution against assuming that anxiety is causing the failure of a breathing trial. Although anxiety can mimic respiratory failure, in the authors' experience anxiety is not usually the cause of failure but rather a consequence of it. In fact, the "art of weaning" centers on the judgment whether weaning-induced distress is a manifestation of agitated delirium, sedative and narcotic withdrawal, pain and tube discomfort, or respiratory failure. When in doubt, the provider should assume the latter. We know of no validated test capable of distinguishing between these entities. To help decide in these situations, we sometimes observe patients who are difficult to wean while keeping them heavily sedated. If under these circumstances, unassisted breathing can be sustained without hypercapnia, hypoxemia, tachypnea, and tachycardia, we conclude that respiratory failure is no longer present, that agitation may be related to pain, anxiety, or sedative/hypnotic withdrawal, and proceed with a trial of extubation if and when we believe that the patient is able to protect his or her airway against the possibility of aspiration.

There are no data to show that attempts at starting the discontinuation of MV in this context lead to adverse consequences. On the contrary, screening patients daily to identify those who can breathe spontaneously can reduce the duration of MV and the cost of intensive care [47]. Because the authors' recommendations are guidelines and not rigorously tested criteria, it may also be appropriate to start the carefully monitored process in an individual patient who has not met all of the previously mentioned guidelines.

Predictive Indices for Total Discontinuation of Mechanical Ventilation

Studies have evaluated a wide variety of physiologic indices to predict a patient's ability to breathe spontaneously without MV [48]. These studies yield conflicting data due in large part to differences in methods and experimental design, such as population studied, choice of physiologic index threshold value, measurement techniques, definitions of success and failure, and perhaps because of selection bias in choosing patients for weaning studies [48].

A collective task force of clinician investigators cofacilitated by the American College of Chest Physicians, the American Association for Respiratory Care, and the American College of Critical Care Medicine developed evidence-based guidelines for weaning and discontinuing ventilatory support [45]. In their report, they evaluated the evidence for predicting success in weaning from MV [48]. A summary of their findings is as follows:

1. A large number of predictors have been found to be of no use in predicting the results of weaning.
2. A few predictors have been shown to be of some use, albeit inconsistent, in predicting discontinuation of the ventilator and successful extubation. Those include respiratory rate (RR) of less than 38 breaths per minute (sensitivity, 88%; specificity, 47%), a RSBI less than 100 breaths per minute per L (sensitivity, 65% to 96%; specificity, 0% to 73%), and an inspiratory pressure/maximal inspiratory pressure ratio less than 0.3. In addition, the combination of a RR of more than 38 breaths per minute and a RSBI more than 100 breaths per minute per L appears to reduce the probability of successful extubation.
3. Likelihood ratios (LRs) appear to provide the best format for presenting the results of weaning predictors.
   a. LR positive = the odds that a patient with weaning success will have a positive test result (RSBI <100), compared to the odds that a patient with weaning failure will demonstrate a positive test.
   b. LR negative = the odds that a patient with weaning success will have a negative test result (RSBI >100),

compared to the odds that a patient with weaning failure will have a negative test.

c. LRs greater than 10 or less than 0.1 imply large, clinically significant outcomes. LRs between 5 and 10 imply moderate, probably clinically significant outcomes. LRs between 2 and 5 imply small, possibly clinically significant outcomes. LRs between 0.5 and 2 are insignificant.
d. The Task Force found LRs greater than 10 or less than 0.1 only twice, and only when data from all trials were pooled. The ratio of airway pressure 0.1 second after the occlusion of the inspiratory port of unidirectional balloon occlusion valve ($P_{0.1}$) to maximal inspiratory pressure (PI_{max}) of 0.09 to 0.14 was highly predictive of successful extubation in two studies with a pooled LR of 16.3. No LRs between 5 and 10 were found.
e. When LRs were calculated for RSBI, pooled results for a test predicting successful discontinuation of ventilation and extubation showed a LR of 2.8; results for a test predicting failure of discontinuation and extubation showed a LR of 0.22. These results suggest mediocre accuracy.
f. The reliability of the RSBI will be diminished when it is measured during the first minute of SB when respiratory drive may still be suppressed, when it is measured in the presence of a small endotracheal tube (internal diameter of 7 mm or less), particularly in women [49], and as patients have the measurement made while receiving pressure support (PS) and/or CPAP [50,51]. It is recommended that RSBI measurements be made while patients are spontaneously breathing, as the test was originally described [52].

Although clinical observation of the respiratory muscles during spontaneous breaths was initially thought to be reliable in predicting subsequent discontinuation failure, respiratory-inductive plethysmographic studies [53] have shown this to be not necessarily the case. Any time there is a substantial increase in load on the respiratory muscles, a change in the rate, depth, and pattern of breathing may be observed. Because these signs may also be manifestations of fatigue, it is useful to note them. If these signs never appear, successful discontinuation is likely. If they do appear, patients must be observed closely for further deterioration because discontinuation inevitably fails if these signs are owing to fatigue.

When Is It Appropriate to Extubate the Patient?

Once MV has been discontinued, consider whether the patient is likely to fail extubation. The most common causes of extubation failure are upper-airway obstruction and inability to protect the airway and clear secretions. Patients at the highest risk of postextubation upper-airway obstruction are those who have been on prolonged MV, are female, and who have had repeated or traumatic intubations [54]. One method of assessing for the presence of upper airway obstruction during MV is the cuff-leak test. It is performed by comparing the exhaled volumes before and after the balloon of the endotracheal tube has been deflated. Although one study [55] showed that a cuff leak of less than 110 mL measured during assist-control ventilation within 24 hours of extubation identified patients at high risk of postextubation stridor, other studies have not [56]. Although the concept of measuring cuff leak is intuitively appealing, the benefits are not clearly identified, and the process and even the actual values for decision making are not broadly agreed upon. Values of 110, 130, and 140 mL are all used in recent studies. Other studies use an approach of auscultation to detect leak. In addition, the appropriate course of action to take for an abnormal test is not defined. Some authors suggest treatment with steroids, some delay of extubation, and some advocate having persons with advanced airway skills present for the extubation. Therefore, because we are unable to scientifically determine which patients should have a test, how we would conduct the test, and what we would do with an abnormal value if we had one, we do not advocate routinely performing or basing decisions on the results of a cuff-leak test. A provider may consider using a cuff-leak test in specific patients to gain a general appreciation of the airway status in a high-risk patient [57–59].

Patients may also fail extubation because they are unable to protect their airways or clear their secretions. A prospective observational study [60] showed that the strongest predictors of extubation failure in patients who passed a SB trial were (a) poor cough defined as a cough peak flow measurement of less than 60 L per minute, (b) secretion volume of 2.5 mL per hour or greater, and (c) poor mentation as determined by the inability to complete any of the four following tasks on command: open eyes, follow observer with eyes, grasp hand, and stick out tongue. In this series, reintubation took place in 12% of patients when one of these predictors was present and 80% when all three were present. (See Chapter 62 for an in-depth discussion of cough effectiveness and how to assess for it.)

Once extubation has taken place, the authors proceed cautiously before instituting feedings by mouth. Because there is no clinically reliable way of assessing the adequacy of swallowing at the bedside, a formal swallowing evaluation (e.g., speech pathology consult and videofluoroscopic evaluation of swallow) should be considered in patients at increased risk of aspiration before resuming oral feedings. Although it is commonly appreciated that older age, debilitation, sedation, oral or nasal enteral feeding tubes, history of dysphagia, acute stroke, cervical spine surgery, muscle weakness, and/or tracheostomy are risk factors for aspiration, it is less commonly known that endotracheal intubation carries the same risk [61,62]. After extubation, swallowing difficulties may exist in up to 50% of patients for up to 1 week, even when endotracheal intubation has been of short duration, and the patient is awake and not seriously ill. In awake, postsurgical patients evaluated for aspiration following extubation, 50% of those who aspirated did so immediately when fed, whereas 25% and 5% aspirated when tested 4 and 8 hours later, respectively. (See Chapter 54 for an in-depth discussion of this subject.)

Perspective

When the patient's clinical condition has been stabilized, it is reasonable to consider starting the discontinuation process even if predictive index thresholds for success have not been met. Valuable time may be lost in liberating patients from the ventilator if one relies solely on these indices because they are not powerful predictors of success or failure. Furthermore, there is no evidence that shows that unsuccessful discontinuation trials have long-term adverse consequences, provided patients are monitored closely and certain pitfalls are avoided. For example, it is unwise to attempt SBTs on patients with active ischemic heart disease because systemic oxygen demand and cardiac output can increase substantially during transition from controlled MV to SB [63,64]. Patients must be prepared psychologically to understand that failing a discontinuation trial has no bearing on their ultimate prognosis. Finally, it is prudent to guarantee sufficient respiratory muscle rest after a failed attempt at SB. With few exceptions, such as patients recovering from general anesthesia or sedation with or without muscle paralysis, the authors usually do not have their patients undergo more than one (failed) discontinuation trial in any 24-hour period. This practice is supported by the work of Esteban

et al. [65], who showed that twice-daily SB trials offered no advantage over once-daily trials. Moreover, the inspiratory effort associated with a failed weaning trial may be sufficient to induce muscle fatigue that may not recover [65], unless it is followed by an extended period of rest.

With respect to extubation, it is reasonable to proceed when the patient's ability to protect the airway suggests that extubation will be successful. We do not routinely administer systemic steroids to prevent postextubation stridor because of the inconsistent benefit seen in studies, and the uncertain timing of extubation encountered in clinical practice, which could potentially lead to extended courses of steroids with their associated side effects [66].

PRINCIPLES AND MODES OF DISCONTINUING MECHANICAL VENTILATION

Principles of Weaning

Discontinuing MV is a time when the load associated with breathing is returned from the ventilator to the patient's respiratory muscles. Because breathing is a form of continuous muscular exercise, discontinuation should incorporate the appropriate principles of muscle training. Training stimuli for weaning must be of the appropriate type, intensity, and timing. These vary depending on where patients are in the continuum of inspiratory muscle fatigue.

There are no consistently reliable predictors of early fatigue. Therefore, the physician must rely on clinical findings (e.g., appearance of new dysrhythmia, worsening tachypnea, tachycardia, hypertension/hypotension, diaphoresis, asynchronous breathing patterns), judgment (e.g., patient complains of worsening shortness of breath and has a poor appearance), desaturation, and acute or acute-on-chronic respiratory acidosis. On the other hand, it is important not to terminate a discontinuation trial before making the patient's muscles work hard enough because this can markedly prolong the total duration of MV support.

How Long Should Discontinuation Trials Last?

The question regarding length of discontinuation trials has not been definitively answered. Therefore, the duration depends on the patient population, the weaning mode, and local practice. With respect to trials of unassisted SB, a number of authors have arbitrarily set a maximum limit of 2 hours per trial [46,63,67–71] and extubated patients who were deemed stable by clinical, respiratory, and hemodynamic parameters. With respect to trials of SIMV and PS modes, some have recommended that stable patients need only be on a SIMV rate of 5 per minute and a PS at a setting of 5 to 7 cm H_2O for 2 hours before extubation. With these guidelines, reintubation rates can be as high as 13.8% for SIMV, 18.9% for PS, and 22.6% for trials of SB [67]. With respect to SB trials, other authors have found no difference in success of discontinuing MV when 30-minute and 2-hour trial intervals have been compared [70,71]. Nevertheless, because reintubation has been prospectively shown to be associated with a significantly greater (a) risk of in-hospital mortality, (b) ICU and hospital length of stay, and (c) transfer rate to a long-term care or rehabilitation facility [68], and because it is prudent to minimize the need for reintubation, we recommend the following:

- The authors prefer SB trials over other modes because they are the most direct way to assess the patient's performance without ventilatory support.
- It is reasonable to consider extubation in patients who have well-tolerated SB trials of 30 to 120 minutes, with the following exceptions [72,73]: (a) patients with a tracheostomy who meet the definition of being on prolonged MV (i.e., at least 21 days for at least 6 hours per day), (b) neurologic patients who are predicted to have difficulty clearing their respiratory secretions, and (c) patients who have had to be reintubated after the recent discontinuation of MV. In the context of these exceptions, it is our practice to observe these patients breathing spontaneously for a period longer than 2 hours (e.g., up to 24 hours) before considering extubation.
- Weaning should be performed using a protocol or clinical practice guideline that allows responsibilities to be clearly defined and empowers nurses and respiratory therapists to act within the scope of their practice.

Conventional Modes of Discontinuing Mechanical Ventilation

Four modes of discontinuing patients from MV are in general use: (a) trials of SB with or without the addition of CPAP, (b) SIMV, (c) PS, and (d) noninvasive positive-pressure ventilation (NIPPV) [74]. Results of randomized controlled trials comparing methods for weaning subjects from MV suggest that both SB and PS trials are superior to SIMV trials [67,75,76]. Therefore, we strongly discourage the use of SIMV for weaning. There are no convincing data to support the superiority of SBTs or PS compared to each other, and no data to support the practice of changing modes in patients who are not weaning successfully. The use of NIPPV should be limited to use in patients with CO_2 retention [77]. In other situations, NIPPV has not been shown to avoid reintubation in comparison to standard modes and can be potentially dangerous by delaying reintubation time [74]. Because we do not recommend SIMV trials, we only provide examples of SB, PS, and NIPPV protocols.

Spontaneous Breathing Discontinuation Trial

SBTs consist of the sudden, complete withdrawal of machine support. Patients are closely observed as they breathe humidified gas mixtures delivered by the T-shaped tube that is connected to the endotracheal or tracheostomy tube; alternatively, they can remain connected to the ventilator and be allowed to breathe spontaneously in the CPAP mode. In contrast to techniques that involve the gradual withdrawal of machine support, such as SIMV and PS, during SBTs the patient's cardiorespiratory response patterns can be assessed without the confounding influence of machine settings. Although there is no generally agreed on standard of applying this method of discontinuation, most practitioners begin SBTs from assisted, not controlled, MV and assess the patient's tolerance.

Although CPAP is not universally used, the authors believe it is physiologically sound to undertake SBTs in conjunction with CPAP irrespective of the underlying disease process. The addition of 5 cm H_2O of CPAP mitigates the fall in end-expired lung volume that results from having eliminated glottic regulation of upper-airway resistance and flow with an endotracheal tube [78]. Furthermore, in patients with airflow obstruction, CPAP can substantially lower the work of breathing by counterbalancing end-expiratory system recoil pressures (i.e., intrinsic PEEP) and by shifting loads from inspiratory to expiratory muscles [79–81]. It is not likely that the 5 cm H_2O of external PEEP will provoke hyperinflation by exceeding intrinsic PEEP. Nevertheless, to guard against hyperinflation, the physician can

monitor the effect of increasing levels of external PEEP on peak or end-inflation hold pressure on the ventilator before beginning weaning. When too much external PEEP has been applied and hyperinflation worsens, these pressures rise.

An alternative mechanism by which CPAP can reduce inspiratory elastic work in airflow obstruction is by recruiting expiratory muscles during SB. CPAP may result in exhalation below the new static equilibrium volume through the recruitment of expiratory muscles. Subsequent relaxation of the expiratory muscles inflates the lungs passively back to the new equilibrium volume. This may have the effect of unloading inspiratory muscles because the expiratory muscles do part of the inspiratory work. However, this mechanism is of limited value in patients with severe obstruction because low maximal flows prevent significant reductions in lung volume below static equilibrium volume.

In patients who continue to require MV only for oxygenation, CPAP may help maintain the benefits of improved oxygenation provided by PEEP without exposing the patient to the hazards of MV. It may also augment cardiac function during weaning.

Spontaneous Breathing Discontinuation Protocol. General guidelines for SB discontinuation are as follows:

1. When it has been decided that the patient is improving and stable, inform the patient that an attempt to remove MV will be made, why you believe he or she is ready, and what to expect. It is important to allow the patient to express fears whenever possible and to try to alleviate them [82].
2. Obtain baseline values and begin monitoring clinical parameters, such as pulse rate, respiratory rate, blood pressure, and subjective distress (e.g., have patients rate their dyspnea from 0 to 10), gas exchange (e.g., by pulse oximetry), and cardiac rhythm (e.g., by electrocardiographic monitoring). Record these values on a flow sheet that should be maintained and kept at the patient's bedside. The authors are unaware of any studies that support the need for frequent arterial blood gas analyses during discontinuation trials.
3. Ensure a calm atmosphere by having the nurse, respiratory therapist, or physician remain at the bedside to offer encouragement and support.
4. Avoid sedation to ensure maximal patient cooperation and effort.
5. Whenever possible, sit the patient upright in bed or in a chair.
6. Fit the patient's endotracheal tube with a T-tube connected to a heated nebulizer with an inspired oxygen concentration 10% greater than that prevailing during the previous course of MV. Ensure that the T-tube flow exceeds the patient's peak inspiratory flow and that the inhaled gas is constantly humidified. If CPAP is being used, the T-tube setup becomes unnecessary and the ventilator system tubing is used. Establishing the SB mode is done via commands on the ventilator.
7. Continue the trial to completion unless the following conditions develop:
   a. New onset diaphoresis
   b. New onset arrhythmias
   c. Systolic BP >180 mm Hg ***or*** a change (increase or decrease) of ≥20% of the original systolic value ***or*** a new requirement for vasopressors.
   d. Heart rate >120 ***or*** a change (increase or decrease) of >30 beats per minute
   e. SaO_2 <90%, FIO_2 >0.6
   f. If a blood gas is obtained, pH <7.30; PaO_2 <60 mm Hg; SaO_2 <90%; rise in $PaCO_2$ of more than 10 mm Hg
   g. Unstable pattern of ventilation
   h. Respiratory rate <8 breaths per minute, >35 breaths per minute for >5 minutes, change of >50% of original respiratory rate, or a RSBI (f/V_T) >100
   i. New onset altered mental status
   j. Signs of respiratory muscle failure including new onset use of accessory muscles of breathing or thoracoabdominal paradox
   k. Subjective discomfort of patient with dyspnea or pain rated as greater than 5/10
   l. Failure as determined by the subjective assessment of nurse, physician, or respiratory therapist

If the trial is terminated, place the patient back on the previous MV settings. The authors do not subject patients to more than one trial in a 24-hour period [75]. If a patient has no underlying lung disease, has been on an MV for only a short time (e.g., less than 1 week), appears to be tolerating SB without dyspnea for 2 hours, and maintains an adequate level of oxygenation, extubation may be performed after considering whether the patient is at risk of postextubation upper-airway obstruction or not being able to protect the airway or clear secretions. See the earlier discussion for additional information on duration of trials.

Pressure-Support Ventilation Discontinuation Trial

PS discontinuation decreases MV gradually, making the patient responsible for a progressively increasing amount of ventilation. Although it is commonly assumed that PS can be decreased to a low level (e.g., 5 to 7 cm H_2O) that compensates for endotracheal tube and circuit resistance, and patients can be safely extubated at that level, there is no simple way of predicting the level of PS that compensates for this resistance.

PS has become a popular mode of discontinuing MV for adults. In the PS mode, a target pressure is applied to the endotracheal tube that augments the inflation pressure exerted by the inspiratory muscles on the respiratory system [83]. As the lungs inflate, inspiratory flow begins to decline because airway pressure and the inflation pressure exerted by the inspiratory muscles are opposed by rising elastic recoil forces. When inspiratory flow reaches a threshold value (that differs among vendors), the machine switches to expiration [84]. Compared to the SIMV mode of discontinuation, during which spontaneous breaths are occasionally augmented by a volume-preset machine breath, PS is thought to offer greater patient autonomy over inspiratory flow, tidal volume, and inspiration time [85]. The popularity of PS is based on the premise that discontinuation from MV should be a gradual process. In addition, proponents of PS over SBTs argue that the work of unassisted breathing through an endotracheal tube is unreasonably high and could lead to inspiratory muscle failure in susceptible patients [86]. For example, it has become popular to assume that PS is an effective means to overcome the resistance of endotracheal tubes. However, this is conceptually incorrect because airway pressure during PS does not vary with flow. Furthermore, a reduction in pulmonary resistance is not demonstrated after extubation [87], and the work of breathing may actually increase [88]. This suggests that, at least immediately after extubation, most patients manifest upper-airway resistance that is, in effect, equal to or greater than that of an 8-mm internal diameter endotracheal tube.

Enthusiasm for using PS in all patients should be tempered by knowledge of its potential adverse patient–ventilator interactions. For example, elderly patients and even healthy individuals [89] are susceptible to PS setting–induced central apneas. The mechanism appears to be intermittent hypocapnia, resulting from the uncoupling of tidal volume from inspiratory effort. Problems may arise when the physician feels compelled to rest susceptible subjects with PS at night. Unless sufficiently high intermittent mandatory ventilation backup rates are used in combination with PS, the mechanical inhibition of inspiratory drive may result in apneas that trigger ventilator alarms

and cause arousals and sleep fragmentation that can prolong the discontinuation process.

Dyssynchrony between patient and machine breaths is common in the ICU, particularly during PS. This is true for patients with high intrinsic respiratory rates, reduced inspiratory pressure output from low drive or respiratory muscle weakness, or airway obstruction, and when ventilator support results in greater than normal tidal volumes. However, the diagnostic and prognostic significance of this dyssynchrony is uncertain. When it impairs ventilatory assistance or causes patient discomfort, sedation and adjustments in CPAP, rate, flow, or trigger mode are required. On the other hand, when wasted inspiratory efforts are not perceived as uncomfortable, it is not clear that adjustments in ventilator settings are warranted. Increases in machine rate to match the rate of patient efforts may cause worsening dynamic hyperinflation in patients with airflow obstruction, and compromise circulation.

Pressure Support Discontinuation Protocol. General guidelines for PS discontinuation are as follows:

1. Repeat steps 1 through 5 of the SB protocol.
2. Switch the MV mode from volume-cycled breathing with assist or SIMV modes to PS, or, if the patient is already on PS as a ventilatory mode, decrease the amount of PS.
3. For patients who have received prolonged ventilator support (e.g., greater than 21 days) for whatever reason, patients with neurologic diseases, or patients who have recently failed extubation, begin PS at a pressure of 25 cm H_2O if switching from another ventilatory mode, or less than the amount previously used during PS ventilation, and increase the fraction of inspired oxygen by 10%. Decrease airway inflation pressure slowly. If the patient fails to assume the increased work of breathing at a lower pressure, increase the pressure to the previously tolerated level and then higher, if necessary, until the patient is stable again. Then, wait 24 hours and begin the process again.
4. In patients who have no underlying lung disease and who have been on MV for only a short time (e.g., less than 1 week), PS can be set at 7 cm H_2O. If this pressure is well tolerated for 2 hours, the patient should be assessed for extubation [69].

Noninvasive Positive-Pressure Ventilation as a Mode of Discontinuing Mechanical Ventilation

A comprehensive description of NIPPV can be found in Chapter 59. Patients can receive this form of ventilation using either a ventilator specifically designed for noninvasive positive-pressure or an ICU ventilator, using PS mode plus PEEP. Ventilation can be delivered with a nose or face mask or, outside the United States, a helmet. Current literature indicates that the use of noninvasive ventilation as a "rescue" therapy for patients who are experiencing respiratory failure following extubation is ineffective in preventing reintubation [90]. Noninvasive ventilation may be an effective strategy in reducing reintubations and mortality among patients with chronic CO_2 retention when used routinely early after extubation [91].

Noninvasive Positive-Pressure Ventilation. General guidelines for NIPPV discontinuation are as follows [92]:

1. Repeat steps 1 through 5 of the SB protocol.
2. Extubate the patient, apply a nose or face mask designed for NIPPV, and begin assisted breathing. Continuously adjust the ventilator settings (see Chapter 59) according to patient comfort, the presence of air leaks, and monitoring.
3. In between periods of 1 to 2 hours of SB with supplemental oxygen, intersperse intermittent periods of ventilation for 2 to 4 hours at a time. Then, gradually increase the duration of the SB periods as tolerated by the patient (e.g., monitor RR, gas-exchange, and cardiorespiratory parameters and dyspnea).
4. When the period of SB spans the entire day and the patient is only receiving nocturnal ventilation, consideration should be given for discontinuing NIPPV.

Unconventional Modes of Discontinuing Mechanical Ventilation

A variety of unconventional techniques have been tried for discontinuing MV. These include inspiratory strength training [93], adaptive support ventilation [94], biofeedback [95,96], automatic tube compensation [97,98], and proportional assist ventilation. None of these techniques are supported by adequate evidence to justify recommendation as routine care.

Uncontrolled reports suggest that inspiratory muscle strength training [93] may be useful in preparing patients who are on prolonged ventilatory support for discontinuation. This method is thought to serve as a means of respiratory muscle endurance training; it is implemented by having patients perform low-repetition, high-resistance SB exercises.

During adaptive support ventilation [94], an automatic microprocessor-controlled mode of MV ensures the delivery of preset minute ventilation. It does this by continuously adapting to the patient's respiratory activity. Adaptive-support ventilation was developed in an attempt to automatically discontinue patients from MV by feedback from one or more ventilator-measured parameters.

Biofeedback, the detection and transmission back to the patient of some biologic function that he or she cannot detect, may be helpful in certain patients [95,96]. For instance, by displaying respiratory volumes on bedside oscilloscopes and having patients make voluntary efforts to push volume tracings beyond limits taped on the screen, Corson et al. [95] allowed two patients with spinal cord lesions—one with a sensory level at C6 who lacked proprioceptive afferents from the chest wall—to gain control over their breathing. These authors assumed that the repeated practice of reaching the criteria of feedback increased the strength of the diaphragm and inspiratory muscles and may have had the net effect of enabling the medullary center to reinstate automatic breathing.

Automatic tube compensation (i.e., a means of resistive unloading during ventilator-assisted SB by compensating for the pressure drop across the endotracheal tube) has been best studied. Compared with SBT in a randomized controlled trial, there was no clear difference in clinically significant outcomes [99].

Proportional assist ventilation (PAV) is a mode of partial ventilatory support in which the ventilator applies pressure in proportion to the inspiratory effort [100]. This has potential value in liberating patients from MV. The theoretical advantage is that the support applied seems to coordinate well with the patient's own respiratory effort, thereby simulating SB but with less respiratory work. No studies have demonstrated a clinical advantage of this method over conventional methods.

MANAGING DISCONTINUATION FAILURE

The authors' general approach to managing patients who have failed to have MV discontinued is based on three tenets: (a) protocol-based weaning yields superior outcomes when compared to nonprotocolized weaning; (b) SBTs or PS trials should be performed once daily; and (c) barriers to weaning are clinical conditions that promote muscle fatigue and weakness. Interventions that address and reverse these barriers are keys to successfully liberate patients from mechanical ventilation.

Protocol-Based Weaning

Multiple randomized controlled clinical trials [46,101,102] and nonrandomized controlled trials [103–105] have shown overwhelming advantages in clinically significant outcomes (e.g., decreased duration of MV, reintubation rates, ICU and hospital LOS) generated by the use of protocol-directed weaning implemented by nonphysician healthcare providers. The only study to dispute those advantages employed a care model in the control group that mimicked many aspects of protocol-directed care such as a closed staffing model and system-based structured rounds [106]. Therefore, the authors recommend that institutions develop protocols or employ existing protocols developed elsewhere to direct interdisciplinary weaning efforts rather than wean by individual physician discretion.

Once-Daily Attempts at Liberation from Mechanical Ventilation

On the basis of multiple randomized controlled trials of methods for weaning subjects from MV [76], the authors recommend that once-daily SB or PS trials be used as the discontinuation mode of choice. Because duration of MV is primarily determined by admitting diagnosis and degree of physiologic derangement [107], there does not appear to be anything to be gained by switching from one mode to another if the discontinuation process is prolonged. Our experience suggests that switching to another mode and waiting to see the response directs the attention of clinicians away from addressing the most important reason why patients are on prolonged MV—the persistence of inspiratory muscle fatigue/weakness.

Addressing Factors That Perpetuate Respiratory Muscle Fatigue

The respiratory muscles play a pivotal role in the onset and perpetuation of respiratory failure. Respiratory muscle fatigue is almost always multifactorial in etiology (Table 60.2). Therefore, clinicians should systematically consider ways to increase muscle strength and decrease muscle demand.

The following measures should be considered to increase respiratory muscle strength:

1. Reverse malnutrition [18,42,43] and deficiencies in phosphorus [22], calcium [21], potassium [19], and magnesium [20].
2. Consider correcting or improving (by correcting metabolic alkalosis) chronic hypercapnia during MV because hypercapnia may adversely affect muscle strength and endurance [28,29,108,109].
3. Reverse hypothyroidism [23].
4. Improve cardiovascular function [40] and minimize cardiac ischemia. Poor cardiac performance may contribute to an inadequate supply of oxygen to the respiratory muscles.
5. Attempt to minimize the use of sedative drugs whenever possible. In randomized controlled clinical trials, daily interruption of sedation compared to continuous infusions significantly decreased duration of MV and length of stay in a medical ICU [110]. Less intense anesthetic/sedative regimens have led to earlier extubation in postcardiac surgery patients [111–114]. The use of a protocol to manage sedation that was paired with a protocol to manage weaning improved on the outcomes achieved with the use of a weaning protocol alone and also led to a mortality benefit [115]. To assist in managing sedation, clinicians are encouraged to use validated and reliable monitoring scales such as the Richmond Agitation-Sedation Scale [116].
6. Attempt to reduce the incidence of delirium. Some authors have advocated for the use of dexmedetomidine in ventilated patients to reduce the incidence of delirium that leads to increase sedation. Dexmedetomidine is used in place of medications, such as benzodiazepines, that are thought to be a cause of delirium in ICU patients. These arguments are supported by the results of a randomized trial that demonstrated reductions in the incidence of delirium and time on the ventilator seen with dexmedetomidine in comparison to midazolam [117].
7. Paradoxically, because sleep deprivation may suppress ventilatory drive [10] and contribute to central fatigue, short-acting sedatives may occasionally be used in selected, sleep-deprived individuals [118].
8. Progesterone may serve as a respiratory center stimulant [119,120] in patients who take few or no spontaneous breaths despite a lack of sedative drugs. The effect of 20 mg of medroxyprogesterone acetate three times per day should begin within 2 days and be maximal within 7 days. This is a controversial therapy because many believe the additional respiratory center stimulation may just be "whipping a tired horse" and precipitate worsening muscle fatigue.
9. Consider and evaluate for the possibilities of myopathy and polyneuropathy [36] and drug-induced neuromuscular dysfunction (e.g., neuromuscular blocking agents and antibiotics, especially aminoglycosides) [35,121]. Critical illness polyneuropathy and myopathy are major causes of persistent respiratory failure [122].
10. By taking advantage of gravity and having the patient sit up, the diaphragm may function better.
11. Consider administering theophylline. Theophylline may act as a direct respiratory center and diaphragm stimulant and can increase the strength of contraction and suppress fatigue of the diaphragm [123,124]. However, its role in MV discontinuation has yet to be determined in randomized, prospective studies. Calcium-channel antagonists were shown in an animal model to inhibit the beneficial effects of theophylline on diaphragm function [125].
12. Mobilize patients to the maximum of their tolerance and initiate physical and occupational therapy early in their course. A protocol of early physical and occupational therapy combined with daily interruption of sedation demonstrated significant improvements in return to baseline functional status at hospital discharge and in number of ventilator free days in the first 28 days of hospital stay [126].

The following measures should be considered to decrease respiratory muscle demand:

1. Maximize treatment of systemic disease (e.g., infection, acute and chronic uremia) to decrease metabolic requirements and mitigate production of chemical mediators with adverse effects on muscle [25–27,127].
2. Give bronchodilators for conditions associated with increased airway resistance (see Chapters 48 and 49); discontinue beta-blockers in asthmatic patients.
3. Assess for adrenal insufficiency because identification of this condition and supplementation with systemic corticosteroids can increase the success of ventilator weaning and shorten the weaning period [128]. Moreover, a course of systemic glucocorticoids is helpful in exacerbations of chronic obstructive pulmonary disease [129,130] and asthma. Conversely, systemic steroids may contribute to the development of myopathy and perpetuate muscle weakness.

4. Use diuretics to reduce lung water in patients with pulmonary edema; this makes the lungs more compliant. Closely monitor renal function and serum sodium to avoid precipitating renal failure and hypernatremia.
5. Routinely evaluate for compromised cardiac function. Echocardiography and assessments for myocardial ischemia can diagnose and facilitate improvement of underlying cardiac disorders. The increased work of breathing during discontinuation may steal oxygen from the heart as well as other organs and precipitate ischemia and heart failure in susceptible patients [40,131,132].
6. In average-size adults, endotracheal tubes less than 8 mm in internal diameter significantly increase airway resistance [133,134], although it is unlikely that tube size adversely affects the discontinuation process unless the tube is prohibitively small (i.e., <6 mm). If an effect on weaning success is suspected, replace the smaller tube with one with a larger internal diameter.
7. Consider CPAP in patients with marginal cardiac function. It may provide support for a failing heart by decreasing left ventricular preload [40,131].
8. Consider that the ventilator is increasing the work of breathing and make adjustments [32,37,135]. Potential factors include (a) the appropriateness of the sensitivity/responsivity of the ventilator triggering system, (b) whether the ventilator flow pattern is synchronized with the patient's demand, (c) the appropriateness of the ventilator settings to avoid dynamic hyperinflation, (d) considering usage of extrinsic PEEP to overcome an increased triggering threshold load from $PEEP_i$, and (e) changing a heat and moisture exchanger to a heated humidifier to overcome the increased dead space and resistance of the exchanger [32,136].
9. Evaluate for overfeeding as the cause of increased CO_2 production. Excess total caloric intake, but not disproportionate carbohydrate intake, may precipitate respiratory acidosis in patients unable to increase their alveolar ventilation adequately when compensating for increased CO_2 production [137]. The treatment for this is to reduce the calorie intake.
10. Consider performing tracheostomy when patients are predicted to require prolonged MV. Tracheostomy may improve patient comfort and mitigate the need for more sedation, decrease airway resistance, decrease ventilator-associated pneumonia, and decrease duration of MV. While the best time to perform tracheostomy is not known, a randomized, controlled clinical trial showed that early tracheostomy (after 6–8 days of laryngeal intubation) compared with later tracheostomy (after 13–15 days of laryngeal intubation) did not result in significant improvement in incidence of ventilator-associated pneumonia [138]. Morevover, long-term outcome between the 2 groups did not differ.
11. Before extubating weak patients, assess whether they are at increased risk of developing postextubation stridor and whether they are able to protect their airway and clear their respiratory secretions (see section When Is It Appropriate to Extubate the Patient?).

TABLE 60.3

SUMMARY OF ADVANCES IN MANAGING DISCONTINUATION FROM MECHANICAL VENTILATION BASED ON RANDOMIZED CONTROLLED CLINICAL TRIALS

- Protocol-directed, ventilator management teams lead to favorable outcomes [46,101,102].
- Spontaneous breathing or pressure support trials are superior to SIMV trials [76].
- 30- and 120-min trials are equally successful [70,71].
- Twice-daily spontaneous trials offer no advantage over once-daily trials [75,76].
- Daily interruption of sedation leads to better outcomes than continuous infusions [110].
- A combination of a daily sedation holiday with once-daily spontaneous breathing trials improves outcomes [115].
- Early physical and occupational therapy reduces ventilator time [126].
- Early identification and treatment of adrenal insufficiency lead to increased weaning success and shorter weaning times [128].

SIMV, synchronized intermittent mandatory ventilation.

CONCLUSIONS

When managing patients with discontinuation failure, it is not likely that they fail for technologic reasons or the discontinuation mode but rather because of their diseases and causes of inspiratory muscle fatigue and how well these are managed. Advances in managing discontinuation from MV, based on randomized, controlled trials or meta-analyses of such trials, are summarized in Table 60.3. A number of studies have now been published that show that the most favorable discontinuation outcomes are most likely achieved by protocol-directed weaning. Such programs can improve the quality of care of patients on MV and decrease their length of ICU stay and hospital costs, especially when the protocol includes a search for and correction of medical barriers that perpetuate inspiratory muscle fatigue. In our protocol, we focus on a daily basis on minimizing or eliminating sedation, keeping the lungs dry without hurting the kidneys, improving nutrition, and maximizing cardiac function.

Although the optimum rate of reintubation is not known, it is the authors' perspective that it should be in the 10% to 15% range and it should be monitored as a quality indicator in ICUs. For example, if the reintubation rate is lower than 10%, it could be argued that too many patients are being "parked" on MV who should be extubated, placing them at risk of unnecessary endotracheal tube complications such as pneumonia. On the other hand, if the rate is much higher than 15%, it could be argued that patients are being prematurely extubated, placing them at risk of harm during the stress of recurrent respiratory failure and reintubation.

CHAPTER 61 ■ GAS EMBOLISM SYNDROMES: VENOUS GAS EMBOLI, ARTERIAL GAS EMBOLI, AND DECOMPRESSION SICKNESS

MARK M. WILSON

The gas embolism syndromes are known to occur in many different settings and may result in life-threatening emergencies. The clinical manifestations of these disorders are varied and the final pathophysiologic consequences depend on where the gas bubbles obstruct the circulation and how they impact the surrounding tissue. The nervous system, heart, lungs, and skin are the primary organ systems involved. The diagnosis of a gas embolism syndrome can be very difficult to establish. Clinicians must depend on a high level of suspicion in the appropriate settings to rapidly identify the problem, prevent further gas entry into the circulation, and begin effective treatment. Each of these entities is discussed in more detail based on the predominant location of the gas collections, although they are not always separate and distinct.

VENOUS GAS EMBOLISM

Although the actual incidence of venous gas embolism (VGE) in the United States is unknown, it has been estimated conservatively that at least 20,000 cases of "air" embolism occur annually [1]. The consequences of VGE range from clinically undetectable to being rapidly fatal.

Etiology

Clinical reports emphasize the high incidence of VGE in association with traumatic injuries and invasive procedures involving the head, neck, and chest (Table 61.1) [1]. Only the most common causes are discussed in detail here.

Surgical

Virtually any surgical procedure that transiently exposes an open vein to a relative negative pressure may be associated with VGE. The best-studied surgical procedure known to be commonly associated with VGE is craniotomy performed in the Fowler's (sitting) position. When monitors for VGE are prospectively used [1], VGE has been documented in 21% to 32% of all craniotomies and up to 58% of occipital craniotomies. Air may also enter the venous system via the occipital emissary veins, the dural sinuses, the diploic veins, the veins of tumors, or through burr holes.

Childbirth, hysterectomy, and abortion have been associated with an increased incidence of VGE [1]. It has been estimated that VGE causes 1% of maternal deaths. The incidence of VGE during cesarean section has been reported to be on the order of 39% to 71% overall, and the majority of episodes occur during uterine repair and placenta removal. During pregnancy, the veins of the uterus are exposed and fixed; when traumatized, they remain open and may serve as a portal of entry for gaseous emboli.

Prospective Doppler monitoring studies have documented a 31% to 83% incidence of VGE during total hip replacement [1]. The presumptive mechanism of embolization involves the forcible entry of air into the venous circulation through vascular openings in the bony medulla of the femur as a result of the high pressures generated in the distal shaft when the prosthesis is inserted.

Sinus lavage and dental surgical procedures have resulted in fatal cases of VGE [1]. Emboli are the result of intraosseous irrigation with water or air under pressure (at least 80 cm H_2O). There are no data available in the literature to suggest just how often VGE occurs during these procedures.

Trauma

Open or penetrating wounds—especially of the chest, neck, head, heart, spine, abdomen, and pelvis—may result in VGE due to the exposure of an open vein to a relative positive pressure gradient (i.e., atmospheric pressure as compared with

TABLE 61.1

CAUSES OF VENOUS GAS EMBOLISM

Surgical
Any head/neck/cardiothoracic surgery
Orthopedic surgery (arthroscopy, endoprosthesis placement)
Hysterectomy, caesarian section
Transurethral resection of the prostate
Abortion, uterine curettage
Normal childbirth, childbirth with placenta previa or extraction procedure
Liver transplantation/resection
Traumatic
Open/penetrating wounds
Vena cava lacerations
Positive-pressure mechanical ventilation
Self-contained underwater breathing apparatus diving
Decompression sickness
Pneumothorax/pneumoperitoneum
Cunnilingus/intercourse during pregnancy
Self-induced
Diagnostic and therapeutic procedures
Central venous catheterization
Pulmonary artery catheterization
Thoracoscopy, thoracentesis
Pleurodesis, percutaneous lung biopsy
Gravity infusion of blood/intravenous products
Pressurized injections/infusions (including contrast media)
Any involving gas insufflation
Hemodialysis
Pericardiocentesis
Pacemaker/defibrillator placement
Radiofrequency cardiac ablation
Endoscopic retrograde cholangiopancreatography
Epidural catheter insertion
Neodymium:yttrium-aluminum-garnet laser therapy
Liquid nitrogen cryosurgery
Hydrogen peroxide irrigation/ingestion
Blood donation

central venous pressure) [1]. Pneumothorax or pneumoperitoneum may result in VGE by the inadvertent puncture of intraabdominal or intrathoracic blood vessels during the mechanism of injury.

Some of the more unusual cases of traumatic embolization include reports of self-induced VGE due to urethral insufflation with an atomizer bulb, scrotal injection of air with a bicycle pump, and attempted suicide in hospital by forcible breathing into an intravenous line [1].

Diagnostic and Therapeutic Procedures

Air embolism in the setting of central venous catheterization has an unknown overall incidence, probably because the diagnosis is made only with large emboli. This fact also impacts the reported mortality rate in the literature of 29% to 43%, and it is possibly as high as 50% [1]. Morbidity is also significant because 42% of all survivors of recognized VGE were left with neurologic deficits. Air can enter the central venous system in several different ways: (a) during needle/wire/catheter insertion; (b) with fracture of the catheter, malfunction of a self-sealing diaphragm, or detachment of external connections; (c) after removal of a catheter that has been in place for several days, such that air is "sucked" into an open subcutaneous tissue tunnel that has formed a skin tract; and (d) as a result of a piggyback infusion running dry [2].

Thoracoscopy may produce VGE presumably due to the associated pneumothorax. Lung biopsy by percutaneous or bronchoscopic techniques creates a direct traumatic opening at the blood–air interface. Significant embolization might result whenever a medium-sized vein is exposed [1].

Gas insufflation procedures have been associated with gaseous embolization [1]. Diagnostic procedures involving the female genital tract, urethra, urinary bladder, kidney, retroperitoneal and perirenal spaces, peritoneal and pleural cavities, joints, cerebral ventricles, epidural space, and paranasal sinuses all carry a risk for VGE. To minimize this risk, the volume of gas introduced, the pressure resulting within the cavity, and the rate of injection should always be as low as possible. It has been suggested that carbon dioxide (CO_2) should be used as the insufflating agent whenever possible due to its high blood solubility and rapid clearance. This last recommendation begs a word of caution, however, because VGE-associated deaths have been reported even with the use of CO_2 [1].

Placement of epidural catheters for anesthesia has been noted prospectively to be associated with Doppler-detectable VGE [1]. In pregnant women placed in the left lateral decubitus position, VGE was noted to occur in 43%, almost half of whom were at least briefly symptomatic. The underlying mechanism relates to the rich plexus of veins of the epidural space, mostly anterior and lateral to the spinal cord. These veins are susceptible to trauma from a needle if the puncture is not directly in the midline or if the needle is rotated once in the epidural space. Because there are no valves in this plexus of veins, the intravascular pressure likely closely follows the central venous pressure. In the left lateral decubitus position, the site of puncture is above the level of the right atrium (RA), and, in pregnant women, uterine compression of the inferior vena cava is relieved, both of which serve to create a subatmospheric pressure in the epidural venous plexus.

Thermal tissue-ablation procedures using application of heat or cold have been associated with VGE [1]. Laser ablation/coagulation of tissues requires a continuous method for cooling of the laser tip. In general, these methods have involved using liquid (saline) or gas [air, nitrogen (N_2), CO_2]. Reports exist in the literature of the entry of these compressed gases into the venous circulation due to opening of vascular channels during the ablative procedure [1]. At the other temperature extreme, cryosurgery with instillation of liquid N_2 is used to extend the surgical margin of excision in many cancer operations. Direct contact between the tissues and the liquid N_2 may lead to entry of N_2 into the circulation in the gaseous state [1]. N_2 gas expands as it is warmed to a volume of greater than 500 times that it occupied in the liquid state. Gas emboli of this magnitude could be rapidly fatal.

Use of hydrogen peroxide (H_2O_2) in closed spaces or body cavities has been shown to result in VGE [1]. Animal and human studies have shown that H_2O_2 is readily absorbed from the intestines and the peritoneum. Oxygen (O_2) emboli arise from the systemic absorption of H_2O_2 as catalase-induced decomposition causes release of water and molecular O_2. One milliliter of a 3% H_2O_2 solution releases an estimated 10 mL of O_2 on contact with catalase [1], which is abundant in human blood.

Case reports of VGE during blood donation and insertion of peripheral intravenous catheters illustrate that there are no circumstances in which a vein is exposed to atmospheric pressure that the hazard of embolization is nonexistent [1].

Pathophysiology

Entry of Gas into the Circulation

VGE has been shown to occur with patients in essentially any position [1]. The critical factor common to all VGE lies in the

pressure gradient created between the right side of the heart and the level of the open vessel. Any increase in the distance of the open vessel above the level of the heart or any decrease in intrathoracic pressure would increase the likelihood of air entering the venous circulation and traveling to the heart. For each 5 in. in vertical height above the level of the RA, there is an approximately 9.3 mm Hg decrease in local blood pressure. Any decrease in mean intrathoracic pressure or mechanisms resulting in a contracted blood volume or low central venous pressure will tend to enhance any existing venous pressure gradient.

Large amounts of gas can rapidly pass into the venous system under the proper conditions. Calculations indicate that approximately 100 mL of air per second would enter a vessel via a No. 14-gauge needle with only a 5 cm H_2O pressure gradient across it.

Travel of Gas to the Heart

Once gas has entered the venous circulation, it travels toward the point of lower pressure until it reaches an obstruction. Animal studies have found that passage of air emboli through the superior vena cava can be retarded or the air even retained at sites proximal to the superior vena cava for an indefinite period [1].

Large venous gas emboli are capable of lodging and then obstructing blood flow in the heart and the pulmonary vasculature [1]. Grossly, these events have been observed to cause immediate dilation of the RA, the right ventricle (RV), and the pulmonary outflow tract. A rapidly expanding zone of RV ischemia follows soon thereafter. Functional obstruction of the RV outflow tract may result due to an "air lock" phenomenon. A blood-froth mixture results from systolic compression of the compressible gas phase with the noncompressible whole-blood phase. This concoction is then able to expand during diastole, the net result being an inadequate pumping action of the RV. It has been postulated that turbulent blood flow results from this "whipping" type of action or from vortex flow around partially obstructing collections of air bubbles. This whipping subsequently enhances fibrin formation, platelet aggregation, and coalescence of intravascular fat.

Smaller collections of air may not impair the heart and they may pass directly to the pulmonary arteries. Larger collections enter the pulmonary arteries with associated collections of fat and fibrin emboli.

Fate of Gas Emboli

Bubbles with the smallest initial radii have the shortest life span and are occasionally seen to pass directly through a capillary bed after attaining a radius of approximately 5 μm [1]. The bulk of excretion of gaseous emboli is accounted for by molecular diffusion across the arteriolar wall into the alveolar spaces. The rate of washout is related to RV performance and mean pulmonary artery (PA) pressure [1].

Surface-tension relationships, vascular pressures, and the size range of the bubbles are several additional interacting factors that may influence passage of emboli across the lungs. Also, the composition of the gas influences the size of the bubbles and the rate of dissolution in the blood. Bubbles of air or N_2 are expected to remain in the blood for longer periods of time than O_2 or CO_2, especially if the ventilatory gases resemble room air composition. This relationship is due to the similarity in the partial pressures of the gases inside the bubbles with those of the surrounding blood, as well as to the different solubilities of the gases. Tonic factors affecting the diameter of pulmonary vessels (e.g., anesthetic agents, neurogenic or hypoxic pulmonary vasoconstriction, arterial tension of CO_2, endogenous mediators) may also influence the passage of bubbles across the lungs.

Cardiopulmonary Consequences of Embolization

Pulmonary vascular obstruction is a major consequence of VGE and can lead to death. Obstruction to blood flow through the RV and through the pulmonary vascular system results from pulmonary vasoconstriction and from the mechanical impediment to flow imposed by the gas bubbles [1]. The change in PA pressures depends on whether the gas emboli are the result of a slow continuous infusion or a rapid bolus injection. In the first instance, a brisk increase in PA pressure to a level of up to 300% of baseline is seen [1]. This rapid increase phase is believed to be due to pulmonary vascular vasoconstriction and is followed by a plateau phase. The plateau response likely represents the opening of anatomic intrapulmonary shunts or a balance between the rate of gas infusion and rate of elimination. In contrast, when approximately 100 mL of air is injected as a bolus, PA pressure declines by as much as 20%, as the right heart is acutely stressed beyond its capabilities. Larger bolus injections (125 to 200 mL) are consistently fatal.

Pulmonary edema from VGE has been described anecdotally in humans [1]. Increased hydrostatic pulmonary vascular pressures (from mechanical occlusion of the PA and from induced vasoconstriction) and increased capillary permeability have been suggested as mechanisms for edema formation [1]. Regardless, the edema proves to be transient and reverses as the gas emboli are rapidly absorbed.

Maldistribution in ventilation–perfusion ($\dot{V}/\dot{Q}$) matching is the major factor leading to hypoxemia and changes in CO_2 concentrations. With small amounts of continuous gas bubble infusion (0.2 mL per minute per kg) into the venous circulation, there is an increase in high $\dot{V}/\dot{Q}$ areas in the lung. With larger volume gas emboli (0.75 to 2 mL per kg), however, shunting and an increase in the physiologic dead space have been shown to occur and to increase proportionally as the volume of embolic gas increases. This effect can involve as much as 35% of the total cardiac output, and it may be severe enough to cause CO_2 retention in addition to hypoxemia.

The end-tidal CO_2 concentration ($ETCO_2$) decreases during VGE as a result of the increase in dead space caused by vascular obstruction. More simply, $ETCO_2$ decreases as CO_2 is "washed out" of alveoli that are ventilated but not perfused adequately. Inadequate $\dot{V}/\dot{Q}$ matching may further worsen in the setting of a reduced cardiac output, resulting directly from VGE or indirectly as a consequence of non–embolic-related events (e.g., blood loss, myocardial ischemia, vasoactive medications). Any reduction in pulmonary blood flow decreases the delivery of air in the venous blood to the alveoli, thereby further decreasing the $ETCO_2$.

Paradoxic Embolism

A paradoxic embolism may occur in the presence or absence of an anatomic intracardiac shunt. A gas embolism may elevate right-sided heart pressures, thus facilitating right-to-left shunting through a patent foramen ovale (PFO). Autopsy studies of patients with no history of cardiac disease document the presence of a probe-patent PFO in 25% to 35% of the general population [1].

Considered an anatomic variant, a probe-patent PFO is generally 1 to 10 mm in diameter and it remains functionally closed as long as left atrial pressure exceeds RA pressure. A reversal of the normal interatrial pressure gradient might be expected to increase the risk of paradoxic embolization. RA pressure has been demonstrated to be higher than left atrial pressure in the seated position in up to 54% of adult humans monitored during neurosurgical procedures [1]. The critical pressure necessary for gas bubbles to be forced through a probe PFO is not known, but it is likely to be small. After cardiac surgery, it has been shown that as little as a 4 mm Hg gradient can produce a 50% right-to-left intracardiac shunt [1].

Clinically, it may be important to distinguish between an anatomic PFO and functional PFO because it is the latter that has an impact on any morbidity and mortality experienced. It has been reported that paradoxic embolization occurs in only 15% to 25% of patients with a PFO [1]. Contrast echocardiography using agitated sterile saline given as a rapid intravenous bolus has documented a lower prevalence of functional PFO (i.e., 10% to 20%) [1], as compared to the known prevalence of 25% to 35% for anatomic PFO. The amount of contrast material crossing from the right heart to the left heart does not correlate with the magnitude of shunt flow, nor does the Valsalva maneuver provoke shunting in all patients with PFO [1]. The question remains as to whether this finding represents a low sensitivity of this method for detecting PFO or whether there are some anatomic PFOs that have no functional role. Consensus opinion is that all PFOs should be considered to have the potential for allowing paradoxic embolization. Multiple reports have documented that the absence of any agitated saline or color flow through the interatrial septum by echocardiography does not exclude the presence of a PFO; it only excludes the presence of a right-to-left interatrial shunt at that moment in time [1].

Bubble passage through the pulmonary circulation has been shown to occur in the absence of intracardiac communications when the rate of venous air infusion exceeds the rate of pulmonary filtration and excretion [1]. Paradoxic air embolization during cardiopulmonary bypass has been reported to occur in the absence of an intracardiac defect when the mean PA pressure exceeds approximately 30 mm Hg [1]. Animal research suggests the existence of this same "critical value" of PA pressure that, once exceeded, dramatically increases the tendency for paradoxic embolization [1]. This increase occurs presumably on the basis of direct arteriovenous anastomoses in the lung (seen only rarely, but may be as large as 500 μm in diameter), bronchopulmonary anastomoses (i.e., flow is from the PA to the bronchial veins and then to the pulmonary veins), or by routine transpulmonary passage of the gas across the capillary beds.

Factors Affecting Mortality

The size of the embolus, its rate of delivery, and the final destinations of the gaseous emboli are the most important factors influencing the severity of injury produced by VGE. In humans, accidental bolus injections of 100 and 300 mL of air have been reported to be fatal [1]. In critically ill patients with minimal cardiopulmonary reserve, smaller emboli could be expected to have a greater morbidity.

In the context of equal volumes, mortality is decreased if the embolism is of CO_2 rather than air or O_2. Animal work indicates that CO_2 may be injected to 5 times the volume of O_2 before symptoms of embolism appear, presumably due to its greater solubility in blood [1]. Although tolerated to a larger extent, it must be remembered that CO_2 emboli are not entirely benign and may lead to similar clinical consequences as air embolization.

When nitrous oxide (N_2O) is used for anesthesia, mortality is increased in the setting of VGE [1]. N_2O attains a high blood concentration because of its high solubility (approximately 20-fold that of O_2 and 34-fold that of N_2). Because a large concentration gradient would exist between this blood and any air embolus, N_2O would be expected to diffuse from the blood into the embolus. As a result, the embolus increases geometrically in size in direct relation to the partial pressure of N_2O because the N_2O molecules can diffuse from the blood into the air embolus much more rapidly than the N_2 can be removed. The end result is a potential worsening of any generated physiologic abnormalities or delay in the ultimate resolution of the embolus. The presence of N_2O in the anesthetic mixture has been shown to reduce the median lethal dose of a given volume of air by a factor of 3.4 [1].

Diagnosis

Clinical Manifestations

The symptoms of VGE are generally nonspecific. Patients may report feeling faint or dizzy, express a fear of impending doom, or even complain of dyspnea or substernal chest pain. This presentation, with or without paradoxic embolism, may mimic an acute cardiopulmonary or central nervous system (CNS) event. Severe VGE may present dramatically with elevated neck veins, "clear lungs," and hypotension, and it may be rapidly followed by altered mental status and death. Because signs and symptoms are nonspecific, the importance of a detailed history, familiarity with the clinical situations in which VGE occurs, and a high degree of clinical suspicion cannot be overemphasized if one is to make an accurate diagnosis.

Physical Examination

Physical examination is usually not helpful in making the diagnosis. The only "specific" sign attributed to VGE is the classic mill-wheel murmur, otherwise reported only to occur in the rare syndrome of hydropneumopericardium. This murmur has been described as the rhythmic splashing or churning sound generated by the agitation of gas trapped with fluid in a closed space. Most often, it is only audible transiently and is heard infrequently at best, even in severe VGE. With large emboli and resultant cardiovascular collapse, a sound resembling the "squeezing of a wet sponge" has been described over the precordium [1].

VGE may occur without any change in vital signs. Wheezing as a result of acute bronchospasm may occasionally be heard. In a prospective study of seated neurosurgical patients, marked hypotension was noted in 78%, respiratory changes in 61%, and ventricular ectopy in 50% [1].

Laboratory Data

Abnormal results may include electrocardiogram (ECG) changes consistent with myocardial ischemia or acute cor pulmonale, premature ventricular contractions, and/or arterial blood gas findings of hypoxemia and hypercapnia.

Radiographic Findings

Chest radiography may verify the presence of VGE, but it should not be relied on for the diagnosis, especially in emergent situations. Air in the main PA is pathognomonic of pulmonary VGE, and it is recognized as a characteristic bell-shaped lucency in the distal main PA. This sign is seen very infrequently, especially in supine patients. Other patterns seen are focal upper-lung zone oligemia, central PA dilation, and air in the systemic veins or the arterial circulation [1]. Pulmonary edema ranging from hilar haziness to generalized vascular redistribution may occur soon after VGE, and it usually persists for at least 16 to 24 hours [1]. Noncardiogenic pulmonary edema has been reported [1], is usually self-limited, and resolves over several days. Progression of noncardiogenic pulmonary edema to full-blown acute respiratory distress syndrome has also been described [1].

Ventilation–Perfusion Lung Scans

VGE may produce patterns consistent with "high probability" for pulmonary venous thromboembolism interpretations. Prompt and complete resolution of these scintigraphic perfusion defects within 24 hours has been documented [1], and

it is probably characteristic for VGE. In contrast, perfusion defects produced by venous thromboembolism are known to resolve more slowly over a period of weeks to months and they may not ever resolve completely. Areas of $\dot{V}/\dot{Q}$ matching (i.e., "indeterminate probability") may coexist with $\dot{V}/\dot{Q}$ mismatches, and they are believed to represent reflex bronchoconstriction in conjunction with occlusion of the PA or its branches. The decreased ventilation is apparently due to the release of bronchoconstricting agents, such as serotonin, from the occluded segments of the PA. This phenomenon is readily reversible within several hours if the PA occlusion is transient, and it is related to rapid resolution of the gaseous emboli.

Detection and Monitoring Method

Precordial Doppler monitoring is generally considered one of the more sensitive techniques for detecting emboli. Because a gas–blood interface is an excellent acoustic reflector, when an ultrasonographic beam strikes a moving gas bubble, a distinctive and characteristic artifact is heard above the background flow signal.

VGE may be missed by this technique due to changes in the position of the detector or blood pressure. False-positive reports of VGE may arise due to arrhythmia. The sound pattern induced by a junctional rhythm may easily mimic changes produced by VGE. With a junctional rhythm, cannon A-waves may be present due to contraction of the RA against a closed tricuspid valve. The resultant turbulence in the RA is detected and confused for VGE.

Serial measurements of PA pressure should be a useful monitoring technique due to the fact that even small emboli may produce significant increases in PA pressures, major increases in PA pressure do not occur unless at least 10% of the vasculature is obstructed, the rise in PA pressure is roughly proportional to embolus size, and the likelihood of paradoxic embolism increases above a mean PA pressure of 30 mm Hg [1].

$ETCO_2$ and N_2 levels fluctuate with VGE. Because these changes probably result primarily from significant mismatch, it would be anticipated that they would detect emboli later than Doppler techniques or changes in PA pressure and that they would be more likely to miss small emboli. Like PA pressure changes, however, variations in $ETCO_2$ stay abnormal longer, and they are more closely related to the volume of gas embolized [1]. Potential confounding factors exist that may also cause a reduction in $ETCO_2$ in the absence of a VGE-related event, and they include any set of circumstances that result in an acute decrease in cardiac output, increases in alveolar ventilation, or increases in alveolar dead space.

Consideration of the advantages and disadvantages of the available VGE detection technology suggests that a combination of transesophageal echocardiography or precordial Doppler ultrasonography with PA pressure, $ETCO_2$, or transcutaneous O_2 devices would provide the sensitivity, the quantitative determination, and the physiologic response monitoring necessary. Across the United States, use of $ETCO_2$ monitoring in combination with precordial Doppler ultrasonography has become the primary, if not the standard, approach for VGE detection perioperatively.

Treatment

Because a fatal outcome may occur long before any diagnostic confirming tests can be performed, treatment must be initiated promptly at the earliest suspicion of gas embolization. Although no systematic studies comparing treatment modalities have been reported, improved detection of VGE appears to have decreased its severity. In combined retrospective and prospective analyses of seated neurosurgical procedures, a significant beneficial role was found for the use of routine precordial Doppler monitoring [1]. Before the advent of routine Doppler monitoring, VGE was clinically detected less often (5.7% before vs. 32% after), but the episodes noted had more severe sequelae. Once precordial Doppler monitoring became standard, the morbidity and mortality directly related to venous or arterial emboli was documented to be 0.5%. This improvement in event detection and reduction in the severity of VGE was ascribed to earlier recognition, allowing for earlier institution of therapy and prevention of further occurrences.

Routine Treatment Measures

Immediate measures should include identification of the site of gas entry and prevention of further gas entry, cessation or correction of exacerbating factors, administration of 100% O_2, and changing position to the left lateral decubitus position. In most patients, the site of gas entry is readily apparent. Failure to stop gas entry in a timely fashion may be fatal. If there is suspicion of a low central blood volume, volume should be rapidly repleted. Immediate cessation of delivery of N_2O and ventilating with 100% O_2 facilitates resolution of any gas emboli experienced during anesthesia with this agent.

Because air emboli are composed of approximately 79% N_2 and 21% O_2, any maneuver that rapidly increases the elimination of dissolved N_2 should decrease the size of the embolus. Administration of 100% O_2 achieves this goal by washing N_2 out of the alveoli and by creating a favorable gradient for N_2 to cross into the alveolus from the blood.

Placing patients in the left lateral decubitus position may facilitate movement of any air obstructing the pulmonary outflow tract toward the apex of the RV, thereby relieving the obstruction and improving survival.

Aspiration and Dislodgement

In patients with witnessed gas embolism or in whom monitoring techniques suggest that the gas is still trapped in the heart, attempts can be made to aspirate or dislodge the gas. Gas may be aspirated from the heart by placing a central venous catheter into the RA or RV or pulling back a PA catheter and then aspirating serially from each successive heart chamber [1]. In unwitnessed gas embolism, this early phase has usually passed before the embolism is detected, and these interventions may result in more harm than benefit. Closed-chest compression may dislodge the embolus from the RV.

Hyperbaric Oxygen

When available, use of hyperbaric oxygen (HBO) may be helpful. HBO is the only therapy demonstrated to have any benefit well after VGE has been clinically established [1]. Even after emboli of 150 to 500 mL, HBO produced rapid improvement of all cardiopulmonary and neurologic abnormalities despite delays in initiating therapy of up to 20 hours. The most common HBO treatment protocols in use today are the U.S. Navy Treatment Tables 5, 6, and 6A [3]. Use of these Tables is discussed later in the Treatment section of Decompression Sickness. Although it is accepted that HBO should be instituted as early as possible, the literature supports that special consideration be given to this modality at late stages, even in a seemingly irrecoverable situation [1].

Managing Unwitnessed Venous Gas Embolism

Given that VGE may mimic or cause a clinical presentation that is difficult to distinguish from venous pulmonary thromboembolism (PE), RV infarct, myocardial infarction (MI), or stroke, clinicians may frequently feel reluctant to consider the difficult-to-establish diagnosis of VGE and to begin treatment until other causes are ruled out. The simple measures indicated

for the immediate management of VGE outlined herein are not contraindicated in the management of any of the other conditions typically in the differential diagnosis.

Little has been published on the clinical management of cardiovascular consequences of VGE. Because myocardial and RV infarct may frequently accompany large VGE, urgent, routine evaluation with ECG and echocardiography would be indicated in most cases. Because myocardial ischemia and subsequent MI in VGE probably result from hypoxemia, the effects of massive overdistention of the ventricle, and perhaps direct embolization of coronary vessels, the value of traditional management techniques for MI is not clear. There are no theoretical contraindications to the use of nitrates, aspirin, beta-blockers, calcium-channel blockers, or vasodilators in patients with ECG changes. The role of thrombolytic therapy in VGE is unclear.

Discrimination between PE and VGE in patients with unwitnessed, unmonitored events can be difficult. Patients at risk for VGE are frequently at risk for PE as well. Once gas has left the RV, changes in PA pressures and $ETCO_2$ values may be similar in both conditions. As noted, the radiologic findings may be similar, but they may resolve within 24 hours with VGE. If the clinical suspicion of PE is high, there is no known contraindication to initiating appropriate anticoagulation in patients with VGE.

Prevention

Preventive measures are likely the most valuable management strategy for VGE. All patients undergoing the procedures listed in Table 61.1 [1] should be considered at high risk. In addition, hyperventilation, obstructive lung disease, and hypovolemia are common clinical conditions that increase the natural pressure gradient between atmospheric air and the central venous compartment; they may, therefore, also increase the chances of VGE during predisposing manipulations. Patients with a known PFO, pulmonary hypertension, previous MI with markedly reduced RV function, known right-to-left shunts, or congenital heart disease with any of the mentioned abnormalities should also be considered at high risk, not for experiencing an embolism per se, but for being susceptible for increased morbidity and mortality of a paradoxic embolism. A high false-negative rate (sensitivity, 64%) limits the usefulness of preoperative transthoracic echocardiography with Valsalva maneuver in predicting the presence of PFO and the risk of paradoxic emboli [1].

In general, patients should have procedures performed in a supine rather than upright position, and the point of potential air entry should be kept lower than the RA. Placement, manipulation, and removal of subclavian and internal jugular venous catheters are probably the most common clinical procedures during which specific measures can be performed to prevent substantial air embolization [2]. All patients should be placed in the Trendelenburg position, and they should be asked to perform the Valsalva maneuver or to hold their breath during needle/wire/catheter insertion. The operator should completely occlude the hub of the needle during manipulations to prevent open communication with atmospheric pressure. During removal of central catheters, patients should also be placed in the Trendelenburg position, the entry site should be compressed, and an occlusive dressing applied.

ARTERIAL GAS EMBOLISM

Arterial gas embolism (AGE) probably occurs daily in most hospitals due to the prevalence of the situations known to be associated with AGE (Table 61.2) [4]. Although the prevalence of AGE is likely not as high as VGE, the clinical significance is potentially much greater than VGE (Fig. 61.1). In the clinical setting, most causes of AGE are preventable, and prompt treatment is frequently effective.

TABLE 61.2

RISK FACTORS AND CAUSES OF ARTERIAL GAS EMBOLISM

All causes listed for venous gas embolism in Table 61.1, via paradoxic embolization
Cardiopulmonary bypass/coronary artery bypass graft/open-heart procedures
Coronary angiography/angioplasty
Cardioplegic solution infusion
Misuse/malfunction of pump oxygenator
Intraaortic balloon pump
Penetrating lung injury/resection
Bronchovenous fistula (due to trauma, mechanical ventilation, biopsy, thoracentesis)
Arterial line, arteriography
Self-contained underwater breathing apparatus diving
Decompression sickness
Carotid endarterectomy

Etiology

Cardiac Surgery and Bypass

AGE during cardiopulmonary bypass has an estimated incidence that ranges from 0.1% to 11.0% [4]. There is evidence that the use of in-line filters and preferential use of membrane oxygenators over bubble oxygenators may decrease this risk significantly.

The importance of trapped air in the left heart as a potential source of AGE after an open cardiotomy has been appreciated for years. Air may remain adherent to the endocardium, sutures, and prosthetic valves, and in cul-de-sacs in the atria, ventricles, or aorta even after the heart is closed and beating spontaneously again. Complete air evacuation, even after specific and meticulous venting techniques, is nearly impossible to achieve [4]. Residual air has been shown to be present in the heart after discontinuation of bypass in approximately two-thirds of patients undergoing open cardiotomies and in approximately 12% of patients undergoing coronary artery bypass grafting (CABG) only, for an overall incidence of approximately 45%. The source of intracardiac air resulting from CABG operations is thought to be due to the ascending aorta being cross-clamped and suction then being applied to the left heart or the aortic root for the purpose of venting. The resultant pressure decrease is transmitted to the coronary arterial circulation, thus allowing air entry via the coronary arteriotomy site, with subsequent passage into the aortic root or left ventricle. Any gases trapped in a proximal coronary artery or in a distally attached vein graft may also pass into the aortic root in the absence of venting if the graft is injected under pressure, as occurs commonly during the administration of cardioplegic hypothermia.

Transcranial Doppler monitoring of the middle cerebral artery during open-heart operations has confirmed the occurrence of cerebral gas embolization [4]. With refined surgical techniques, over time there has been a considerable reduction in the incidence of major neurologic injury after cardiac surgery and CABG, with a currently reported incidence of approximately 5% to 10% [4]. Detailed neuropsychiatric function testing, however, has shown persistent impairment of cerebral function in up to 70% of patients after CABG [4].

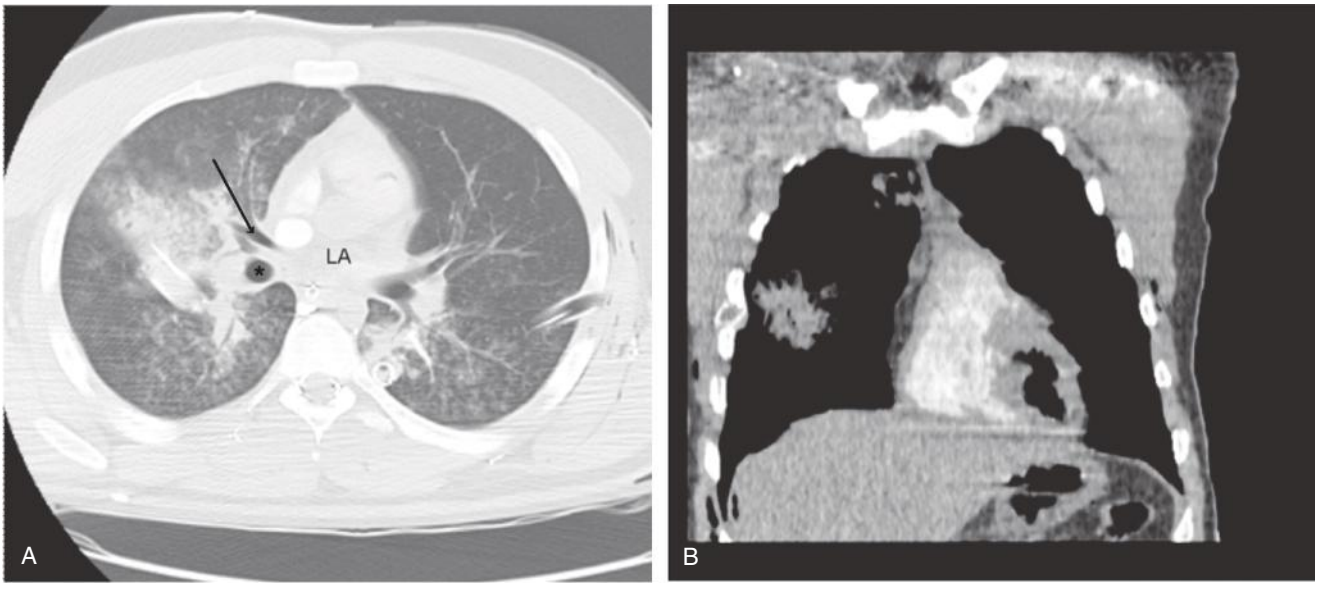

FIGURE 61.1. Fatal air embolism after massive facial trauma and prolonged extrication in an unbelted, backseat passenger in a car accident. **A:** Cross section of the chest showing air outlining the right superior pulmonary vein (*black arrow*) emptying into the left atrium (LA). Black* indicates the bronchus intermedius. **B:** Coronal reconstruction showing a massive air collection in the left ventricle.

Lung Trauma

Systemic AGE is a frequent and unrecognized cause of death in patients with blunt or penetrating lung trauma [4]. The mode of air entry after percutaneous lung puncture, penetrating or blunt lung trauma, or with positive-pressure mechanical ventilation is via creation of a bronchovenous fistula. Risk factors enhancing the chance of AGE include underlying emphysema, uncooperative patients, sneezing or coughing bouts, use of large-diameter needles, hypotension, hypovolemia, Valsalva maneuver, and site of involvement in close proximity to the hila. In patients with preexisting pulmonary fibrosis, one should expect an increased frequency and severity of systemic embolism due to the inability of the injured veins to retract and constrict. What has been referred to in the past as "pleural shock" (i.e., fainting, seizures, or even sudden death during a thoracentesis or therapeutic pneumothorax for treatment of tuberculosis) has since become recognized as a manifestation of AGE. Percutaneous procedures with needle calibers less than 20 gauge (0.9 mm) have generally been considered safe, despite a case report describing a cerebral AGE after transthoracic aspiration with a 23-gauge (0.6-mm) needle. The reported incidence for this complication for needles of 16 to 20 gauge (0.9 to 1.6 mm) has been variably estimated at 0.5 to 0.8 in 1,000 cases [4].

Arterial Lines

Cerebral AGE via retrograde flow from an indwelling radial arterial line has been reported as a case study and then followed up with a laboratory investigation [4]. Radioactive xenon mixed with 2 to 5 mL of air and injected at a rate of 0.6 to 2.5 mL per second into the radial artery resulted in demonstrable retrograde passage into the cerebral circulation. This low-flow rate is approximately fivefold to 25-fold less than the reported "safe range" of previous work [4]. Because the true "safe" amount of air that can remain in an arterial flush catheter without the risk of retrograde embolization remains unknown, medical personnel need to be vigilant and meticulous in ensuring removal of any entrapped air in arterial flush lines.

Percutaneous Transluminal Coronary Angioplasty

Most coronary artery gas emboli resulting from percutaneous transluminal coronary angioplasty are reportedly extremely small, and they do not result in symptoms or hemodynamic consequences [4]. Of the symptomatic episodes, most cause rapid onset of chest pain with ECG evidence of ischemia or infarction. The systemic blood pressure may be unaffected, or it may decrease mildly. In almost all patients, these effects clear spontaneously within 5 to 10 minutes, similar to experimental models. Only rarely does percutaneous transluminal coronary angioplasty–related AGE result in bradycardia, hypotension, ventricular fibrillation, MI, or asystole [4].

Pathophysiology

In AGE, gas enters the arterial system by the direct rupture of a blood–air interface, by direct passage from the PA to pulmonary venous system, or through a functional right-to-left cardiac shunt. Gas bubbles distribute themselves throughout the body primarily directed by the relative blood flow at the time. Bubble buoyancy is actually a minor factor unless there is a significant depression in forward systemic flow [4]. Because the heart, lung, and brain receive the greatest amount of blood flow, the consequences of embolization are most apparent in these organs. Pulmonary manifestations of AGE are uncommon, perhaps because the redundancy of the pulmonary vascular supply limits the consequences of bubble occlusion.

Systemic Mechanical and Biophysical Effects

Bubble formation results in two broad categories of effects: mechanical—physical obstruction to blood flow with distortion or tearing of tissues as the bubble forms and expands, and biophysical—where the blood–gas, blood–tissue or gas–endothelial interfaces stimulate a cascade of leukocyte, platelet, coagulation, fibrinolytic, and complement-mediated activations [4]. Research over the last two decades now recognizes

the importance of oxidative stressors causing impairment of endothelium-dependent vasorelaxation (i.e., the endothelial dysfunction hypothesis). This is primarily caused by loss of nitric oxide activity in the vessel wall [5–7].

Similar to VGE, the trapped bubbles may pass through the circulation and exit in the lungs, or they may be slowly metabolized by body tissues. Unlike the situation when bubbles are trapped in a vein, an arterial occlusion may have an immediate clinical impact. Uptake and release of inert gas by a particular tissue depends on the rate of blood flow to that tissue, as well as the rate of gas diffusion out of the blood into the tissue.

When bubbles do form, the inert gas becomes isolated from the circulation, and it cannot be removed by blood flow until it diffuses back into tissues. The speed of diffusion is the result of the difference between the N_2 partial pressure in the air bubble compared with the N_2 partial pressure in the tissue. The partial pressure of the inert gas in the bubble also varies directly with the bubble's loss of O_2 through metabolic conversion into CO_2, which is 21 times more soluble than O_2.

Cardiovascular Effects

The heart is extremely intolerant of even minute amounts of arterial gas. AGE may produce MI, left ventricle compromise, dysrhythmia, hypotension, or hypertension. As little as 0.025 to 0.05 mL of air directly entering a coronary artery may result in transient impairment of ventricular function, focal MI, ventricular fibrillation, or death [4].

Central Nervous System Effects

Cerebral embolism produces stroke-like symptoms and cerebral edema. Injury is probably more a result of damage from endothelial mediators rather than being directly due to ischemia or edema. After 5 to 30 seconds of arrested cerebral blood flow, most gas bubbles easily pass through the pial arteries. Significant volumes of gas may subsequently be collected in "air traps" in the jugular veins [4]. Larger emboli (e.g., large enough to obstruct several generations of arteriolar branching) are also generally only temporarily obstructing, and they relocate to the cerebral and the jugular veins during the period of reactive hyperemia that follows periods of arrested cerebral blood flow. It has been proposed, therefore, that the CNS dysfunction that follows cerebral AGE is not the result of bubble entrapment alone; it is instead due in large part to effects on vascular endothelium or blood components.

Diagnosis

AGE, whether traumatic, iatrogenic, or dysbaric (i.e., solely as a result of changes in ambient pressures) in origin, typically presents immediately after the insult occurs. A myriad array of dramatic manifestations is possible, typically with symptoms suggestive of coronary or CNS involvement. Two general clinical patterns have been recognized: fulminant collapse and isolated CNS injury. In the former, the initial presentation is apnea, coma, and cardiac arrest. This pattern is known to occur in 4% to 5% of patients with dysbaric air embolism but has an unknown incidence for other types of AGE. The responsible mechanism is believed to be direct coronary artery embolization with resultant MI or gaseous embolization of the cerebral circulation, resulting in hypertension and marked dysrhythmias. This subgroup is generally unresponsive to resuscitative efforts (Fig. 61.1).

In the latter group, the initial presentation is that of stable respiratory and heart rates, but with a wide spectrum of neurologic signs and symptoms. Usually, the symptoms are abrupt in onset, and they progress rapidly to overt signs. Patients may feel faint or dizzy or have an apprehensive fear of death. There may be loss of consciousness, convulsions, visual disturbances (including blindness), headache, confusion or other mental status changes, coma, vertigo, nystagmus, aphasia, sensory disturbances, weakness or hemiparesis, or even focal or more widespread paralysis. The pupils are usually dilated, and, occasionally, air may be seen in the retinal vessels. Liebermeister's sign may be present and is recognized as sharply defined areas of tongue pallor. Marbling of the skin of the uppermost portions of the body is another pathognomonic sign of AGE (along with retinal gas and Liebermeister's sign) [4]. With prompt recompression therapy, the majority of these cases have the potential for full recovery.

Other clinical manifestations of extra-alveolar gas are related to the traumatic entry of air into the interstitium after alveoli rupture. The air may dissect along the perivascular sheaths into the mediastinum, causing pneumomediastinum, usually associated with a substernal aching or tightness that may have a pleuritic nature and may radiate to the neck, back, or shoulders. There may be coexistent subcutaneous emphysema and a notable "crunching" sound with each heartbeat (Hamman's sign) due to air in the mediastinum. Air may dissect further to cause a pneumothorax in up to 10% of cases [4]. Tension pneumothorax may occur in patients on positive-pressure mechanical ventilation or during decompression. Pneumopericardium and air in the retroperitoneum and subcutaneous tissues of the neck, trunk, or limbs may also occur. This extra-alveolar gas also has access to torn pulmonary blood vessels when the intrathoracic pressure decreases during normal inspiration after barotrauma has occurred. Once egress into the pulmonary venous circulation has occurred, migration to the left side of the heart and then to the arterial circulation may follow. Hemoptysis has often been mentioned as a cardinal sign of dysbaric air embolism, but it actually occurs in a minority (approximately 5%) of patients [4].

Treatment

Management of AGE and decompression sickness is similar. Appropriate therapy involves prompt recognition, initial stabilization (with emphasis on preventing further damage), and definitive specific therapy (Table 61.3) [4]. All patients undergoing cardiopulmonary procedures or with recent lung trauma must be considered at high risk for AGE. Therefore, it cannot be emphasized strongly enough that a high index of suspicion for these diagnoses is one of the most important elements of care. Like many other true medical emergencies, therapeutic interventions should not be delayed to implement diagnostic testing. Details of therapy are found in the next section.

DECOMPRESSION SICKNESS

Decompression sickness (DCS) occurs only when a transition is made to an environment with a relatively lower ambient pressure. Any rapid lowering of ambient pressure, regardless of the initial pressure level or saturation of inert gas, results in the release of bubbles of inert gas into the blood and tissues. This is equally true for too quick a return to a normobaric state after a hyperbaric exposure (as in diving or compressed air mining), or for rapid progression from a normobaric state into a hypobaric exposure (as in aviators, astronauts, or mountain climbers). It is estimated that around 9 to 10 million divers are currently active worldwide, performing more than 250 million dives annually. Statistics compiled by the Divers Alert Network (www.diversalertnetwork.org) indicate

TABLE 61.3

TREATMENT SUMMARY OF ARTERIAL GAS EMBOLISM AND DECOMPRESSION SICKNESS

Of time-tested benefit
Prevent further bubble formation and extension of other injuries
Cardiopulmonary life support as needed
100% concentration of inspired oxygen
Maintain intravascular volume with isotonic fluids
Treat coexisting problems
Transport as soon as possible to recompression facility
Hyperbaric therapy
Unproven benefit (but generally believed to be helpful)
Trendelenburg/Durant position if arterial gas embolism suspected or unconsciousness with vomiting (would not maintain >30–60 min due to possible increased cerebral edema)
Avoid glucose-containing infusions
Avoid hypertension, anxiety
Diazepam for seizures, severe agitation, intractable vomiting (not used prophylactically)
Experimental or of questionable benefit
Consider aspirin
Corticosteroids (possible central nervous system toxicity)
Calcium channel blockers
Lidocaine
Combination nonsteroidal anti-inflammatory drug, heparin, and prostaglandin I_2
Perfluorochemicals and/or other surface-active agents
Induced hypothermia
Cerebral venoarterial perfusion
Proven detrimental
Recompression while submerged
Alcohol/analgesics
Delayed transport to hyperbaric oxygen facility
Additional hypobaric exposures

that there are more than 1,000 diving-related injuries annually in the United States alone, of which nearly 10% are fatal. DCS is the most frequent serious complication of self-contained underwater breathing apparatus (scuba) diving with an overall incidence of 4 to 6 cases per 10,000 dives [4,8,9]. DCS ranks third, after drowning and barotrauma/AGE (estimated incidence of 7 cases per 100,000 dives), as a cause of death among divers [4]. Strict enforcement of work regulations for tunnel workers and pilots has greatly decreased the incidence of DCS in these two groups.

Etiology

Diving

The turn of the 20th century saw the origin of decompression tables, which define set depths and time limits of hyperbaric exposure to be used by divers to minimize the risk of DCS. Although derived empirically by J. S. Haldane, all common schedules since have been based on his original methods. Haldane's work demonstrated that the human body could tolerate a twofold reduction in ambient pressure without symptoms of DCS. Haldane also formulated the concept that the tissues of the body absorb nitrogen at varying rates, depending on the type of tissue and its vascularity. Experience has shown that modern scuba divers can surface with a significant net accumulation of inert gas and yet remain without symptoms [4,10,11]. There is an important inter- and intraindividual variation in the degree of bubbling after a dive, indicating a significant, but as yet poorly characterized, influence of personal factors affecting gas saturation and desaturation [12,13].

Flying

DCS due to rapid hypobaric exposures from altitudes higher than approximately 18,000 ft is a syndrome indistinguishable from that produced in divers, and it is usually the result of accidental loss of cabin pressure in a pressurized aircraft. The altitude threshold for DCS is generally reported to be approximately 18,000 ft, but unless a person has had a hyperbaric exposure within the past 24 hours, there are rarely any difficulties with exposure to altitudes of up to 25,000 ft [4]. Exposures above this level up to approximately 48,000 ft for durations of 30 minutes to 3 hours have resulted in a DCS incidence of 1.5% [4]. More prolonged exposures and even greater altitudes increase the severity of an episode of DCS. Modern airline transportation has minimized these risks by pressurizing aircraft to maintain cabin pressures equivalent to 8,000 ft while flying at actual altitudes of greater than 40,000 ft. DCS may also occur while flying after a diving trip, and it may be produced by exposure to altitudes of as little as 4,000 ft, even when "no-decompression" type of diving took place. Current recommendations are to avoid all flying for at least 12 hours after any dive. For flights exceeding a cabin pressure equivalent of approximately 8,000 ft, or in the case of divers requiring decompression stops, at least a 24-hour delay is recommended before flying.

At the extreme of human hypobaric exposures is the astronaut. Astronauts performing activities outside their space vehicles are decompressed from a cabin pressure equivalent to sea level, down to a suit pressure equivalent of approximately 30,000 ft [4]. To minimize the risk of DCS, astronauts breathe 100% O_2 before decompression ("prebreathing") to reduce the partial pressure of N_2 before entering the space-suit environment. Only time and further space exploration will elucidate the risks of DCS from these types of exposures [14].

Pathophysiology

Bubble Formation

In DCS, gas dissolved in the body is released into the tissues and the bloodstream by decompression. Boyle's law states that the volume of a gas varies inversely with its surrounding absolute pressure. At sea level, the weight of air that we breathe is equal to 14.7 pounds per square inch, 760 mm Hg, or 1 atmosphere absolute (ATA), depending on the choice of units. Table 61.4 indicates that for every 33 ft of seawater a diver descends, the ambient pressure increases by 1 ATA and the volume occupied by that same gas decreases proportionally. The same table also demonstrates the reduction in pressure and volume expansion that accompanies increases in altitude.

The gear divers use to allow them to breathe underwater is designed to deliver air at the ambient pressure of the surrounding water, allowing the diver's lungs to remain fully expanded. As a scuba diver ascends slowly from depth, pressure in the lungs equalizes with ambient pressure as long as proper exhalation is achieved. If, for some reason, these expanding gases are not allowed to escape from the lungs (e.g., breath holding, localized gas trapping), overdistention of the alveoli may occur, which results in pulmonary barotrauma. The fragility of alveoli is not generally appreciated, but it is highlighted by the

TABLE 61.4

PRESSURE–VOLUME RELATIONSHIPS

Distance from sea level (ft)	Pressure equivalents			Bubble volume (%)
	Pounds per inch^2	mm Hg	Atmosphere absolute	
+48,000	1.85	96	0.126	794
+40,000	2.72	141	0.185	541
+32,000	3.98	206	0.271	369
+24,000	5.70	295	0.388	258
+16,000	7.97	412	0.542	185
+8,000	10.92	565	0.743	135
Sea level	14.70	760	1	100
−33	29.40	1,520	2	50
−66	44.10	2,280	3	33
−99	58.80	3,040	4	25
−132	73.50	3,800	5	20
−165	88.20	4,560	6	17

fact that with the lungs fully expanded on compressed air, a pressure differential of only 95 to 110 cm H_2O (equivalent to an ascent from a depth of only 4 to 6 ft) may be sufficient to rupture alveolar architecture [4]. With very few exceptions, all scuba diving is done at pressures less than 7 ATA, and most is done in the 2 to 4 ATA range [4,9].

Dalton's law of partial pressures states that the total pressure exerted by a mixture of gases is equal to the sum of the partial pressures of its constituent gases. The composition of gases that make up our atmosphere remains essentially constant up through an altitude of approximately 70,000 ft: 78.08% N_2, 20.95% O_2, and the remaining fraction of CO_2, hydrogen, helium, argon, and neon [4]. In most settings, N_2 is the predominant constituent of any inhaled gas mixture. N_2 is inert (i.e., it is unused/unchanged by passage through the body). This fact is in contrast to CO_2 and O_2, which are actively transported and therefore do not depend entirely on purely physical laws for removal. N_2 is more soluble in fat than in water, which suggests that during decompression, bubbles more likely form in lipophilic tissues such as bone marrow, fat, and spinal cord.

Henry's law of gas solubility states that the amount of gas that dissolves in a fluid is directly proportional to the pressure of that gas on that fluid. The deeper one descends underground or in the ocean, the greater the driving pressure for the gas on the blood and the bodily fluids. The total accumulation of dissolved N_2 into the tissues of the body is, therefore, dependent on the depth achieved and the time spent at that depth. As ambient pressure decreases on ascent, solubility decreases and gas is released from body fluids.

Studies on bubble formation suggest that of the total absorption of inert gas that occurs during a dive, only 5% to 10% is released as bubbles after a rapid decompression [4]. The site of origin of intravascular bubbles is controversial, but overwhelming human and animal experimental evidence shows that gas bubbles are first detected in the venous circulation during decompression. It is most probable that AGE in DCS arises from the venous circulation or from pulmonary barotrauma with entry of gas bubbles into the pulmonary veins (i.e., dysbaric air embolism).

Biophysical effects result from the blood–gas, blood–tissue and gas–endothelial interfaces, where an enormous chemical and physical discontinuity activates and amplifies reactive systems that are usually quiescent during normal blood flow. Electrochemical forces also exist at any blood-damaged endothelial interfaces, and they activate coagulation, complement, kinin, and fibrinolytic systems and allow for the denaturation of proteins. In DCS, and presumably in AGE, a localized hypercoagulable state develops, with a coexistent reduction in platelet count due to aggregation at the blood–bubble interface with leukocytes, red blood cells, and formed fibrin strands. The end result of this diffuse activation is to amplify any existing mechanical obstruction to blood flow with progressive sludging and clotting [4]. Further tissue injury then results from a decrease in local blood flow, edema formation, leukocyte chemotaxis, and the release of toxic O_2 radicals. These effects are likely to be most important in cases of CNS involvement, in which small areas of reduced blood flow can produce severe disability or death. A disturbance in barrier function would best account for the well-established features of AGE and DCS which are otherwise difficult to reconcile with simple vascular occlusion as the sole explanatory mechanism.

It is important to emphasize that divers perform safe decompressions millions of times each year. For most, this process involves only a slow ascent after a short-duration dive. Others may require staged ascents, with one or more stops at intermediate depths to give more time for N_2 elimination. Still others require planned periods of chamber recompression after diving to prevent DCS. The overall safety of decompression exposures has withstood the test of time, and it has improved with experience and use of preventive measures. Safe decompression is by far the rule, rather than the exception.

Diagnosis

The clinical manifestations of DCS are protean, reflecting the effects of bubbles distorting tissues, obstructing blood flow, and perhaps most importantly by endothelial activation and initiation of an inflammatory response. Symptoms will occur within 1 hour of a decompression event in approximately 75%, and within 12 hours in over 90% of afflicted individuals. A gross classification system is in common use based on the perceived severity of the clinical situation and the anticipated response to therapy [4]. Type I DCS encompasses 75% to 90% of patients and includes those with musculoskeletal pain; skin or lymphatic manifestations; or nonspecific symptoms of anorexia, malaise, and fatigue. Generally, these patients require no treatment or only a brief period of repressurization. Caution is still in order because up to 20% to 30% of this group may progress to a type II illness. Type II DCS is characterized by those cases with CNS or peripheral nerve involvement or any cardiorespiratory dysfunction. Overall, 10% to 25% of patients have

type II DCS, and it generally represents a more severe illness with the potential for greater difficulties in treatment. The presence of a PFO is associated with a four- to sixfold increase in the odds ratio of developing a type II DCS [15–18].

Type I Decompression Sickness

Type I DCS includes the most common and classic manifestations usually associated with DCS. The majority of patients report an "aching" pain in a limb during decompression or within the first 36 hours after surfacing (95% of patients experience onset within 6 hours of surfacing). Initially, there may be a vague feeling that "something is wrong," and the limb discomfort is dull and poorly localized. With time, this may progress to an intense throbbing pain within a more circumscribed and specific location. The affected area is generally nontender to palpation, and movement of any affected joints does not exacerbate the pain, except in severe cases.

The limbs are the most common sites of symptoms of DCS (in approximately 92% of cases of DCS overall and as the initial clinical manifestations of DCS in approximately 77%) [4,9,10]. Shoulders, elbows, hips, and knees are the most commonly affected joints. More than one site may be involved, but rarely is the distribution bilaterally symmetric. Heat, ice, immobilization, and potent analgesics do not relieve the pain, which is due to collections of gas in the periarticular and perivascular tissues. The most striking characteristic of this pain is its rapid relief with recompression. This rapid relief of discomfort with the application of pressure, and especially the tendency for this pain to return to the same site if recompression is inadequate, distinguishes the pain of "the bends" from any coexistent musculoskeletal strain or from the ischemic pain resulting from AGE.

Usually, there are no objective physical signs associated with limb DCS, except for a potential "peau d'orange" appearance of the skin from local lymphatic obstruction. The skin exhibits two distinct types of manifestations of DCS: (a) a transient pruritus involving ears, trunk, wrists, and hands (more common after exposure in hyperbaric chambers); and (b) a more intense itching, usually limited to the trunk, that begins as erythema (from dermal vasodilation) and progresses to a characteristic mottling with confluent rings of pallor surrounding areas of cyanosis. This lesion blanches to the touch and is known as *cutis marmorate*. These changes are thought to result from bubble obstruction of the skin's venous drainage or bubble-induced vasospasm [4]. These abnormalities generally resolve spontaneously over a few days.

Type II Decompression Sickness

Type II DCS may occur separately or in combination with the musculoskeletal pain of type I DCS in up to 30% of patients [4,9,10]. The primary organ systems affected in this category are pulmonary, nervous, and vestibular.

Pulmonary DCS, known as "the chokes," occurs rarely in diving (approximately 2% of the overall cases [4,10]), and it is generally the result of very rapid or emergency-type ascents. Aviators, astronauts, and submarine trainees are also in situations in which sudden dramatic decompression may occur, and pulmonary DCS has been noted in nearly 6% in these groups [4,10]. Clinically, this condition usually begins with a substernal discomfort that starts within minutes of reaching the surface. As it progresses, the discomfort may take on a respirophasic nature. The respiratory pattern becomes more rapid and shallow, with occasional paroxysms of a nonproductive cough. Evidence of right heart strain or failure may develop and may progress to full-blown cardiovascular collapse. The underlying mechanism involves direct and indirect effects of massive pulmonary gas embolization from VGE.

Neurologic DCS has a varied incidence among different populations [4,10]. A wide range of possible presenting signs and symptoms may be produced by neurologic DCS, and all must be taken seriously even when there are no objective findings on neurologic examination. The spectrum of neurologic dysfunction ranges from pruritus with skin rash or "pins and needles" sensation (15% of cases) to full paralysis (6%) or convulsions (1%) and death. Personality changes and agitation occur in 3%, but they are very rarely the presenting symptoms. Visual disturbances (7%) and difficulties with cerebellar function (18%) are also frequently seen. The pathogenesis underlying CNS injury from DCS is the subject of much debate and controversy. Most researchers would agree that the notion of CNS tissue ischemia arising from obstructing arterial gas bubbles is too simplistic. As mentioned previously, the endothelial dysfunction hypothesis is currently under investigation as a better candidate mechanism to explain the varied manifestations of DCS.

Vestibular DCS, "the staggers," occurs relatively commonly as the initial manifestation of DCS, and it comprises a syndrome of nausea, vomiting, dizziness, and nystagmus. Frequently, tinnitus or hearing loss may also be present. Typical onset is immediately after decompression, and it occurs in 13% to 72% of patients with type II DCS. The underlying pathology has been demonstrated in animals to be the result of rupture of the fragile membranes in the cochlea and semicircular canals.

Treatment

Prompt Recognition and Diagnosis

The most common problem in DCS and AGE is making the initial diagnosis. Particularly in the case of DCS, there is an early tendency by patients for denial of the existence of any problems. Any neurologic or cardiorespiratory symptoms after diving must be assumed to relate to DCS until proven otherwise.

Stabilization

Nonspecific therapy may help to stabilize the patient and prevent an extension of injury. Immediate institution of cardiopulmonary resuscitation may be needed, and it takes precedence over all other measures. Endotracheal intubation is sometimes necessary to ensure patency and protection of the airway. All balloon cuffs (endotracheal and Foley) should be inflated with sterile water rather than air to minimize the volume changes of these compartments during recompression therapy.

When AGE is suspected, most authorities recommend the flat, supine position initially. If the patient is unconscious or vomiting, the left lateral decubitus (Durant) position is also recommended. The benefits of the Trendelenburg position have been questioned with the realization that maintaining this body position for extended periods may worsen any associated cerebral edema, and that keeping the head lower than the heart does not prevent migration of bubbles into the cerebral circulation unless the patient is in total circulatory arrest or an extremely low-output state [4].

Once any life-threatening concerns have been addressed, maintenance of intravascular volume and the administration of 100% O_2 become the next most important features of treatment while arranging transport to a hyperbaric facility. The 100% O_2 can be delivered intermittently or continuously for extended periods (generally up to 16 to 18 hours) without any serious concern for any resulting significant pulmonary toxicity. The high fraction of inspired O_2 is used to alleviate any tissue hypoxia and to provide a strong concentration gradient that will wash out as much inert gas as rapidly as possible.

As a result of capillary endothelial injury, the more severe the DCS syndrome, the greater the magnitude of plasma leakage from the vascular space, the reduction in blood volume, and the resultant hemoconcentration [4]. Increased blood viscosity resulting from hemoconcentration may further impair any compromised microcirculation; therefore, normovolemia should be the goal of infusion therapy. Intravascular volume maintenance can be achieved with isotonic fluids given at a rate sufficient to keep the urine output at 1 to 2 mL per kg per hour or more, and it is recommended for patients who are vomiting, unconscious, or having any symptoms more severe than isolated limb bends. Glucose-containing solutions are probably best avoided in the first 12 hours after suspected cerebral embolization because an increased serum glucose levels is one of the major determinants of the brain's lactate production, which has been associated with increased neuronal damage in the ischemic state [4,10]. Conscious patients may be given judicious amounts of oral liquids, such as nonacidic fruit juices or balanced electrolyte solutions. Alcohol-containing beverages should be strictly avoided.

When the diagnosis of cerebral air embolism is evident on clinical grounds, comprehensive diagnostic testing is not necessary. Diagnostic testing should never delay transport to a facility equipped to provide hyperbaric therapy or initiation of this specific therapy. If hyperbaric therapy is not immediately available, a noncontrast head computed tomography scan, chest radiography, and an ECG should be obtained while awaiting transport. In coma due to AGE or DCS, the head computed tomography would typically reveal multiple, small, well-defined, low-density areas in the brain. Head computed tomography scanning is also useful in ruling out possible correctable causes of intracerebral bleeding. Magnetic resonance imaging and single-photon emission tomography techniques, where available, are likewise potentially useful to document the presence of cerebral gas collections. Because these tests are highly insensitive, negative studies alone should never deny patients' access to HBO therapy in the appropriate clinical situation.

Patient Transport

When air evacuation is necessary to transfer a patient to a recompression facility, it is of utmost importance that the patient not be exposed to any further decreases in barometric pressure, as occurs with travel at increasing altitudes. In general, unless the aircraft is capable of maintaining a cabin pressure equivalent to sea-level pressure, flight altitude should not exceed 500 to 1,000 ft above the departure point because deaths have resulted from exposure to altitudes of only 4,000 to 5,000 ft [4,19]. It is believed to be preferable to await the arrival of a pressurized transport than to risk exposing a patient with DCS or AGE to further hypobaric insult.

To obtain a listing of the nearest recompression facility as well as advice on treatment options from a medical diving specialist on a 24-hour emergency basis, contact the Divers Alert Network at Duke University at (919) 684-8111 or (919) 684-4DAN (4326), collect.

Drug Therapy

To date there are no drugs of proven benefit in treating DCS or AGE. There is an unfortunate paucity of randomized controlled trials to guide treatment options. Several agents are used frequently, but this therapy is primarily based on expert opinion and limited trials involving small numbers of animal and human subjects [4,20–22].

Many authorities still prescribe intravenous corticosteroids for patients with DCS (and sometimes AGE) who have any documentable neurologic impairment, in an effort to reduce the impact of any inflammatory components of these diseases. Usually, dexamethasone (10- to 30-mg intravenous bolus followed by 4 mg intravenously every 6 hours) or hydrocortisone (1-g intravenous bolus followed by dexamethasone every 6 hours) is given for a total of 2 to 3 days. There is no solid evidence of effectiveness for steroids [4,8]. On the contrary, there is evidence that steroid use may actually increase the risks for CNS O_2 toxicity during recompression therapy [4,8]. Corticosteroid use in cases of documented neurologic impairment should, therefore, be made on an individual basis in consultation with a medical diving specialist.

Intravenous diazepam is effective in the control of seizures, severe agitation, and the intractable vomiting resulting from "the staggers." The typical regimen is a 5-mg intravenous bolus given over 3 minutes and then repeated every 5 minutes as needed (maximum dose, 20 to 30 mg) to control seizures. If intravenous access is not available, the intravenous preparation may be given rectally to adults in a dose of 7.5 to 10 mg every 5 minutes as needed. Diazepam is not recommended for use prophylactically because of its sedative properties and its propensity to mask the onset of CNS toxicity, thus affecting the ability of physicians to assess response to hyperbaric treatment. Generalized seizures unresponsive to benzodiazepine therapy may be suppressed with barbiturates [4,8].

Analgesics should be avoided because they also tend to mask the progression or new onset of symptoms. Given its low-risk profile, some authorities recommend administration of 0.5 to 1 g of oral aspirin to reduce platelet aggregation. Prior animal experimentation had shown no benefit to nonsteroidal agents (indomethacin, aspirin) when given alone; however, a recent double-blind, randomized, controlled trial of a small number of human subjects raised the possibility that the nonsteroidal agent tenoxicam may reduce the number of recompression sessions required for symptom resolution [23].

Intravenous lidocaine may have potential use in DCS and AGE due to its anticonvulsant and antidysrhythmic effects. Lidocaine may be given as a 0.5 to 1 mg per kg intravenous bolus at a rate of 25 to 50 mg per minute, followed by 0.5 mg per kg intravenously every 5 to 10 minutes as needed, to a maximum total of 225 mg or 3 mg per kg, whichever is lower. Patients with hypotension, cardiac arrest, or biventricular heart failure should receive only a single loading dose of 100 mg. After the loading doses, a continuous intravenous infusion at 2 to 4 mg per minute may be used to achieve and maintain a blood level of 2 to 4 μg per mL. Although not corroborated by any studies in humans, animal studies have shown an increased rate of neuronal recovery when lidocaine is given after experimental cerebral AGE [4,11]. The exact mechanism by which this recovery is accomplished is unknown, but it does not appear to be due to any direct vasoactive effects of lidocaine. Instead, it is more likely that any efficacy of this agent may be due to an ability to reduce cerebral metabolism and to stabilize neural membranes by decreasing the flux of sodium and potassium levels [4,11]. There are case reports of the successful use of lidocaine as an adjunct to recompression in divers with neurologic DCS [4,11]. Some caution is warranted, however, because moderately high doses of lidocaine may precipitate seizures in some patients. Use of lidocaine is currently not standard in the care of patients with DCS.

Calcium channel blocking agents have had limited or no beneficial effects in the treatment of cerebral ischemia in numerous animal models, as well as several human trials [4]. Efficacy seems to vary with the drug used and with the subject population studied. Currently, no consensus exists on the use of calcium channel blockers in AGE or DCS.

Until further study is performed, discretionary therapy with these adjunctive agents should be considered the realm of "clinical judgment" and "expert opinion." Evidence-based recommendations await results from further controlled trials.

Hyperbaric Therapy

Hyperbaric therapy involves exposing the entire body to prolonged periods of higher-than-atmospheric pressure; it specifically treats AGE and DCS [24]. Anecdotal reports of success in isobarically occurring AGE lends credence to the recommendation for early consideration of hyperbaric therapy for any suspected cerebral gas embolism [4]. Many treatment protocols have been proposed [25,26], and no one of them would be expected to be fully efficacious and life sustaining in each individual. As of 2009, no randomized controlled human studies exist that compare these different treatment options. A review of the pertinent literature on humans since the 1960s reveals a decrease in cerebral air embolism mortality from 93% for those not receiving therapy to 28% to 33% with closed-chest massage and "conventional therapy," and then to 7% with addition of HBO [4], and would seem to argue strongly for this modality in AGE [4].

Fully 80% to 90% of all patients with DCS or AGE effectively respond to recompression therapy [8,9,26,27]. While there is generally an inverse relationship between any delay to treatment and complete symptom resolution, evidence supports the use of HBO for AGE and DCS even after delays of more than 24 hours. Delays in initiating recompression therapy of up to 10 days have been anecdotally reported in the literature to be successful in up to 90% of these patients [4]. Recompression treatments may be repeated as needed until symptoms resolve entirely or until improvement reaches a plateau and there is no further improvement [9]. Approximately 40% of injured divers show complete resolution after the first treatment and only 20% require more than three rounds of recompression therapy [9].

The mechanism of action of HBO therapy involves a decrease in volume of any gas-filled spaces and resorption of bubbles back into body fluids. This process presumably results in a diminution in tissue distortion, vascular compromise, and bubble–endothelial surface contact. HBO therapy should be undertaken for at least 4 hours because elimination of bubbles may be reduced in areas of poor flow where sludging and edema exist [8,24]. It must be remembered that recompression acts only on the primary cause of these syndromes and not necessarily on any of the secondary effects that may result (e.g., endothelial dysfunction, activation of the inflammatory cascade).

Hyperoxygenation results from a markedly enhanced arterial O_2 content, primarily from O_2 dissolving more readily into the plasma. Although the oxyhemoglobin dissociation curve remains unchanged, the arterial partial pressure of O_2 may reach 2,000 mm Hg on a fractional inspired oxygen concentration of 100% and an ambient pressure of 3 ATA [8,24]. In the clinical setting, however, these high plasma O_2 concentrations are never transmitted fully to the tissue level due to progressive arteriolar vasoconstriction from the disease process itself, as well as a direct effect from the increasing O_2 concentration. Local tissue perfusion, although reduced further by HBO, is still sufficient to cause supranormal tissue partial pressure of O_2 levels of approximately 500 mm Hg. HBO allows the delivery of nearly 60 mL per L of blood (vs. 3 mL per L at atmospheric pressure), a rate sufficient to support resting tissues just on the basis of the O_2 dissolved in solution alone. In practice, the physiologic effects of high concentrations of O_2 to induce generation of O_2 free radicals and pulmonary O_2 toxicity necessitates that periods of hyperoxygenation be alternated with periods of lower fraction of inspired O_2 breathing to avoid potentially severe complications [3,24,25,27].

Opinions regarding the optimal hyperbaric regimen for AGE (whether or not dysbaric in origin) have varied in terms of the simulated depth (i.e., pressure) required, recompression time necessary, and inspired gas concentrations used. The time-tested method used by military and commercial diving operations in the United States has been a rapid recompression to 6 ATA (equivalent to the pressure exerted at a depth of 165 ft seawater), followed by periods of intermittent 100% O_2 from a level of 2.8 ATA (pressure equivalent of 65 ft seawater) back to sea level. This treatment regimen is well known as the U.S. Navy Treatment Table 6A and is illustrated in Figure 61.2 and Table 61.5 [3,4,25,27]. Other popular recompression tables in use worldwide include COMEX Table 30 and Royal Navy Tables 71 and 72 [9].

Extensive clinical experience has found no objective benefits to starting recompression at levels greater than 2.8 ATA [4,24,25]. Consensus opinion now recommends that if chamber treatment can be begun within approximately 4 to 6 hours from the time of the incident, then these "early" cases of AGE should undergo therapy following U.S. Navy Table 6A beginning at 6 ATA. The basis for this recommendation is that there may be a benefit in achieving maximal recompression before the occurrence of any significant intravascular bubble–blood interactions, and thereby minimize activation or release of mediators or any arteriolar vasoactivity. In contrast, a delay in hyperbaric therapy of more than 6 hours may allow for maximum endothelial dysfunction and the formation of solid thrombi that would not be expected to respond to any amount of increased ambient pressure. In this latter situation, HBO beginning at 2.8 ATA and following U.S. Navy Treatment Table 6 guidelines (Fig. 61.2, Table 61.5), with extensions as needed, would appear more logical.

Hyperbaric treatment recommendations for DCS are loosely based on the general category of illness patterns described previously [3,4,25,27]. In general, those patients with type I "pain only" DCS are in a more stable medical condition on arrival to a recompression facility; therefore, more time is available to perform a thorough and detailed physical examination before chamber treatment. Particular emphasis should be placed on the neurologic examination so that serial examinations can document the presence of any subtle findings and progress with therapy can be monitored. U.S. Navy Treatment Table 5 (basically a shortened version of U.S. Navy Table 6) is appropriate in this group who presents within 6 hours of reaching the surface and would be expected to achieve resolution of symptoms within 10 minutes of beginning recompression.

It has been suggested that an inadequate response to U.S. Navy Table 5 or the presence of any neurologic abnormality, no matter how subtle, requires initial treatment according to at least U.S. Navy Treatment Table 6. This would allow for more optimal therapy of any developing neurologic deficits, and it would therefore be expected to decrease the overall occurrence of progression to type II DCS. Mild cases of type II DCS may also allow sufficient time for more detailed neurologic examinations to assess the degree of spinal cord or brain involvement. Although these patients are generally reported to respond well to standard therapy with U.S. Navy Treatment Table 6 treatment, severe life-threatening DCS is believed to require immediate treatment following U.S. Navy Treatment Table 6A. In patients who do not respond adequately to standard protocols, extension periods or change to other established protocols might be indicated and decided on an individual basis [3,4,25,27].

Prevention

There are a limited number of time-tested recommendations that can be made in an effort to minimize the occurrence of DCS. These would include (a) following prescribed "no-decompression" limit diving profiles that factor in the duration of time spent at specific depths and duration of surface intervals between repetitive dives; (b) limiting ascent rates from depth to speeds slower than the ascent rate of the diver's exhaled air bubbles; and (c) avoiding any hypobaric insults in the postdive period with no flying for at least 12 hours in all divers, delay

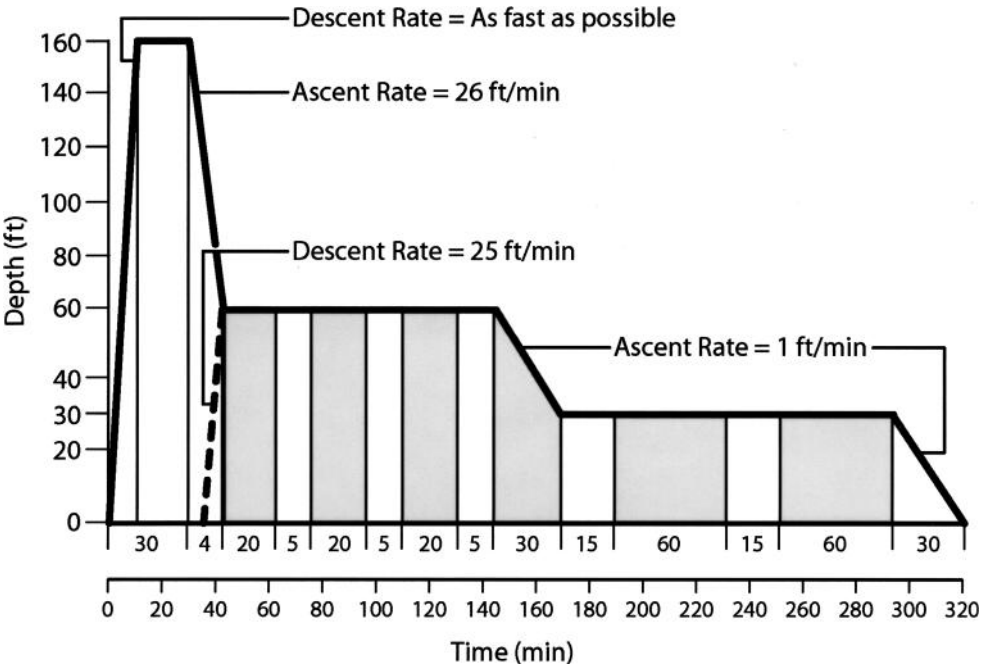

FIGURE 61.2. U.S. Navy Treatment Tables 6 and 6A. Treatment Table 6A is shown in its entirety and is used when symptoms are suspected to be due to arterial gas embolism or severe decompression sickness. Treatment Table 6 is superimposed (starting at *dotted line*) and is seen to begin with a simulated pressure descent on 100% fractional concentration of oxygen to 60 ft at a rate of 25 ft per minute. Thereafter, the tables are the same. Treatment Table 6 is recommended for treatment of type II or type I decompression sickness when symptoms are not relieved within 10 minutes at 60 ft. Nonshaded areas are periods of breathing room air. Shaded areas are periods of breathing 100% fractional concentration of oxygen. Individual time periods are shown first, with total elapsed time indicated underneath. in flying for 24 hours or more if a dive profile included any mandatory decompression stops, and finally, flying should be prohibited for at least 72 hours after recompression therapy has been given to patients with DCS or AGE. As alluded to earlier, hypobaric stresses in these instances may result in new onset of one of these syndromes or in the recurrence of one of these previously treated disorders.

Extensive ongoing research is underway to evaluate the potential preventative roles of predive exercise [28,29], during-dive exercise [30,31], exogenous nitric oxide [29,32,33], predive normobaric O_2 [34], and predive hyperbaric O_2 [35,36]. These preconditioning agents are hypothesized to upregulate endogenous antioxidants, moderate inflammatory injury, and/or inhibit reperfusion injury.

CHAPTER 62 ■ RESPIRATORY ADJUNCT THERAPY

SCOTT E. KOPEC AND RICHARD S. IRWIN

Various adjunct therapies are available to aid in the management of critically ill patients with existing or anticipated pulmonary dysfunction. In this chapter, we review several adjunct therapies, emphasizing any randomized trials determining efficacy and indications. We will specifically discuss the following: (a) aerosol therapy and humidification; (b) lung expansion techniques; (c) airway clearance techniques; (d) administration of medical gases; (e) nasal continuous positive airway pressure (CPAP) and bilevel positive airway pressure for sleep-related breathing disorders; and (f) communication alternatives for the patient with an artificial airway. A discussion of the use of bilevel positive airway pressure to provide noninvasive ventilatory support can be found in Chapter 59.

AEROSOL THERAPY

An *aerosol* is a stable suspension of solid or liquid particles dispersed in air as a fine mist. Bland aerosols are generally used to humidify inspired gases. Aerosol drug therapy represents the optimal modality for site-specific delivery of pharmacologic agents to the lungs in the treatment of a number of acute and chronic pulmonary diseases. Due to the cost and potential hazards of aerosol therapy, use should be limited to aerosols whose clinical value has been objectively shown [1].

Bland Aerosols

Bland aerosols include sterile water or hypotonic, normotonic, and hypertonic saline delivered with or without oxygen. These are typically delivered via an ultrasonic nebulizer in an effort to decrease or aid in the clearance of pulmonary secretions. The routine use of bland aerosols in the treatment of some specific diseases has demonstrated mixed results. An evidence-based recommendation for the use of bland aerosols has recently been released by the British Thoracic Society (BTS) [2]. The use of bland aerosols in the treatment of chronic obstructive pulmonary disease (COPD) and croup appears not to be of any benefit [2,3]. For patients with cystic fibrosis (CF), the use of 7% (hypertonic) saline, administered twice daily, may result in a significantly higher forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV_1), and a decrease in the number of acute exacerbations when compared to the use of normotonic saline [4]. The use of nebulized saline or sterile water may improve sputum clearance in patients with non-CF bronchiectasis [2]. Delivery of bland aerosols is ineffective in liquefying secretions because sufficient volumes of water fail to reach the lower airways. Furthermore, bland aerosols may provoke bronchospasm and place patients at risk for nosocomial pneumonia [3,5].

Mist therapy, the delivery of a continuous aerosol of sterile water or saline, is frequently used to treat upper-airway infections in children, but has not been shown to be more effective than air humidification [3].

Humidity Therapy

Theoretic reasons for using humidified inspired gas are to prevent drying of the upper and lower airways, hydrate dry mucosal surfaces in patients with inflamed upper airways (vocal cords and above), enhance expectoration of lower-airway secretions, and induce sputum expectoration for diagnostic purposes [3]. Although adequate humidification is critical when dry medical gases are administered through an artificial airway (endotracheal or tracheostomy tube), there is little evidence to support the use of humidification in the nonintubated patient.

Humidity therapy is water vapor and, at times, heat added to inspired gas with the goal of achieving near-normal inspiratory conditions when the gas enters the airway [6]. Because adequate levels of humidity and heat are necessary to ensure proper function of the mucociliary transport system, humidification is imperative when the structures of the upper airway that normally warm and humidify inspired gases have been bypassed by an artificial airway. During mechanical ventilation, humidification is crucial to avoid hypothermia, atelectasis, inspissation of airway secretions, and destruction of airway epithelium because of heat loss, moisture loss, and altered pulmonary function [7]. Optimal humidification is the point at which normal conditions that prevail in the respiratory tract are simulated [8].

Several external devices are available to artificially deliver heat and moisture. Two such devices for mechanically ventilated patients are: (a) a heated waterbath humidifier, which is an external *active* source of heat and water, and (b) a heat and moisture exchanger filter (HMEF), which *passively* retains the heat and humidity, leaving the trachea during expiration and recycles it during the next inspiration. HMEFs are also known as *hygroscopic condenser humidifiers* or *artificial noses*. The HMEF is designed to combine air-conditioning and bacterial filtration. In a randomized controlled trial, both devices were shown to be equally safe [9]. Potential advantages of HMEFs over heated waterbath humidifiers include reduced cost and avoidance of airway burns and overhydration. A potential disadvantage is that resistance of airflow through an HMEF may progressively rise, increasing the work of breathing and conceivably impeding weaning from the ventilator [9].

Cold-water devices such as bubble humidifiers are frequently used to add humidity to supplemental oxygen administered to spontaneously breathing patients. Due to a lack of objective evidence to support the practice, the American College of Chest Physicians recommends elimination of the routine use of humidification of oxygen at flow rates of 1 to 4 L per minute when environmental humidity is sufficient [10], while the BTS does not recommend its use [2].

Patients requiring high flow rates of oxygen (>10 L per minute) frequently develop discomfort due to upper-airway dryness. There are several devices available to deliver humidification via nasal cannulae at high flow rates (high flow oxygen delivery), including Vapotherm (Vapotherm, Annapolis, MD) and the Fisher & Paykel 850 (Fisher and Paykel Healthcare Corp, Auckland, New Zealand). Although these devices have been shown to improve patients' comfort [11], we are not aware of any studies determining therapeutic benefits. Potential risk of exposure to *Ralstonia* spp in patients using Vapotherm has been reported [12], but by switching to disposable filters, the problem appears to have been addressed.

Pharmacologically Active Aerosols

Inhaled therapy has several well-recognized advantages over other drug delivery routes. The drug is delivered directly to its targeted site of action; therefore, when compared to other routes of administration, a therapeutic response usually requires fewer drugs, there are fewer side effects, and the onset of action is generally faster [13]. A broad range of drugs is available as aerosols to treat obstructive lung diseases. These include β-adrenergic agonists, anticholinergics, anti-inflammatory agents, and anti-infectives. Additionally, the inhaled route is used to deliver drugs that are not effective when delivered by the oral route (e.g., pentamidine) [14].

Although a variety of drugs are currently available in aerosolized form, dosing to the lung remains inexact because deposition is affected by several patient-, environment-, and equipment-related factors. Potential hazards of aerosol drug therapy include (a) a reaction to the drug being administered, (b) the risk of infection, (c) bronchospasm, and (d) the potential for delivering too much or too little of the drug [14]. With respect to the use of aerosolized ribavirin, there are potential hazards to healthcare providers administering the medication (see later).

Bronchodilators

There are two classes of inhaled bronchodilators: (a) β_2-adrenergic receptor agonists (short-acting and long-acting) and (b) anticholinergic agents.

Short-Acting β_2-Adrenergic Receptor Agonists. Although β_1- and β_2-adrenergic receptors are present in the lungs, β_2-adrenergic receptors appear to be entirely responsible for bronchodilation. Therefore, β_2-adrenergic receptor agonists (e.g., albuterol, pirbuterol, and terbutaline) are the agents commonly preferred for the relief of acute symptoms of bronchospasm. In addition to the bronchodilating properties of β_2-adrenergic receptor agonists, other actions include augmentation of mucociliary clearance; enhancement of vascular integrity; metabolic responses; and inhibition of mediator release from mast cells, basophils, and possibly other cells [3].

Inhalation of β_2-selective agonists is considered first-line therapy for the critically ill asthmatic [15] and COPD patient [5,16]. Although these agents can be administered orally, by inhalation, or parenterally, the inhaled route is generally preferred because fewer side effects occur for any degree of bronchodilation [3]. For most patients experiencing acute asthma attacks, inhalation is at least as effective as the parenteral route [3]. Inhaled β_2 agonists can be delivered as an aerosol from a jet or ultrasonic nebulizer or from a metered-dose inhaler (MDI). The relative efficacies of the nebulizer and MDI are dependent on the adequacy of technique. Although it was formerly a standard practice to deliver bronchodilators by nebulizer, several prospective, randomized controlled trials have challenged this practice. Delivering β_2 agonists by MDI with a spacer device (holding chamber) under the supervision of trained personnel is as effective in the emergency setting as delivery by nebulizer for adults and children [3]. In hospitalized patients, β_2 agonists delivered by MDI are as effective as therapy with a nebulizer and can result in a considerable cost savings [3]. An analysis of 16 trials (686 children and 375 adults) to assess the effects of MDIs with holding chambers compared to nebulizers for the administration of β_2 agonists for acute asthma concluded that MDI with a holding chamber produced at least equivalent outcomes as nebulizer delivery [17].

Ideal frequency of administration and dosing of β_2 agonists has not been determined. For emergency department and hospital-based care of asthma, the National Institutes of Health Expert Panel Report 2 [15] recommends up to three treatments in the first hour. Subsequent treatments should be titrated to the severity of symptoms and the occurrence of adverse side effects, ranging from hourly treatments for moderate severity to hourly or continuous treatments for severe exacerbations. Recommendations for initial treatment of severe acute exacerbations of COPD are for the administration of short-acting β_2 agonists every 2 to 4 hours if tolerated [5].

When given by jet nebulizer, the usual adult dose of albuterol is 0.5 mL of an 0.5% solution (2.5 mg) diluted in 2.5 mL of saline (or 3 mL of 0.083% unit-dose nebulizer solution). The frequency of dosing varies depending on the disease and the situation. It can range from every 4 to 6 hours in patients with COPD and stable asthma to every 20 to 30 minutes for six doses in patients with status asthmaticus [3]. In patients with acute asthma, albuterol solution has also been continuously nebulized for 2 hours [18]. In this randomized controlled trial of spontaneously breathing patients with FEV_1 less than 40% predicted, continuous delivery of high-dose (7.5 mg per hour) or standard-dose (2.5 mg per hour) albuterol were both superior to hourly intermittent treatments with 2.5 mg in increasing FEV_1. Although there was no difference in FEV_1 improvement between the two continuous doses, the standard dose had fewer side effects.

Although the usual dosage of bronchodilator by MDI is two puffs (90 μg per puff) every 4 to 6 hours in stable hospitalized and ambulatory adult patients, the dosage must be increased up to sixfold in acute severe asthma to achieve results equivalent to those achieved with small-volume nebulizers [3]. In an emergency department treatment study of severe asthma, four puffs of albuterol by MDI every 30 minutes for a total of six dosing intervals (24 puffs) was found to be safe and equivalent to 2.5 mg of albuterol diluted in 2 mL of saline given every 30 minutes for six doses [3]. Others have treated acute episodes of asthma in the emergency department in a dose-to-result fashion as follows: initially four puffs by MDI of bronchodilator of choice, followed by one additional puff every minute until the patient subjectively or objectively improved or side effects (e.g., tremor, tachycardia, arrhythmia) occurred [3]. In mechanically ventilated patients, the bronchodilator effect obtained with four puffs (0.4 mg) of albuterol from an MDI with holding chamber is comparable to that obtained with 6 to 12 times the same dose given by a nebulizer and is likely to be more cost-effective [19].

Tremor is the principal side effect of β_2 agonists, due to the direct stimulation of β_2-adrenergic receptors in skeletal muscle. Tachycardia and palpitations are less frequent with the selective β_2 agonists (e.g., albuterol) than with nonselective β_1-β_2 agonists such as isoproterenol. Although vasodilation, reflex tachycardia, and direct stimulation of the heart can occur even with the use of selective β_2 agonists, cardiac adverse occurrences are uncommon when usual doses of inhaled β_2 agonists are administered. A transient decrease in arterial oxygen tension may occur in patients with acute, severe asthma. This response is likely

due to the relaxation of the compensatory vasoconstriction in areas of decreased ventilation together with increased blood flow due to increased cardiac output [3].

β_2-adrenergic agonists can cause acute metabolic responses including hyperglycemia, hypokalemia, and hypomagnesemia [3]. Although typically not seen in standard doses, if large and frequent doses of β agonists are given, electrocardiogram and serum potassium monitoring are indicated. After inhalation of 10- and 20-mg doses, the maximal decreases in potassium can be 0.62 ± 0.09 mmol per L and 0.98 ± 0.14 mmol per L, respectively [20].

Perinatal outcomes of 259 pregnant women with asthma who were treated with β_2-adrenergic agonists during pregnancy were compared to those of 101 women who were not treated with these agents, and 295 nonasthmatic women [3]. There were no differences in perinatal mortality rates, congenital abnormalities, preterm delivery, low birth weights, mean birth weights, or the number of small-for-gestational-age infants. In addition, there were no differences in Apgar scores, labor or delivery complications, or postpartum bleeding.

Levalbuterol (Xopenex, Sepracor Inc, Marlborough, MA) inhalation solution, the (R)-enantiomer of racemic albuterol, is a relatively selective, third-generation β_2-adrenergic receptor agonist approved for treatment of bronchospasm in adults and children aged 12 years or older. Levalbuterol appears to offer little benefit over albuterol in improving FEV_1 in patients with asthma, and is not associated with any fewer systemic side effects such as tachycardia and hypokalemia [21]. For further discussion of aerosolized β agonists in asthma and COPD, see Chapters 48 and 49.

Long-Acting Inhaled β_2 Agonists. Long-acting inhaled β_2 agonists (e.g., salmeterol and formoterol) are currently not recommended for use in acute exacerbations of asthma (Expert Panel Report 2) [15] or COPD [5]. One prospective, double-blind, randomized, placebo-controlled trial demonstrated a possible role for salmeterol as an adjunct to conventional therapy for hospitalized asthmatic patients [22], but larger studies are needed to clarify whether there is a potential benefit in the setting of acute asthma. If patients are using these agents as controller medications for asthma or COPD and are hospitalized for other reasons, consider continuing them for asthma maintenance during the hospitalization. These agents should be administered at regular intervals; additional doses to relieve symptoms should not be prescribed.

Anticholinergics. Anticholinergics appear to have a role in acute asthma when combined with sympathomimetic drugs [3], in exacerbations of COPD when combined with albuterol [5], in intubated patients to prevent bradycardia induced by suctioning [23], and in selected patients with severe bronchorrhea [24]. Ipratropium bromide is dosed at 500 μg in 2.5 mL normal saline (1 unit 0.02% unit-dose vial) or two to six puffs by MDI (18 μg per puff) every 6 to 8 hours. Ipratropium (18 μg per puff) and albuterol (103 μg per puff) are available as a combined MDI product (Combivent, Boehringer, Ingelheim; Ridgefield, CT). Ipratropium by MDI can be given to ventilated patients with the same spacer device used for β-agonist delivery. Tiotropium, a selective muscarinic antagonist, is available in a dry powdered form. Its use should be limited to the chronic management of patients with COPD. For further discussion of anticholinergic use in asthma and COPD, see Chapters 48 and 49.

Combined Bronchodilator Therapy. Although inhaled short-acting β-adrenergic receptor agonists remain first-line agents in the treatment of acute asthma, the addition of ipratropium bromide may result in an added benefit [25]. Anticholinergics may be of benefit as additive agents or as single agents in situations in which the patient cannot tolerate β-adrenergic side effects. Both agents appear effective in smoking-related chronic bronchitis.

Mucolytics

***N*-Acetylcysteine.** Theoretically, mucolytic agents facilitate expectoration of excessive lower-airway secretions and improve lung function [3]. Although *N*-acetylcysteine (Mucomyst, Apothecon, Princeton, NJ), the prototypic mucolytic agent, liquefies inspissated mucous plugs when administered by direct intratracheal instillation [26], it is of questionable clinical use when administered as an aerosol to nonintubated patients because very little of the drug is actually delivered to the lower respiratory tract. Inhaled *N*-acetylcysteine failed to prevent deterioration in lung function or exacerbations in patients with COPD [27], and failed to demonstrate any benefit of nebulized *N*-acetylcysteine in patients with CF [28]. However, a small randomized trial suggested that nebulized *N*-acetylcysteine in combination with aerosolized heparin reduced the incidence of acute lung injury (ALI) and decreased mortality in patients with acute smoke inhalational injuries [29]. Because mucolytic instillations or aerosols can induce bronchospasm in patients with airway disease [30] (especially asthma), mucolytics should be administered to these patients in combination with a bronchodilator [3]. However, given the lack of evidence from randomized trials supporting its benefits, we do not recommend the routine use of aerosolized *N*-acetylcysteine.

Recombinant Human DNase. Recombinant human DNase (Pulmozyme, Genentech, South San Francisco, CA), when given as an aerosol in a dose of 2.5 mg once or twice a day to patients with CF, led to a moderate but significant decrease in dyspnea, a reduction in costs related to exacerbations of respiratory symptoms, and a modest improvement in FEV_1 after 3 months [2]. However, there may not be any statistically significant therapeutic benefit of rhDNase when added to antibiotics and chest physical therapy [31].

Two double-blind, placebo-controlled clinical trials evaluated the safety and efficacy of nebulized rhDNase in the treatment of non-CF–related bronchiectasis [32,33]. In these studies, rhDNase was consistently found ineffective (and possibly harmful [32]) to patients with non-CF–related bronchiectasis.

In a randomized double-blind, placebo-controlled trial of patients with respiratory syncytial virus (RSV) bronchiolitis, significant improvement in chest radiographs occurred with the use of nebulized rhDNase compared to significant worsening in a placebo group. Although further investigation is needed, results of this trial indicate a possible future role for this therapy in the treatment of RSV in infants and young children [34].

Other Mucolytics. Studies to determine the efficacy of other mucolytic agents, including water, have produced conflicting results. Current evidence does not appear to justify their use in clinical practice. Consensus guidelines for asthma [15] and COPD [5] do not recommend the use of mucolytic agents in the treatment of acute exacerbations.

Anti-infectives

Aerosolization of antimicrobial solutions has been shown to be effective in CF patients with tracheobronchial infections and colonization [2]. In addition, inhaled antibiotics have also been used to treat tracheobronchial infections in patients with non-CF–related bronchiectasis, to treat and prevent ventilator-associated pneumonia, to treat chronic bronchitis in patients with COPD, to treat bronchiolitis in children, and to treat patients with multidrug-resistant tuberculosis (MDR-Tb) and mycobacterium avium complex (MAC) [13]. However, unlike their use in treating patients with CF, the benefits of using

inhaled antibiotics for these other indications is less defined. Inhaled tobramycin has been demonstrated to decrease sputum bacteria counts, improve lung function, decrease the number of exacerbations, and improve quality of life in patients with pulmonary infections or colonization from CF [35]. For patients with non-CF–related bronchiectasis, inhaled antibiotics are not as well studied, but may decrease sputum bacteria counts and decrease the number of hospitalizations, but have no impact on lung function or survival [36]. Inhaled antibiotics have not been shown to provide any benefit in patients with chronic bronchitis or COPD [37]. Prophylactic use of inhaled antibiotics to decrease the risk of developing ventilator-associated pneumonia has not been shown to be of any benefit [37]. In addition, inhaled antibiotics appear to have no benefit over systemic antibiotics in treating ventilator-associated pneumonia [37]. A few small studies suggest that inhaled amikacin and rifampicin may be of some benefit in treating severe MDR-Tb and severe infections with MAC [38].

Only tobramycin is currently FDA approved for inhalational use. Other antibiotics occasionally administered via an aerosol include colistin, amikacin, gentamicin, aztreonam, azithromycin, vancomycin, ceftazidime, and imipenem. Inhaled colistin should be used with great caution. Colistin decomposes into several toxic compounds that, if inhaled, can result in acute lung injury and respiratory failure. Colistin suspension should be administered within 6 hours after it is prepared [39].

Inhaled tobramycin is approved for treatment of patients with CF who are (a) at least 6 years of age, (b) have FEV_1 greater than or equal to 25% and less than or equal to 75% predicted, (c) are colonized with *Pseudomonas aeruginosa*, and (d) are able to comply with the prescribed medical regimen [35]. When nebulizing tobramycin, it has been shown that different nebulizers and solutions and techniques may result in very different amounts of tobramycin being inhaled [40]. For example, the addition of albuterol lowered the surface tension of the solution in the nebulizer and resulted in a greater output of tobramycin. A prospective study [41] determined that antibiotics aerosolized by nebulizer could be effectively delivered to tracheostomized, mechanically ventilated patients. In this study, antibiotic concentrations similar to or greater than those achieved in spontaneously breathing individuals were "consistently demonstrated" in patients with a tracheostomy tube.

Aerosolized ribavirin has been used for patients with RSV infection and severe lower respiratory tract disease, or infants with chronic underlying conditions such as cardiac disease, pulmonary disease, or a history of prematurity [3]. However, proof of effectiveness in treating RSV infections is lacking. One study failed to establish the efficacy of inhaled ribavirin in immunocompromised adults with RSV infections [42]. Two prospective double-blind, randomized, placebo-controlled trials addressing the use of aerosolized ribavirin in treating children and adults with respiratory failure from RSV infections failed to show any improvement in length of time requiring mechanical ventilation, length of stay in the intensive care unit, and oxygen requirements or alter immediate outcome [3]. Aerosolized ribavirin has been suggested to be beneficial in treating infections due to influenza A and B [43]. However, a randomized double-blind, placebo-controlled trial found that aerosolized ribavirin only resulted in accelerating normalization of temperature in children with influenza, but had no effect on respiratory rate, pulse rate, cough, or level of consciousness [44].

Ribavirin, in combination with systemic corticosteroids, was used empirically for the treatment of severe acute respiratory syndrome (SARS). However, a review of 14 clinical reports failed to demonstrate that ribavirin decreased the need for mechanical ventilation, or mortality, in patients with SARS [45].

There are several potential hazardous effects of aerosolized ribavirin. It can cause nausea, headaches, and bronchospasm [46]. In addition, it poses potential risks to healthcare workers who administer the medication. It has been shown to cause conjunctivitis as it can precipitate on contact lenses, and bronchospasm in healthcare workers administering the medication [46]. In addition, ribavirin is highly teratogenic. Although studies suggest that absorption of ribavirin by healthcare workers administering the medication is minimal [3], the short-term and long-term risks to women remain unknown. Therefore, conservative safety practices must be followed [3,46]. Given the lack of evidence supporting its efficacy, its known and potential side effects, and the availability of more efficacious treatment options, we do not recommend the use of aerosolized ribavirin in treating infections with RSV. Further studies are needed to determine its efficacy in treating influenza.

Although studies in patients with acquired immunodeficiency syndrome suggest that aerosolized pentamidine can be effective and well tolerated in mild *Pneumocystis jiroveci* pneumonia, it is not recommended for routine clinical practice [47]. Although aerosolized pentamidine has been used with success for primary and secondary *P. jiroveci* pneumonia prophylaxis [47], trimethoprim-sulfamethoxazole has been recommended as the drug of choice for prophylaxis in both situations. Aerosolized pentamidine (300 mg reconstituted with sterile water, administered every 4 weeks), delivered by a Respirgard II nebulizer (Marquest, Englewood, CO), has been approved for *P. jiroveci* pneumonia prophylaxis [47]. A retrospective study suggested that a standard ultrasonic nebulizer (Fisoneb, Fisons, NY) would yield similar effects to Respirgard II, a jet nebulizer, in providing primary and secondary prophylaxis with aerosolized pentamidine [48]. Because toxicity studies on the secondhand effects of aerosolized pentamidine exposure on healthcare personnel are limited [49], conservative safety practices are necessary.

Corticosteroids

At present, there is no indication for the use of inhaled corticosteroids in the treatment of the critically ill with acute exacerbations of obstructive lung disease. Systemic corticosteroids (oral or intravenous) are the recommended first-line agents for the treatment of acute asthma [15] and COPD [5]. Because inhaled corticosteroids are an integral component of asthma therapy, on discharge, they should be used in all patients receiving tapering doses of oral prednisone. They are considered the most effective anti-inflammatory therapy for control of persistent asthma [15]. Inhaled corticosteroids are available as MDIs, dry-powder inhalers, or inhalation suspension (budesonide) for aerosolized use.

When patients are hospitalized for reasons other than acute airway obstruction, inhaled corticosteroids may be continued if patients have been taking these agents for asthma or COPD maintenance therapy. To reduce the risk of oral candidiasis, mouth rinsing and use of a spacer device with MDI are recommended.

Racemic Epinephrine

Racemic epinephrine is effective in decreasing laryngeal edema by causing vasoconstriction [3]. The usual adult dose is 0.5 mL of a 2.25% solution diluted in 3 mL of normal saline every 4 to 6 hours. Because rebound edema frequently occurs, patients must be observed closely. Tachycardia is common during treatment and may precipitate angina in patients with coronary artery disease [3]. The role of racemic epinephrine aerosol in epiglottitis is not known. Similarly, inhaled racemic epinephrine is used to treat postextubation stridor, but this use has not been rigorously studied. Nebulized racemic epinephrine appears to have no benefit over nebulized albuterol in the management of bronchiolitis [50]. Because racemic epinephrine aerosol is associated with potentially serious side effects in

patients with coronary artery disease, administration of inhaled mixtures of helium and oxygen should be considered first to decrease airway resistance and, therefore, the work of breathing associated with laryngeal edema or other upper-airway diseases (see the section Helium-Oxygen [Heliox]).

Aerosolized Vasodilators. Iloprost is an approved inhaled prostacyclin analog used for the chronic treatment of primary pulmonary hypertension and pulmonary hypertension due to use of appetite suppressants, portopulmonary syndrome, connective tissue disease, and chronic thromboembolic disease. It has also been used in patients with acute pulmonary hypertension after coronary bypass surgery, and may be more effective than inhaled nitric oxide [51]. It is currently FDA approved for patients with primary pulmonary hypertension and New York Heart Association (NYHA) class III (symptoms with minimal activity) and class IV (symptoms at rest) symptoms. Iloprost is administered as 2.5 to 5 μg doses, six to nine times per day. It needs to be delivered via a specialized nebulizer system, the Prodose AAD system (Respironics, Murrysville, PA), to ensure proper dosing. A randomized double-blind, placebo-controlled trial demonstrated that iloprost produced improvements in 6-minute walk, hemodynamics, dyspnea, and quality of life after 12 weeks of therapy [52].

Inhaled Cyclosporin. A randomized double-blind, placebo-controlled trial demonstrated improvement in survival and longer periods free of chronic rejection in lung transplant patients treated with inhaled cyclosporin [53]. The patients in the treatment group received 300 mg of aerosolized cyclosporin (Novartis, East Hanover, NJ) three times a week for the first 2 years after lung transplantation, in addition to usual systemic immunosuppression. There was no increase risk of side effects or opportunistic infections in the treated group.

Modes of Delivery

In the critical care setting, there are generally two types of aerosol delivery devices in use: those that create and deliver wet particles (air-jet nebulizers) and those that deliver preformed particles (pressurized MDIs) with or without MDI auxiliary delivery systems (spacers). Patients on mechanical ventilation or patients breathing through a tracheostomy cannot use dry-powder inhalers. Successful aerosol therapy is dependent on the percentage of the drug that is delivered to the lungs. Factors that influence aerosol deposition and effectiveness, such as flow rate, breathing pattern, and incoordination, have been largely overcome with newer and more advanced designs.

Nebulizers

Air-jet nebulizers are a nonpropellant-based option for inhaled drug delivery. Jet nebulizers rely on a high gas flow (provided by a portable compressor, compressed gas cylinder, or 50-psi wall outlet), Venturi orifices, and baffles to generate respirable particles, generally in the range of 1 to 5 μm diameter [3]. Small-volume nebulizers, equipped with small fluid reservoirs, are used for drug delivery [3]. Factors that affect their performance include design, characteristics of the medication, and gas source. Large-volume nebulizers have reservoir volumes greater than 100 mL and can be used to deliver aerosolized solutions over an extended period. Large versions are used to deliver bland aerosols into mist tents.

Nebulizers are frequently used in pediatric and elderly populations as well as in the hospital setting. Nebulizer delivery of aerosolized drugs is indicated when a drug is not available in MDI form and when a patient cannot coordinate the use of an MDI. Disadvantages include the need for a gas flow source, lack of portability, cost, and the risk of bacterial contamination if not properly cleaned [54].

Metered-Dose Inhalers

An MDI is a pressurized canister that contains drug suspended in a propellant and combined with a dispersing agent. The canister is inverted, placed in a plastic actuator, and, when pressed, delivers a metered dose of drug. The MDI is capable of delivering a more concentrated drug aerosol, as a bolus, than the solutions commonly available for nebulizers [3]. Delivery of a therapeutic dose is dependent on the quality of the patient's technique, which requires a slow, deep inhalation followed by a breath hold (approximately 10 seconds). Because this maneuver can be difficult, especially if the patient is experiencing respiratory distress, it is essential that the technique be taught and supervised by trained personnel.

Older MDIs use chlorofluorocarbon propellants (CFCs). Their use has now been phased out after the United Nations passed the 1987 Montreal Protocol that called for the banning of substances that may adversely affect the ozone layer. Although medical devices were initially exempted, many pharmaceutical companies began to formulate alternative preparations and delivery systems. Hydrofluoroalkane-134a (HFA) has been found to be an effective alternative to chlorofluorocarbon propellants. In addition, dry-powder inhalers for long- and short-acting β agonists, corticosteroids, and tiotropium have been developed. Another advantage of the HFA-containing MDIs and the dry-powder inhalers is that lung deposition of the medication appears to be greater when compared to the CFC-containing MDIs.

Metered-Dose Inhaler Auxiliary Devices. To overcome problems such as incorrect administration, oropharyngeal deposition, and inconsistent dosing associated with MDI aerosol delivery, several auxiliary devices (i.e., spacer, holding chamber) were developed [3]. When used properly, these devices have the following advantages: (a) a smaller, more therapeutic particle size is achieved; (b) oropharyngeal impaction is decreased; (c) fewer systemic side effects are experienced due to less oropharyngeal deposition compared to MDI alone; and (d) the risk of oral thrush associated with inhaled corticosteroids is decreased. It has been shown that among patients who have difficulty with coordination—particularly the elderly, handicapped, infants, and children younger than 5 years of age—spacer devices improve the efficacy of MDIs [55].

Choice of Delivery System

Since the development of the first MDI in the 1960s, there has been continuing debate about which aerosol delivery system, nebulizers, or MDI is superior. In 1997, Turner et al. [56] published a meta-analysis of 12 studies that compared bronchodilator delivery via nebulizer to delivery via MDI. Studies included in the review were all randomized clinical trials of adults with acute asthma or COPD who were treated in the emergency department or hospital and measured FEV_1 or peak expiratory flow rate. In all but two of the trials, spacers were used with MDIs. Based on the results of these studies, the authors concluded that there was no difference in effectiveness between the two delivery methods.

A Cochrane Library meta-analysis by Cates et al. [17] compared the clinical outcomes of adults and children with acute asthma who received β_2 agonists by nebulizer or MDI with spacer. In this review that included 16 randomized controlled trials, the authors concluded that the outcomes (hospital admission, length of stay in the emergency department, respiratory rate, heart rate, arterial blood gases, tremor and lung function) of both groups were equivalent.

In the United States, MDIs are underused in the acute care setting [3]. Barriers to selection of these devices include reimbursement issues and the misconception of clinicians regarding efficacy. Many third-party payors reimburse for the nebulizer/drug package but not for the MDI. In the critical care setting, selection of an aerosol delivery system for the spontaneously breathing patients should be based on several factors. In general, because the MDI with or without spacer is the most convenient and cost-effective method of delivery, it should be chosen whenever possible. Its use may be limited by factors such as the patient's ability to actuate and coordinate the device, either of which can affect aerosol deposition to the lungs; patient preference; practice situations; and economic evaluations. Additionally, parenchymal dosing with drugs such as pentamidine and ribavirin requires the use of a nebulizer [3]. Cost considerations may determine which delivery system is chosen in different settings. Studies show that use of MDIs with spacers likely produce considerable reductions in hospital costs [57]. The cost of a disposable nebulizer system in a hospital setting may be lower than the cost of a MDI and spacer device if patients are discharged with a second spacer device [17].

Aerosols can be delivered to intubated and mechanically ventilated patients with small-volume side-stream nebulizers connected to the inspiratory tubing or MDIs with an aerosol holding chamber. Although both delivery systems are effective in delivering aerosolized medications to the ventilated patient [3], drug delivery can be significantly reduced if proper technique in setting up and using both devices is not followed.

LUNG-EXPANSION TECHNIQUES

A *lung-expansion technique* is any technique that increases lung volume or assists the patient in increasing lung volume above that reached at his or her usual unassisted or uncoached inspiration. Rationales for the use of various strategies to promote lung inflation include (a) increasing pulmonary compliance, (b) increasing partial arterial pressure of oxygen (PaO_2), (c) decreasing work of breathing, and (d) increasing removal of secretions [58]. Lung-expansion techniques are meant to duplicate a normal sigh maneuver. Theoretically, sighs or periodic hyperinflations to near-total lung capacity reverse microatelectasis [3].

Lung-expansion techniques are indicated to prevent atelectasis and pneumonia in patients who cannot or will not take periodic hyperinflations [3], such as postoperative upper-abdominal and thoracic surgical patients and patients with respiratory disorders due to neuromuscular and chest wall diseases. Adequately performed, maximum inspirations 10 times each hour while awake significantly decrease the incidence of pulmonary complications after laparotomy [59]. Whatever technique is used postoperatively (e.g., coached sustained maximal inspiration with cough, incentive spirometry, volume-oriented intermittent positive-pressure breathing, intermittent CPAP, or positive expiratory pressure [PEP] mask therapy [60]), it should be taught and practiced preoperatively. When properly used, coached sustained maximal inspiration with cough and incentive spirometry—the least expensive and safest techniques—are as effective as any other method [61]. Of the several commercially available incentive spirometers, the one chosen should combine accuracy, low price, and maximum patient accessibility [62]. Because there are no definitive studies comparing the relative efficacy of volume- and flow-oriented incentive spirometers, the choice of equipment must be based on empiric assessment of patient acceptance, ease of use, and cost. When chest percussion with postural drainage is added to the previously mentioned expansion techniques in patients without prior lung disease, it has failed to affect the incidence of postoperative pulmonary complications [63].

AIRWAY CLEARANCE

Efficient mucociliary clearance and effective cough are the two basic processes necessary for normal clearance of the airways. In abnormal situations, this system may be dysfunctional and lead to mucus retention. Recently both the ACCP [64] and the BTS [2] have published evidence-based guidelines reviewing both pharmacological and nonpharmacological methods of augmenting pulmonary clearance. Both guidelines are complete reviews on this topic. A summarized discussion of techniques aimed at enhancing airway clearance follows.

Augmentation of Mucociliary Clearance

Mucociliary clearance is one of the most important defense mechanisms of the respiratory system. Mucociliary dysfunction is any defect in the ciliary and secretory elements of mucociliary interaction that disturbs the normal defenses of the airway epithelium [65]. Ineffective mucociliary clearance leads to retention of tracheobronchial secretions. Mucociliary clearance may be ineffective because of depression of the clearance mechanisms or oversecretion in the face of normal mucous transport, or both. Mucus is ineffectively cleared and overproduced in smokers with or without chronic bronchitis and in asthmatic patients [3]. It is also ineffectively cleared in the following situations: (a) in patients with emphysema, bronchiectasis, and CF; (b) during and up to 4 to 6 weeks after viral upper respiratory tract infections; (c) during and for an unknown period after general anesthesia due to the inhalation of dry gas and cuffed endotracheal tubes used during surgery; and (d) during prolonged endotracheal intubation due to the presence of the cuffed tube, administration of elevated concentrations of inspired oxygen, and damage to the tracheobronchial tree from suctioning [3]. The most important consideration in improving mucociliary clearance is to remove the inciting cause(s) of ineffective clearance and overproduction of secretions.

Treatment

Mucociliary clearance can be enhanced pharmacologically and mechanically. Numerous drugs with potential mucociliary effect have been studied, but only a few are clinically useful. Pharmaceutical therapy is frequently used in conjunction with physical therapy.

Pharmacologic Augmentation. β agonists and aminophylline stimulate mucociliary clearance [3]. These drugs should be given in the same dose as given for bronchodilatation. Mucolytics and expectorants (e.g., potassium iodide, glyceryl guaiacolate, guaifenesin, ammonium chloride, creosote, and cocillana) have not been shown to increase mucociliary clearance [3]. There is no evidence to support the use of mucokinetic agents in COPD exacerbations [5]. In a randomized controlled trail, healthy volunteers and patients with mild asthma showed no improved mucociliary clearance when given inhaled furosemide [66].

In vitro studies have demonstrated that corticosteroids reduce mucous secretion from human airway cells [67], and the use of inhaled corticosteroids has been recommended in the management of bronchorrhea (i.e., mucus secretions of more than 100 mL per day) [68]. However, we know of no randomized controlled trials demonstrating the benefit of inhaled corticosteroids in the management of bronchorrhea.

Mechanical Augmentation

Chest physiotherapy (CPT). Usually, chest physiotherapy involves (a) gravity (therapeutic positioning), (b) percussion to the chest wall over the affected area, (c) vibration of the chest wall during expiration, and (d) coughing. Coughing appears to be the most important component of CPT (see the section Augmentation of Cough Effectiveness). It is felt to be beneficial in patients with CF and bronchiectasis, in the unusual COPD patient who expectorates more than 30 mL of sputum each day [64], and in patients with lobar atelectasis [2]. It is not indicated in asthmatic patients [64] or in those with uncomplicated pneumonias [2]. CPT does not improve FEV_1, provides only modest short-term effects, and long-term benefits are unproven [64]. In patients with COPD, alternative methods of airway clearance (see below) have not proven more effective than CPT, and the effects of CPT itself on patients with COPD may be minimal [69].

Complications of CPT are infrequent yet potentially severe [70]. They include massive pulmonary hemorrhage (perhaps caused by clots dislodged during percussion), decreased PaO_2 from positioning the "good" lung up in spontaneously breathing patients, rib fractures, increased intracranial pressure, decreased cardiac output, and decreased FEV_1.

Oscillatory devices. These devices include the flutter device (Varioraw SARL, Scandipharm Inc, Birmingham, AL), intrapulmonary percussive ventilation (Percussionator, IPV-1; Percussionaire, Sand Point, ID), and high-frequency chest wall oscillation. The flutter mucus clearance device is a small, handheld, pipe-like device used to facilitate the removal of mucus from the lungs. As patients exhale through the device, a steel ball rolls and bounces, producing vibrations that are transmitted throughout the airways. It is postulated that vibrations of the airways intermittently increase endobronchial pressure and accelerate expiratory airflow, thereby enhancing mucus clearance [71]. In a randomized controlled trial, the flutter device was compared to standard, manual chest therapy in hospitalized CF patients experiencing an acute exacerbation [72] and found to be a safe, efficacious, and cost-effective alternative to standard, manual chest percussion. Konstan et al. [71] compared periods of vigorous voluntary cough, postural drainage, and flutter-valve treatment. Among the therapies compared, the volume of sputum was three times greater with the flutter treatment. Although larger clinical trials are needed, it appears to be a useful device for self-administration of CPT and as an equal alternative to CPT [64].

Intrapulmonary percussive ventilation uses short bursts of air at 200 to 300 cycles per minute, along with entrained aerosols delivered via a mouthpiece [64]. In a study on patients with CF, this was found to be equal to chest physiotherapy [73]. A small study suggested that high-frequency chest well oscillation decreased breathlessness and fatigue in patients with ALS [74]. High-frequency chest wall oscillation delivered through an inflatable vest appears to offer no benefit over standard CPT [3].

PEP mask. In PEP therapy, a mask is applied tightly over the mouth and nose, and a variable-flow resistor is adjusted to achieve PEP during exhalation between 5 and 20 cm H_2O. This, combined with "huff" coughing, allows mobilization of peripherally located secretions upward into larger airways. A Cochrane review of 20 studies in patients with CF failed to demonstrate that PEP had any short-term benefits over CPT [75].

Mechanical insufflation–exsufflation. Mechanical insufflation–exsufflation (cough in-exsufflator) increases the volume inhaled during the inspiratory phase of cough, thereby increasing cough effectiveness [64]. Cough efficiency can be further enhanced by applying negative airway pressure for 1 to 3 seconds after the initial inspiration. This method appears to be most beneficial in patients with impaired cough due to neuromuscular disease [76].

In summary, the data available, although not abundant, indicate that in patients with copious secretions, clearance of secretions can be enhanced with selected physical therapy procedures. Although these modalities appear to increase expectoration of mucus, it is not clear what clinical benefit this achieves. There is no information about the influence of physical therapy maneuvers on healthcare outcomes, including frequency of hospitalization, hospital length of stay, longevity, and quality of life. It is clear that these techniques are well entrenched in the management of patients with mucus hypersecretion, especially those with CF; it is time for us to prove that they lead to clinically important outcomes. Evidence-based guidelines for the use of these modalities can be found elsewhere [2,64].

Suctioning. Although mechanical aspiration or suctioning is routine in most hospitals, many are unaware of the numerous potential complications associated with suctioning, such as tissue trauma, laryngospasm, bronchospasm, hypoxemia, cardiac arrhythmias, respiratory arrest, cardiac arrest, atelectasis, pneumonia, misdirection of catheter, and death [3]. Complications are generally avoidable or reversible if proper technique and indications are adhered to strictly.

Endotracheal. Endotracheal suctioning is performed in patients with an artificial tracheal airway in place. It should be used only when there is definite evidence of excessive retained secretions. Routine suctioning according to a predetermined schedule may cause excessive mucosal tissue damage, excessive impairment of mucociliary clearance, unnecessary exposure to the potential risks of hypoxemia associated with the procedure, arrhythmias, atelectasis, and bronchoconstriction [3]. Endotracheal suctioning is indicated when there is a need to (a) remove accumulated secretions, (b) obtain a sputum specimen for microbiological or cytologic examination, (c) maintain the patency and integrity of the artificial airway, and (d) stimulate cough in patients with ineffective cough [77].

Suction catheters are generally 22 in. long (adequate in length to reach the main stem bronchus) and sized in French units. Most have a side port to minimize mucosal damage. To avoid obstruction of the artificial airway, the outer diameter of the suction catheter should be less than half the size of the internal diameter of the endotracheal tube [rule of thumb: multiply the inner diameter of the endotracheal tube by 2 and use next smallest size (e.g., 8.0-mm endotracheal tube: $2 \times 8 = 16$, choose next smallest size = 14 French)] [78].

For patients receiving ventilatory support, closed, multiuse systems that are incorporated into the ventilator circuit are available. Because patients remain connected to the ventilator during suctioning, positive end-expiratory pressure (PEEP) and high fractional inspiration of oxygen (FIO_2) can be maintained, reducing the risk of hypoxemia. Preoxygenation with 100% O_2 is still necessary. The use of closed, multiuse systems may reduce cost and the risk of cross-contamination. However, these systems may increase tension on the tracheal tube and add resistance to the airway.

The practice of instilling normal saline into the airway before suctioning to aid secretion removal is common, but it is unclear whether it is effective and it may increase the risk of nosocomial pneumonia. The routine use of saline irrigation is not recommended [78].

Nasotracheal. While nasotracheal suctioning may be considered in patients who do not have an artificial tracheal airway, it is not recommended because of the potential side effects,

and there are other, safer alternatives. It is rarely indicated because CPT can be used in conscious patients, and semicomatose or comatose patients with retained secretions can be intubated. Nasotracheal suctioning has been associated with fatal cardiac arrest, life-threatening arrhythmias presumably due to hypoxemia, and bacteremia [3]. Because quantitative cultures acquired with plugged telescoping catheters at bronchoscopy can be obtained more safely and are definitely more reliable than nasotracheal suction (see Chapter 9) in obtaining uncontaminated lower respiratory tract secretions for culture, nasotracheal suction is not recommended for this purpose.

Nasopharyngeal. Nasopharyngeal suctioning is indicated to clear the upper airway. Because the catheter does not reach the vocal cords or enter the trachea, nasopharyngeal suctioning is associated with fewer complications than nasotracheal suctioning [3]. The catheter should not touch or go beyond the vocal cords. This requires insertion to a depth that corresponds to the distance between the middle of the patient's chin and the angle of the jaw, just below the earlobe.

Endotracheal extubation. Before removal of the endotracheal tube, perform nasopharyngeal and oropharyngeal suctioning to clear secretions that have pooled above the vocal cords for the inflated cuff. Replace the catheter and perform endotracheal suctioning. In preparation for deflating the cuff, place the endotracheal suction catheter tip just distal to the endotracheal tube to aspirate any secretions that gravitate downward when the cuff is deflated. Deflate the cuff and intermittently suction while removing the tube and catheter as a unit.

Augmentation of Cough Effectiveness

Although mucociliary transport is the major method of clearing the airway in healthy subjects, cough is an important reserve mechanism, especially in lung disease [3]. All studies suggest that cough is effective in clearing secretions only if secretions are excessive.

Pathophysiology of Ineffective Cough

The effectiveness of cough in clearing an airway theoretically depends on the presence of secretions of sufficient thickness to be affected by two-phase, gas-liquid flow and the linear velocity of air moving through its lumen [3]. The ineffectiveness of voluntary coughing in normal subjects to clear tagged aerosol particles in the lower airways is probably due to the inability of the moving airstream to interact appropriately with the normally thin mucus layer on which the particles were deposited [3]. Once there is sufficiently thick material in the airways, the effectiveness of cough depends on achieving a high flow rate of air and a small cross-sectional area of the airway during the expiratory phase of cough to achieve a high linear velocity (velocity equals flow/cross-sectional area); therefore, any condition associated with decreased expiratory flow rates or reduced ability to compress airways dynamically places affected patients at risk of having an ineffective cough.

All conditions that may lead to an ineffective cough interfere with the inspiratory or expiratory phases of cough; most conditions affect both. Cough effectiveness is likely to be most impaired in patients with respiratory muscle weakness because their ability to take in a deep breath in (flow rates are highest at high lung volumes) and to compress their airways dynamically during expiration are impaired, placing them at double liability. The muscles of expiration appear to be the most important determinant in producing elevated intrathoracic pressures, and they are capable of doing so even with an endotracheal tube in place [3]. Therefore, tracheostomy should not be performed in the intubated patient just to increase cough effectiveness.

Assessment of Cough Effectiveness

Ideally, clinicians would like to predict clinically or physiologically when a patient is at risk of developing atelectasis, pneumonia, or gas-exchange abnormalities because of an ineffective cough. There are no such studies, however. The existing data that relate to assessment of cough effectiveness were generated in patients with muscular dystrophy and myasthenia gravis [3,79]. These studies suggested that mouth maximum expiratory pressure (MEP) measurements may be useful for assessing cough strength, but they did not correlate these measurements with any clinical outcomes. Using the absence of peak flow transients (i.e., a spike of flow with a cough to the otherwise sustained maximal expiratory flow) during cough flow–volume curves as an indication that expiratory muscle strength during coughing was not adequate to compress the airways dynamically, investigators found that MEP was the most sensitive predictor of flow transient production during coughing [3]. All patients who could produce cough transients had MEP values greater than 60 cm H_2O; those who could not produce transients had MEP values of 45 cm H_2O or less. This latter value is consistent with the clinical observations of Gracey et al. [79], who found in patients with myasthenia gravis that MEP values less than 40 cm H_2O were frequently associated with difficulty in raising secretions without suctioning.

Bach and Saporito [80] prospectively evaluated measurement of peak cough flows (PCF) (assisted and unassisted) as a predictor of successful extubation and decannulation in 49 patients with primary neuromuscular ventilatory insufficiency. In this study, the ability to generate at least 160 L per minute of PCF (measured with Peak Flow Meter, HealthScan Inc, Cedar Grove, NJ) resulted in successful extubation or decannulation, whereas no patients with PCFs under 160 L per minute were successfully extubated or decannulated. The authors concluded that the assisted PCF could be used to predict the ability to safely extubate or decannulate patients with neuromuscular disease regardless of the extent of ventilatory insufficiency.

Protussive Therapy

When cough is useful yet inadequate, protussive therapy is indicated (e.g., bronchiectasis, CF, pneumonia, postoperative atelectasis) [3]. The goal of protussive therapy is to increase cough effectiveness with or without increasing cough frequency. It can be of a pharmaceutical or mechanical nature.

Only a small number of pharmacologic agents have been adequately evaluated as protussive agents [81]. Of these, aerosolized hypertonic saline in patients with chronic bronchitis and amiloride aerosol in patients with CF have been shown to improve cough clearance [81,82]. Although aerosolized ipratropium bromide diminished the effectiveness of cough for clearing radiolabeled particles from the airways in COPD, aerosolized terbutaline after CPT significantly increased cough clearance in patients with bronchiectasis [3]. The conflicting results with these two types of bronchodilators suggest that terbutaline achieved its favorable effect by increasing hydration of mucus or enhancing ciliary beating, and these overcame any negative effects that bronchodilation had on cough clearance. If bronchodilators result in too much smooth muscle relaxation of large airways, flow rates can actually decrease even in healthy individuals when more compliant large airways narrow too much because they cannot withstand dynamic compression during forced expirations [3]. Although hypertonic saline, amiloride, and terbutaline by aerosol after CPT have been shown to increase cough clearance, their clinical use remains to be determined in future studies

that assess short-term and long-term effects of these agents on the patient's condition.

Expiratory Muscle Training

Because expiratory muscle weakness diminishes cough, strengthening the muscles may improve cough effectiveness. In quadriplegic subjects, there was a 46% increase in expiratory reserve volume after a 6-week period of isometric training to increase the clavicular portion of the pectoralis major [83]. This technique may improve cough by allowing patients with neuromuscular weakness to generate higher intrathoracic pressures [3].

Mechanical Measures

A variety of mechanical measures have been advocated as possible therapies to improve cough effectiveness [3], including (a) positive mechanical insufflation, followed by (b) manual compression of the lower thorax and abdomen in quadriparetic patients (an abdominal push maneuver that assists expiratory efforts in patients with spinal cord injuries), (c) mechanical insufflation–exsufflation, (d) abdominal binding and muscle training of the clavicular portion of the pectoralis major in tetraplegic patients, and (e) CPT in patients with chronic bronchitis. The usefulness of the first four measures in improving clinical outcomes has yet to be studied, and in patients with CF, one technique does not appear to be superior to the others [3]. In patients with chronic bronchitis, the combination of short bouts of PEP breathing, forced expirations, and CPT resulted in reduced coughing, less mucus production, and fewer acute exacerbations compared with patients who received CPT alone. Except in patients with CF, there is no clear benefit of combining CPT with coughing over vigorous coughing alone [64].

The effect of deep lung insufflation on maximum insufflation capacities and peak cough flows for patients with neuromuscular disease was investigated [84]. In this study, the authors concluded that with training, the capacity to stack air to deep insufflations can be enhanced despite neuromuscular weakness, and this can result in increased cough effectiveness.

ADMINISTRATION OF MEDICAL GASES

Oxygen Therapy

Indications for Oxygen Therapy

In the acute setting, administration of supplemental oxygen is indicated for (a) acute respiratory failure (hypoxemic and hypercapnic), (b) acute myocardial infarction (MI), (c) acute asthma, (d) normoxemic hypoxia (states characterized by the potential or actual documentation of tissue hypoxia despite a normal PaO_2 such as carbon monoxide poisoning), (e) the perioperative and postoperative states, and (f) cluster headaches [3,85–87]. Additionally, oxygen should be administered empirically in cases of cardiac or respiratory arrest, respiratory distress, hypotension [88], shock, and severe trauma [85].

A dosage sufficient to correct the hypoxemia should be prescribed. The goal of oxygen therapy is to correct hypoxemia to a PaO_2 greater than 60 mm Hg or arterial oxygen saturation (SaO_2) greater than 90%. Due to the shape of the oxyhemoglobin dissociation curve, there is little benefit from increasing the PaO_2 to values much greater than 60 mm Hg, and in some cases, it may increase the risk, albeit small, of CO_2 retention [5].

Clinicians are cautioned regarding the haphazard use of oxygen, as there are potential complications associated with the administration of supplemental oxygen, particularly at high concentrations (i.e., FIO_2 >0.50). Oxygen therapy should not be used in place of but in addition to mechanical ventilation when ventilatory support is indicated [85].

Respiratory Failure. Oxygen therapy is used in acute pulmonary conditions to prevent tissue hypoxia and the serious and often irreversible effects on vital organ function that can result from untreated hypoxemia. In the absence of hypercarbia, the risk of worsening alveolar hypoventilation with the administration of supplemental oxygen is essentially nonexistent. Even in patients with chronic hypercapnic respiratory failure, the administration of supplemental oxygen to achieve a PaO_2 of approximately 60 mm Hg is associated with only a small risk of worsening hypercapnia. The mechanism by which oxygen administration results in CO_2 elevation in patients with COPD is multifactorial. It cannot be explained solely by the effect of oxygen on ventilatory drives. It may also be due to an oxygen-induced increase in dead space resulting from relaxation of hypoxic vasoconstriction, and it also requires the presence of other respiratory abnormalities preventing compensatory hyperventilation [3]. Furthermore, in acute situations in which supplemental oxygen is necessary to maintain adequate tissue oxygenation, it should not be withheld even if there is a risk that ventilatory support may be required. Care should be taken, however, to avoid the administration of excessively rich oxygen mixtures. See Chapter 49 for further discussion of oxygen therapy in COPD.

Acute Myocardial Infarction Without Respiratory Failure. Based on studies demonstrating that breathing enriched oxygen mixtures limited infarct size in animals, it has become common practice to administer oxygen to patients suspected of experiencing ischemic-type chest discomfort [85]. Therefore, administration of supplemental oxygen, usually by nasal cannula, is recommended in the setting of acute ischemic-type chest discomfort. If SaO_2 is monitored, oxygen should be administered when the saturation is less than 90% [89]. The rationale for its use is based on the observation that even with uncomplicated MI, patients may be somewhat hypoxemic initially, probably due to ventilation-perfusion mismatch and excessive lung water [90].

Because nitroglycerin dilates the pulmonary vascular bed and increases ventilation-perfusion abnormalities, supplemental oxygen is recommended in the initial hours for all patients suspected of having an acute MI. Experimental studies have shown that supplemental oxygen may limit ischemic myocardial injury [91] and reduce ST-segment elevation in patients experiencing MI [92]. There appears to be little justification for continuing its routine use beyond 2 to 3 hours [89]. Whether it is of value to give concentrations greater than 40% is unclear. In the setting of MI complicated by left ventricular failure, arrhythmias, or pneumonia, the appropriate oxygen concentration should be determined by monitoring of the PaO_2 or SaO_2 [85].

Acute Asthma. Supplemental oxygen protects against hypoxemia resulting from pulmonary vasodilation induced by β agonists and minimizes hypoxemia-induced vasoconstriction [93]. Normal levels of oxygen (normoxia) may protect against cardiac arrhythmias and may also help oxygen delivery to peripheral tissues [3].

Supplemental oxygen is recommended for patients with hypoxemia and for patients with FEV_1 or peak expiratory flow less than 50% of the predicted value during an acute attack when arterial oxygen monitoring is not available. The Expert Panel Report 2 recommends oxygen administered via

nasal cannula or mask to maintain an SaO_2 greater than 90% (greater than 95% in pregnant women and in patients with a history of heart disease) [15]. SaO_2 monitoring should continue until a definite response to bronchodilatory therapy occurs.

Normoxemic Hypoxia. *Normoxemic hypoxia* encompasses conditions that are characterized by the potential or actual documentation of tissue hypoxia but with a normal PaO_2 [85,94]. Tissue hypoxia occurs as a result of abnormalities in the function of hemoglobin or deficient delivery or use of oxygen by the tissues, or both. Examples of such conditions include acute anemia, carboxyhemoglobinemia (perhaps the most lethal), and homozygous sickle-cell crisis.

Recommendations for the use of supplemental oxygen for normoxemic hypoxic conditions are outlined as follows:

1. *Acute anemia*. Although the definitive treatment is sufficient blood replacement, supplemental oxygen is a reasonable temporizing measure.
2. *Carboxyhemoglobinemia* (carbon monoxide [CO] poisoning) [3]. Because a partial pressure of CO of less than 1 mm Hg can saturate 50% of hemoglobin and not interfere with lung function, measurements of oxygen tension are not useful in predicting the presence of CO poisoning or in directing oxygen therapy. Carboxyhemoglobin levels must be measured to detect CO poisoning. Administration of high concentrations of inspiratory oxygen is important in treating CO poisoning for two reasons: a higher amount of oxygen may be placed in the solution in the blood to supplement the oxygen already present, and a high PaO_2 accelerates the dissociation of CO from hemoglobin. In the absence of hyperbaric oxygen, a nonrebreathing mask driven by pure humidified oxygen is the treatment of choice. This should be given immediately and without interruption until it is verified that carboxyhemoglobinemia has fallen to less than 5%. Although hyperbaric oxygenation represents a potentially, albeit controversial, more effective alternative, it is not readily available to most patients. If it is available, patients with carboxyhemoglobin levels greater than 40% or with cardiac or neurologic symptoms should be considered for immediate transportation to the hyperbaric oxygen facility for treatment. (See Chapter 64 for further discussion of CO poisoning.)
3. *Sickle-cell crisis*. The role of oxygen therapy in sickle-cell crisis is unknown [95]. Because deoxygenation makes cells sickle, however, it seems reasonable to give supplemental oxygen in this setting. Because of the risk of oxygen toxicity, concentrations in excess of 50% should not be given for more than 48 hours.
4. *Cluster headache* [87,96]. A recent randomized placebo-controlled trial demonstrated that 100% oxygen delivered at a flow rate of 12 L per minute via a full-face mask can significantly reduce pain from cluster headaches within 15 minutes [87]. Oxygen inhalation's mechanism of action is unknown.

Prevention of Surgical Wound Infections. The perioperative administration of supplemental oxygen appears to be advantageous in reducing the incidence of postoperative surgical wound infections. In two randomized prospective, double-blind clinical trials of patients who underwent elective colorectal surgery, patients received either 80% or 30% supplemental oxygen during the perioperative period and for 2 hours or 6 hours postoperatively [97,98]. Supplemental oxygen was given regardless of the patient's SaO_2. The incidences of surgical wound infections were 5.2% [97] and 14.9% [98] in patients who received 80% oxygen, compared to 11.2% [97] and 24.4% [98] in the group who received 30% oxygen.

Postoperative State. An increase in the alveolar-arterial partial pressure of oxygen (PO_2) gradient and a decrease in the functional residual capacity are common perioperatively and postoperatively. Ventilation-perfusion abnormalities and intrapulmonary shunting may occur, and while generally corrected within the first few hours after most types of peripheral surgery, it may be more significant in the elderly, the obese, in patients with preexisting cardiopulmonary conditions, and after surgery of the upper abdomen and thorax. In these situations, PaO_2 may not normalize until postoperative day 2. Because the PaO_2 usually increases with the administration of supplemental oxygen, low concentrations of supplemental oxygen should be administered to those at risk of postoperative hypoxemia [99]. In some cases, lung-expansion maneuvers may be necessary if oxygen fails to correct the PaO_2 [84].

Oxygen Delivery Systems

In the acute setting, bulk supply systems are used as a relatively inexpensive means of oxygen delivery. When transporting hospitalized patients, gas cylinders and liquid tanks are used.

Oxygen Delivery Devices

A variety of devices are available to deliver supplemental oxygen. Selection should be based on the amount of oxygen the system can deliver and its clinical performance. Factors capable of affecting performance include the type of device chosen, flow rates used by the device, the fit of the device, respiratory rate, inspiratory flows, and tidal volumes. Types of devices are as follows:

1. Standard dual-prong nasal cannulas are the most commonly used oxygen delivery devices for administering low-flow oxygen. Flow rates of 0.5 to 1.0 L per minute by nasal prongs approximate an inspired oxygen concentration of 0.24, and a rate of 2 L per minute approximates 0.28. Nasal cannulas are easy to use, relatively comfortable, fairly unobtrusive, do not interfere with eating or talking, and relatively inexpensive. Generally, it is unnecessary to humidify oxygen administered by nasal cannulae at flow rates of 4 L per minute or less [85,86].
2. Simple oxygen masks deliver FIO_2 of approximately 0.35 to 0.50 oxygen with flow rates of 5 L per minute or greater. Because nasal cannulas and simple oxygen masks deliver an overlapping range of FIO_2, the nasal cannulas should be used unless the nares are unavailable or prone to irritation from the cannula. Face masks must be removed when eating and drinking, and caution should always be exercised in using oxygen face masks on sedated, obtunded, or restrained patients. Because these masks have a reservoir of 100 to 200 mL, there is a risk of rebreathing CO_2. For this reason, flow rates of at least 5 L per minute are recommended. Because relatively high flow rates are needed with simple masks, they are generally not appropriate for the delivery of a low FIO_2 (i.e., less than 0.30 to 0.35) [85].
3. Masks with reservoir bags, nonrebreathing and partial-rebreathing oxygen masks, can deliver a high FIO_2 (>0.50) with oxygen flowing into the reservoir at 8 to 10 L per minute to partially inflate the reservoir bag throughout inspiration. They are designed to deliver short-term high FIO_2 in situations when hypoxemia is suspected [100]. After the patient has been stabilized, if a high FIO_2 is required, a fixed performance device with a known FIO_2 should be substituted. Theoretically, the partial-rebreathing mask should deliver an FIO_2 of approximately 0.60, and the nonrebreathing mask should deliver 1.00. For the nonrebreathing mask to deliver an FIO_2 of 1.00, however, a tight-fitting mask is required so that, in clinical practice, both masks function similarly.

4. If an accurate FIO_2 is required, a Venturi-type mask can be used. Supplied by high oxygen flows, it maintains a fixed ratio of oxygen to room air so that the FIO_2 remains constant. These masks can deliver oxygen concentrations to the trachea of up to 0.50. FIO_2 settings are typically 0.24, 0.28, 0.31, 0.35, 0.40, and 0.50.

Oxygen-Conserving Devices

Several devices have been developed to improve the efficacy of oxygen delivery. Three such methods are reservoir cannulas [101], demand-pulse oxygen delivery, and transtracheal catheters [3].

1. The reservoir nasal cannula stores 20 mL of oxygen during exhalation and delivers this oxygen as a bolus at the start of inspiration.
2. Electronic demand devices deliver a pulse of oxygen during early inspiration rather than continuously throughout the ventilatory cycle.
3. Transtracheal catheters bypass the anatomic dead space, and oxygen is delivered directly into the trachea using the central airways as a reservoir for oxygen during end-expiration [3]. When caring for patients with transtracheal catheters in place before admission to the hospital, it is important to secure them with tape or sutures to prevent accidental dislodging. There is no need to remove the catheter before or during endotracheal intubation. While the patient is intubated, however, the transtracheal catheter should be capped.

Patients receiving transtracheal oxygen are at risk of developing inspissated secretions, mucus airway casts, and mucus balls, especially when the transtracheally delivered gas is not adequately humidified. Consequently, whenever a patient receiving transtracheal oxygen develops worsening hypoxemia or respiratory distress, mucus obstruction of the airway should be considered. In this setting, oxygen should be administered via nasal cannula and the transtracheal catheter removed. This maneuver can often shear off a mucus ball attached to the end of the catheter, allowing the patient to expectorate the accumulated mucus, and thereby improve the hypoxemia and eliminate the respiratory distress. The catheter can then be cleaned and reinserted with provision for adequate humidification of the transtracheally delivered gas. Transtracheal air and oxygen mixtures as therapy for obstructive sleep apnea [102] and as a nocturnal mechanical ventilation–assist device [3].

Choice of Oxygen Delivery Device

In the hypercapnic, hypoxemic patient, therapy can begin with 0.5 to 2.0 L per minute by nasal cannula or 0.24 to 0.28 FIO_2 by Venturi-type mask. If the PaO_2 remains less than 55 mm Hg 30 minutes later, administration of progressive increments of inspired oxygen is undertaken. Assessment of gas exchange is measured at frequent intervals, usually every 30 minutes [3] for the first 1 to 2 hours or until it is certain that the PaO_2 is 55 mm Hg or greater and CO_2 narcosis is not developing. In the hypercapnic patient, titration of supplemental oxygen is best assessed by arterial blood gas analysis rather than oximetry because the arterial blood gas provides $PaCO_2$ and oxygenation data. An initial modest increase in $PaCO_2$ (5 to 10 mm Hg) is expected in most hypercapnic patients given supplemental oxygen [103].

If a well-fitted Venturi-type mask delivering FIO_2 of 0.50 fails to achieve an oxygen saturation of at least 90% or a PaO_2 of 60 mm Hg or greater, the patient usually has severe cardiogenic pulmonary edema, acute respiratory distress syndrome (ARDS), overwhelming pneumonia, or a cardiac or pulmonary vascular shunt. In these settings, a nonrebreathing mask is recommended for two reasons. First, when properly worn, it has the potential to deliver the most predictable oxygen concentration (close to 1.00) of all the high-concentration delivery mask devices (e.g., aerosol masks, partial rebreathing masks, or face tents). Second, it can reveal the presence of a right-to-left shunt. If the PaO_2 is 60 mm Hg or less in the face of an inspired oxygen concentration of close to 1.00, a right-to-left shunt of approximately 40% of the cardiac output is present (see Chapter 46). If the chest radiograph in this setting demonstrates diffuse pulmonary infiltrates and the patient does not improve rapidly with diuretics, then generally it can be assumed that mechanical ventilation with PEEP is necessary.

Oxygen therapy should never be abruptly discontinued when hypercapnia has worsened and CO_2 narcosis is a possibility. This causes PaO_2 to fall to a level lower than it was before any oxygen was given [3] because the patient is breathing in a slower, shallower pattern.

Long-Term Continuous Oxygen Therapy

Continuous (24-hour) oxygen therapy significantly prolongs and improves the quality of life in hypoxemic patients with COPD [3]. If used for 15 hours per day or more, it decreases mortality 1.5 to 1.9 times for up to 3 years. Patients who should be given continuous oxygen during hospitalization and as outpatients include those with a PaO_2 of 55 mm Hg or less and those with a PaO_2 of 59 mm Hg or less plus peripheral edema, hematocrit of 55% or greater, or P pulmonale on electrocardiogram. Because many of these patients continue to improve as outpatients, the need for continuous oxygen therapy should be reassessed at 1 month [104].

Complications of Oxygen Therapy

In adults, decreased mucociliary clearance, tracheobronchitis, and pulmonary oxygen toxicity are the major complications of oxygen therapy. Mucociliary clearance is decreased by 40% when 75% oxygen is breathed for 9 hours and by 50% when 50% oxygen is breathed for 30 hours [3]. Symptomatic tracheobronchitis is caused consistently by the inhalation of high concentrations of oxygen (0.90 or higher) for 12 hours or more; it is manifested by substernal pain, cough, and dyspnea [105].

To avoid clinically significant pulmonary oxygen toxicity, prolonged administration of concentrations greater than 0.50 should be restricted, whenever possible, to 48 hours [3]. The pathology of oxygen toxicity is that of ARDS; it can lead to death from refractory and progressive hypoxemia due to interstitial fibrosis. It is best avoided by restricting delivery of oxygen to the lowest concentration and shortest duration absolutely necessary to achieve a satisfactory PaO_2. Therefore, prophylaxis consists of using any and all measures that allow a decrease in the concentration of inspired oxygen to a subtoxic level. PEEP has been shown to be useful in achieving this goal.

Mak et al. [106] studied the effects of hyperoxia on left ventricular function in patients with and without congestive heart failure and concluded that hyperoxia was associated with impairment of cardiac relaxation and increased left ventricular filling pressures in both groups. Based on these findings, the cautious use of high FIO_2 in normoxic patients, especially those with congestive heart failure, is advised.

For patients with previous bleomycin exposure, there appears to be a synergistic effect with subsequent exposure to high concentrations of inspired oxygen, resulting in the development of bleomycin pneumonitis [107]. Although it is unclear how long after bleomycin exposure that breathing high-inspired oxygen concentrations predisposes to pneumonitis, the risk appears highest within 6 months of bleomycin exposure.

A similar interaction can be seen in patients taking long-term amiodarone and exposure to high concentrations of inspired oxygen [108]. This risk appears higher in patients receiving high concentrations of inspired oxygen via mechanical ventilation. These patients can develop diffuse alveolar damage and ARDS, and mortality rates may be as high as 33% [109]. For patients with a history of either bleomycin or amiodarone exposure, we recommend using the lowest amounts of supplemental oxygen possible to maintain adequate oxygenation.

Although the complications of retrolental fibroplasia and bronchopulmonary dysplasia from oxygen toxicity have been limited in the past to pediatric patients, reports of adults with bronchopulmonary dysplasia, the eventual result of ARDS, have appeared [3]. Central nervous system dysfunction manifested by myoclonus, nausea, paresthesias, unconsciousness, and seizures is limited to hyperbaric oxygenation at pressures in excess of 2 atm [3].

Hyperbaric Oxygen Therapy

Hyperbaric therapy, 100% oxygen at 2 to 3 times the atmospheric pressure at sea level, is used as primary therapy in the treatment of patients with decompression sickness, arterial gas embolism, and severe CO poisoning [110]. In the case of CO poisoning, although hyperbaric therapy accelerates the resolution of symptoms, it does not appear to affect the rate of late sequelae [110] or long-term mortality in non–life-threatening cases [111]. It is used as adjunctive therapy in the treatment of osteoradionecrosis, clostridial myonecrosis/necrotizing fasciitis [112], and compromised skin grafts [113], although there is evidence to suggest that it does not improve outcomes in patients with necrotizing soft tissue infections [114]. Although hyperbaric oxygen therapy has been used for several other medical conditions, there is no current evidence demonstrating its benefits when used for treating traumatic brain injuries, acute ischemic cerebral accident, multiple sclerosis, or acute coronary syndrome [3,115–117].

Helium-Oxygen (Heliox)

Because helium is less dense than nitrogen, it has the potential to improve airflow where airflow is likely to be turbulent (i.e., density dependent). However, this primarily occurs in large airways when there is an upper airway–obstructing lesion. Heliox has successfully decreased airway resistance in patients with postextubation upper-airway obstruction [118], in children with severe croup who were refractory to inhaled racemic epinephrine [118], and in upper-airway obstruction due to tracheal tumors or extrinsic compression [119]. Although there have been favorable physiologic effects shown in a number of randomized controlled trials in spontaneously breathing patients with acute severe asthma [3], one large meta-analysis of seven studies [120] and an extensive review by the Cochrane Database [121] failed to show any benefit of using Heliox in the management of acute asthma patients. At this time, there is no definitive evidence to support the use of Heliox in the treatment of acute asthma. Heliox has been used with nebulized albuterol in the treatment of asthma, but any benefit is unclear as there are conflicting results in the literature [122,123]. In addition, Heliox has been shown to adversely impact the particle size of the medication [124], potentially limiting its delivery to the distal airways.

Heliox has not been shown to be beneficial in children with croup [125]. Heliox has been shown to improve oxygenation in patients undergoing fiberoptic bronchoscopy through endotracheal tubes with internal diameters less than 8 mm [126]. Therefore, if a bronchoscopy must be preformed in this setting, and changing the endotracheal tube to a larger size is not possible, performing the procedure with Heliox may be helpful.

The effect of increasing concentrations of helium in decreasing airway resistance is linear, but most reduction takes place when the concentration of helium reaches 40% [126]. Therefore, Heliox mixtures should contain a minimum of 40% helium, with the balance of the mixture being oxygen. For patients in respiratory distress with little hypoxemia due to laryngeal edema, a Heliox mixture of 80% helium and 20% oxygen would suffice. For patients in respiratory distress with profound hypoxemia due to pulmonary edema associated with laryngeal edema, however, a Heliox mixture of 40% helium and 60% oxygen would be most advantageous.

In an uncontrolled trial, intubated patients with status asthmaticus on mechanical ventilation [127] were successfully ventilated with a mixture of 60% helium and 40% oxygen and experienced a decrease in airway pressures and $PaCO_2$ with a resolution of acidosis. Because helium may affect how ventilators work, monitoring of ventilator outputs must be undertaken.

Jet nebulizers that are powered with Heliox rather than oxygen or air may be adversely affected. Heliox has been shown to alter the available inhaled mass and the particle size of albuterol if settings are not adjusted and flow rates changed. The clinical implications of this effect have not been determined [128]. Nebulizer performance with Heliox needs to be determined and correction factors derived before proceeding to clinical use.

Although Heliox may provide favorable short-term physiologic effects in patients with acute exacerbations of COPD [3], review of the literature has concluded that there is insufficient evidence to support the use of Heliox in the management of ventilated and nonventilated patients with acute exacerbations of COPD [129].

In summary, Heliox should only be considered a support modality that serves as a bridge, allowing specific therapies more time to work [130]. Only its use in the treatment of severe upper-airway obstruction can be supported at this time. Current studies do not support its routine use in the management of acute exacerbations of COPD and asthma, or croup and acute bronchiolitis in children. Nevertheless, in acute asthma and bronchiolitis, it is reasonable to consider the use of Heliox when conventional therapies have failed.

Nitric Oxide

Inhaled nitric oxide (NO) is a potent, selective pulmonary vasodilator. Early studies reported the clinical application of inhaled NO in adult patients with primary pulmonary hypertension and since then, hundreds of trials have been conducted to identify additional applications [131]. In a randomized controlled trial, inhaled NO reduced the need for extracorporeal membrane oxygenation (ECMO) in newborn infants with persistent pulmonary hypertension [132]. The results of a prospective, uncontrolled clinical trial [133] demonstrated that inhaled NO improved systemic oxygenation in infants with persistent pulmonary hypertension, reducing the need for more invasive treatments, such as ECMO. Although inhaled NO has been shown to improve oxygenation in newborns with persistent pulmonary hypertension and reduce the need for ECMO, it has not been shown to increase overall survival [131]. One- and 2-year follow-ups of infants with persistent pulmonary hypertension of the newborn who were treated with inhaled NO showed medical and neurological developmental outcomes to be similar to previous reports of patients treated with conventional therapy and ECMO [134].

Inhaled NO has been investigated in a variety of other areas, including (a) acute lung injury and ARDS, (b) status asthmaticus, (c) intestinal ischemia reperfusion, (d) thrombotic

disorders, and (e) sickle-cell crisis [3]. An extensive review of the use of inhaled NO therapy in adults can be found elsewhere [135]. The benefits of using NO in these conditions are questionable. Inhaled NO appears to only transiently improve oxygenation and does not appear to decrease mortality in patients with severe lung injury [136]. In addition, a substantial number of patients are nonresponders to inhaled NO, showing no pulmonary vasodilation or improvement in oxygenation [3].

Delivery and monitoring systems for inhaled NO, as outlined by a workshop of the National Heart, Lung, and Blood Institute in 1993, have been summarized elsewhere [137]. The application of inhaled NO requires trained personnel with expertise and knowledge specific to the delivery systems, ventilator circuitry, and monitoring of patients.

Risks associated with the use of inhaled NO include vasodilation of the pulmonary circulation with increased blood flow to the left ventricle, causing an increase in left arterial pressure and pulmonary artery balloon occlusion pressure that may lead to pulmonary edema. Because rebound pulmonary arterial hypertension, increased intrapulmonary right to left shunting, and decreases in PaO_2 after abrupt discontinuation of inhaled NO have been described [138], gradual weaning is recommended. Before initiating inhaled NO, consideration should be given to the potential acute and long-term toxic effects. Acute inhaled NO overdose (>500 to 1,000 ppm) can result in the formation of nitrogen dioxide, methemoglobinemia, pulmonary alveolar edema and hemorrhage, hypoxemia, and death [139].

In summary, inhaled NO represents an experimental and costly therapy used to treat disease states characterized by pulmonary hypertension. Although it is useful in assessing potential pulmonary vasoresponsiveness to pharmacologic therapy, there is no evidence that the use of NO has any effects on survival [135,140].

NASAL CONTINUOUS POSITIVE AIRWAY PRESSURE FOR SLEEP-RELATED BREATHING DISORDERS

CPAP is an effective treatment for clinically significant obstructive sleep apnea/hypopnea syndrome, oxyhemoglobin desaturation, and respiratory event-related sleep arousals. This therapy is associated with improved morbidity due to reductions in daytime somnolence and improved cardiopulmonary function. Although further study of the long-term effects of CPAP is necessary, data suggest a possible reduction in mortality [141]. Since 1981, its efficacy has been repeatedly demonstrated [142]. Multiple controlled studies have shown that nasal CPAP can also be effective in patients with chronic left ventricular failure and Cheyne–Stokes respirations [3]. In these patients, nasal CPAP improved cardiac function and alleviated symptoms of heart failure and sleep-disordered breathing. Nasal CPAP has been shown to reverse central sleep apneas in some patients [143]. Simple snoring that is not associated with pauses in respiration or with clinical impairment is generally not treated with CPAP [141]. The use of CPAP and bilevel positive airways pressure (BiPAP) in the management of patients with acute respiratory failure is discussed in Chapter 59.

Application

Nasal CPAP acts as a pneumatic splint to prevent upper airway collapse. Patients usually respond rapidly to 3 to 15 cm H_2O. The optimal CPAP pressure is determined by a nocturnal polysomnogram in which pressure is titrated upward until sleep-related breathing events are eliminated [144]. Lack of response is often due to a poorly applied mask or patient intolerance [143]. Compliance rates can vary considerably (46% to 89%) [144].

Multiple nasal delivery devices are available that may improve patient comfort, including a variety of nasal and full-face masks. Rare serious complications [145] include bilateral bacterial conjunctivitis, massive epistaxis due to drying of nasal mucosa in a patient with coagulopathy, and worsening obstruction in a patient with a large lax epiglottis.

Because nasal CPAP is very effective, safe, and reasonably well tolerated, it has become the technique of choice in the treatment of idiopathic obstructive sleep apnea (i.e., no correctable anatomic abnormality identified). Relative contraindications include the presence of bullous lung disease and recurrent sinus or ear infections. There are no absolute contraindications [3]. It is important to realize that uvulopalatopharyngoplasty may compromise nasal CPAP therapy by increasing mouth air leak and reducing the maximal level of pressure that can be tolerated, and it benefits only some patients [146].

Alternative Modality

For patients with sleep apnea/hypopnea syndrome who cannot tolerate nasal CPAP because of the sensation of excessive pressure, nasal or full-face mask bilevel ventilation may be more tolerable. This permits independent adjustments of inspiratory positive airway pressure and expiratory positive airway pressure and has eliminated sleep-disordered breathing at lower levels of expiratory airway pressure compared with conventional nasal CPAP therapy in some patients [3].

COMMUNICATION ALTERNATIVES FOR THE PATIENT WITH AN ARTIFICIAL AIRWAY

Anxiety and fear are common emotions experienced by patients during mechanical ventilation. These emotions have been associated with the experience of agony/panic and insecurity related to the inability to communicate [147]. Patients with endotracheal and tracheostomy tubes in place experience these feelings because the tubes interfere with normal verbal communication. Providing a means of communication for patients undergoing mechanical ventilation has been shown to significantly increase patient satisfaction [148].

Intubation with cuffed, inflated intratracheal tubes impairs verbal communication because it blocks the normal airflow through the vocal cords. Deflated cuffed or cuffless tubes, generally reserved for spontaneously breathing patients, allow verbal communication, provided there is no pathologic obstruction (e.g., edema and granulation tissue or excessive secretions) blocking the passage of air through or above the vocal cords.

Communication Aids and Devices

A variety of communication aids are available depending on the situation [148]. A speech therapist can be indispensable in helping to select which aid is best for your patient.

Partial cuff deflation methods can be used in nonventilator- and ventilator-dependent patients. They are most commonly used in the nonventilator situation. Their use in the ventilator situation requires extremely close monitoring of the patient along with ventilator adjustments.

In the nonventilator-dependent patient, one can use deflation of the tracheostomy cuff with intermittent gloved finger occlusion of the tube or a device with a one-way valve (e.g., Passy-Muir Valve [PMV], Passy-Muir, Inc, Irvine, CA). The PMV is a one-way, positive-closure, no-leak valve that attaches to the hub of tracheostomy tubes (including cuffless fenestrated and nonfenestrated tubes, metal tubes, and cuffed tubes with the cuff fully deflated) [149]. It is indicated for awake and alert tracheostomized patients with sufficient air passage around the tracheostomy tube (or through a fenestrated tube) and through the upper airway. When the patient inhales, the PMV opens, allowing air to enter the lungs through the tracheostomy tube. As exhalation begins, the PMV closes, and remains closed through exhalation so that air is redirected around (or through) the tracheostomy tube, allowing for speech as the air passes through the vocal cords. Oxygen can be administered with the PMV in place at the tracheostomy tube site via oxygen mask, trach collar, or O_2 adapter. When using the PMV on tracheostomy tubes that have an inner cannula grasp ring that extends beyond the hub of the tube, the inner cannula should be removed when the PMV is in use to avoid obstruction of the valve's diaphragm movement.

In the ventilator-dependent patient, one can use partial deflation of the tracheostomy cuff alone or the one-way valve with *full* cuff deflation. During mechanical ventilation, both methods require close monitoring of the patient and the ventilator. Because use of the PMV with ventilator-dependent patients requires the cuff to be deflated, adjustments in tidal volume may be necessary to offset the volume loss caused by the air leak. Contraindications to the use of the one-way valve include the presence of an inflated cuff, absolute necessity for the cuff to remain fully inflated, tracheal/laryngeal obstruction or secretions preventing air from moving around or above the tube, laryngectomy, bilateral vocal cord paralysis, unconsciousness, and unstable medical condition [3]. Use of the valve with an inflated cuff can result in breath stacking with resultant intrinsic PEEP and barotrauma [150]. Because less-exhaled volume is returned to the ventilator with the deflated cuff methods, ventilator-exhaled volume alarms have to be adjusted [151]. Lack of intact oral and laryngeal musculature in some patients with neuromuscular diseases may preclude effective use of the valve [151].

For patients who cannot tolerate cuff deflation, a talking tracheostomy tube (Trach Talk, Portex, Inc, Keene, NH) is available to allow for whispered speech. A gas line is connected to air or oxygen, and when the thumb seal on the line is occluded, gas passes through the larynx, allowing the patient to speak.

The electronic larynx is a handheld mechanical device that can be used by patients who have undergone laryngectomy.

TABLE 62.1

ADVANCES IN RESPIRATORY ADJUNCT THERAPY

Topic	Reference	Findings
Aerosolized mist for croup	[2]	No benefit
Bland aerosols for CF	[2,4]	7% Saline improved FVC and FEV_1 vs. 0.9% saline
Humidification for ventilated patients	[9]	No difference in safety between heated water baths and HMEFs
Delivery of inhaled β agonist	[3]	No difference between MDI and nebulizer
NAC for COPD	[27]	No improvement on lung function or exacerbations vs. placebo
DNase of CF	[2]	Decrease in dyspnea and exacerbations vs. placebo
DNase for bronchiectasis	[32,33]	No benefit over placebo
DNase for RSV bronchiolitis	[34]	Improvement in chest radiographic findings vs. placebo
Aerosolized ribavirin for RSV	[3,42]	No effect vs. placebo
Iloprost for PPH	[52]	Improved 6-min walk, dyspnea, and hemodynamics vs. placebo
Inhaled cyclosporin for lung transplant	[53]	Improved survival and less rejection vs. placebo
Furosemide for mucociliary clearance	[66]	No improvement vs. placebo
Flutter valve for CF	[70]	As efficacious as CPT
High-frequency oscillation for CF	[72]	As efficacious as CPT
High-flow oxygen for cluster headaches	[87]	Significantly decreases pain within 15 min
Inhaled NO	[135,140]	No improvement in survival in ARDS/ALI
Iloprost for acute pulmonary hypertension after cardiac surgery	[51]	More effective than inhaled NO
Perioperative supplemental O_2	[96]	Decreases wound infections with 80% FIO_2 vs. 30% FIO_2

CF, cystic fibrosis; COPD, chronic obstructive pulmonary disease; DNase, recombinant human deoxyribonuclease; FEV_1, forced expiratory volume in 1 second; FIO_2, fractional inspiration of oxygen; FVC, forced vital capacity; HMEF, hydroscopic condenser humidifier; MDI, metered-dose inhaler; NAC, *N*-acetylcysteine; PPH, primary pulmonary hypertension; RSV, respiratory syncytial virus; NO, nitric oxide.

When pressed into the soft tissue of the neck, it generates a vibratory sound that escapes through the mouth and is articulated by the lips, tongue, and palate. Its disadvantage is the metallic-type sound that is produced [152]. The Blom–Singer tracheostoma valve (Forth Medical Ltd., Berkshire, UK) is available for prosthesis-assisted tracheoesophageal speech in postlaryngectomy voice rehabilitation [153]. Finally, a variety of computer-assisted communication devices and electric typewriters are available, but are usually considered for patients requiring long-term mechanical ventilation because of their complexity and expense [3].

Advances in respiratory adjunct therapy, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 62.1.

CHAPTER 63 ■ CHEST RADIOGRAPHIC EXAMINATION

CYNTHIA B. UMALI* AND JERRY P. BALIKIAN

Radiographic examination of the critically ill patient in the intensive care unit (ICU) or coronary care unit (CCU) is often necessary to evaluate clinical status. In this setting, the basic role of radiology is to follow the patient's progress or changes in status after admission or after surgery; the primary diagnosis has been already established. Radiographic examinations are thus requested to evaluate the course of the primary disease and to diagnose complications that may ensue. Henscke et al. [1] studied the diagnostic efficacy of bedside chest radiographs and found that in 65% of the 1,132 consecutive radiographs analyzed, there were new findings or changes affecting patient management. Bekemeyer et al. [2], after analyzing 1,354 radiographs from a respiratory ICU, found a 34.5% incidence of new or increased abnormalities or tube or catheter malpositions. They concluded that routine morning radiographic examinations frequently demonstrated unexpected or changing abnormalities, many of which prompted changes in diagnostic management. The American College of Radiology established the appropriateness criteria for the need of ICU studies [3] and Trotman-Dickenson detailed the role of radiology in the ICU [4,5].

Critically ill patients in the ICU or CCU often cannot take advantage of numerous radiologic modalities that are readily available to mobile patients. Because these patients cannot be transported while their circulatory functions are labile and they are connected to electrocardiogram monitors, ventilators, catheters, and surgical appliances, usually one is left with the portable bedside radiographic examination. Most often, it is a chest examination that is needed; the chest film is especially important because physical examination to determine the presence of a complication such as atelectasis, pneumothorax, pneumonia, or pulmonary edema is difficult in the presence of a ventilator.

Until recently, portable radiographic examinations were restricted by inherent machine limitations in kilovoltage, milliamperage, and radiograph tube currents and by variations in battery charge. The need for adequate penetration to see line and catheter positions necessitated increasing normal exposure time (thereby increasing motion unsharpness) and using a higher kilovoltage (thereby increasing scatter radiation, which increases film fogging). A high kilovoltage also reduces subject contrast. These alterations and limitations cause deterioration of the image, often rendering the film of suboptimal quality for evaluation of subtle changes in the lung parenchyma. During the past few years, most of the above problems have been

*Deceased

practically eliminated with the use of state-of-the-art computed radiography.

Interpretation of portable examinations is fraught with pitfalls. Magnification of the cardiac silhouette cannot be eliminated because of the short tube-film distance and the often supine position of the patient. Signs used to evaluate postcapillary (pulmonary venous) hypertension are not valid on the supine film and may necessitate use of a horizontal beam (cross-table lateral view) to visualize the discrepancy between the dependent and nondependent vessels, which is far more difficult.

Films are often taken after a poor inspiratory effort because of the patient's inability to cooperate. Unless the type of respirator, phase of cycle, and pressure setting are indicated on the film, the appearance of parenchymal abnormalities is difficult to evaluate. Increased inflation of the lung may cause the opacities to appear less dense, but the apparent improvement secondary to increased aeration does not correspond to a true anatomic improvement. The reverse situation can occur as well.

A portable C-arm fluoroscope is often used at the bedside to monitor catheter placement (especially Swan–Ganz). The fluoroscope also can be used to evaluate alignment of fracture fragments during closed reduction and to visualize diaphragmatic motion. Portable ultrasound equipment is particularly useful for detecting fluid collections, including effusions (pericardial and pleural) and subdiaphragmatic abscesses. Portable gamma cameras are useful for evaluating possible pulmonary embolism in these patients.

With PACCS systems in many ICUs, digital images are now available on ICU monitors immediately after the images are taken.

EVALUATION OF TUBES AND CATHETERS

Endotracheal Tubes

The location of endotracheal tubes should be checked as soon as possible after insertion (see Chapter 1). To evaluate the position of the tube properly, Goodman et al. [6] showed that one must evaluate the head and neck position simultaneously because tube position can change with flexion and extension of the neck [7] by as much as 4 cm. Thus, to ensure that the tip of the tube is above the carina, one should follow these guidelines:

1. When the inferior border of the mandible is at or above C4, the tip should be 7 ± 2 cm from the carina.
2. When the inferior border of the mandible is at the C5-C6 level, the tip of the tube should be 5 ± 2 cm from the carina.
3. When the inferior border of the mandible is at T1 or below, the tip of the tube should be 3 ± 2 cm from the carina.

When the tube is too high, it may slip into the pharynx. If it is just below the vocal cords, its inflated cuff can cause glottic or subglottic edema, ulceration, and, ultimately, scarring. If it is too low, it can enter a bronchus and cause atelectasis of the lung supplied by the obstructed bronchus (Fig. 63.1).

Ideally, the tube should be one-half to two-thirds the width of the trachea, and the inflated cuff should fill the trachea without causing the lateral walls to bulge. When the ratio of the cuff diameter to the tracheal lumen exceeds 1.5%, tracheal damage is likely to result [8]. Ravin et al. [9] observed that repeated overdistention of the cuff on chest film, despite careful cuff inflation to the minimal leak level, should lead to suspicion of tracheomalacia (Fig. 63.2).

Immediately after intubation, and especially after difficult intubation, a film should be obtained to define the position of the tube. The radiologist should also look for signs of perforation of the pharynx, such as marked subcutaneous emphysema, pneumomediastinum, and pneumothorax. Dislodging of teeth, dental caps, and portions of dentures into the tracheobronchial tree has been reported after intubation. If this is suspected, a foreign body in the tracheobronchial tree should be carefully sought.

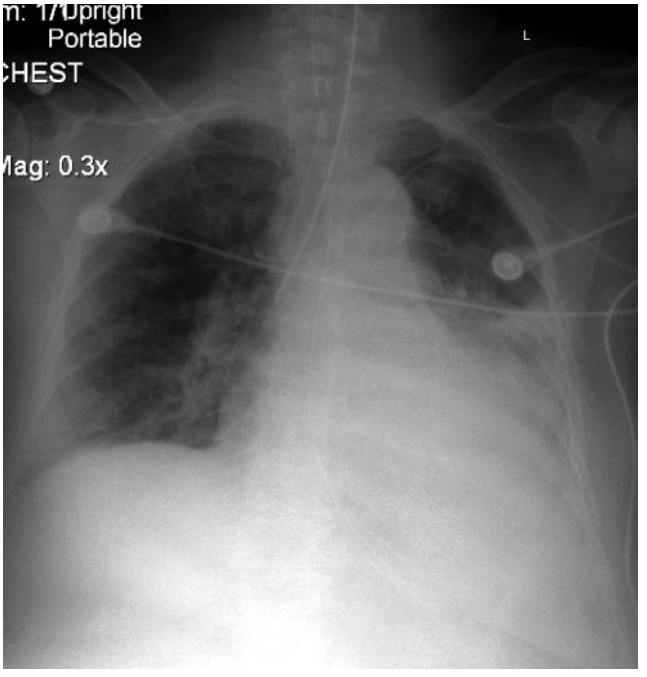

FIGURE 63.1. Endotracheal tube is 2 cm within the right main bronchus. As a result, there is partial obstruction of the orifice of the left main bronchus causing left lower lobe atelectasis. Recommend approximately 4 cm upward repositioning.

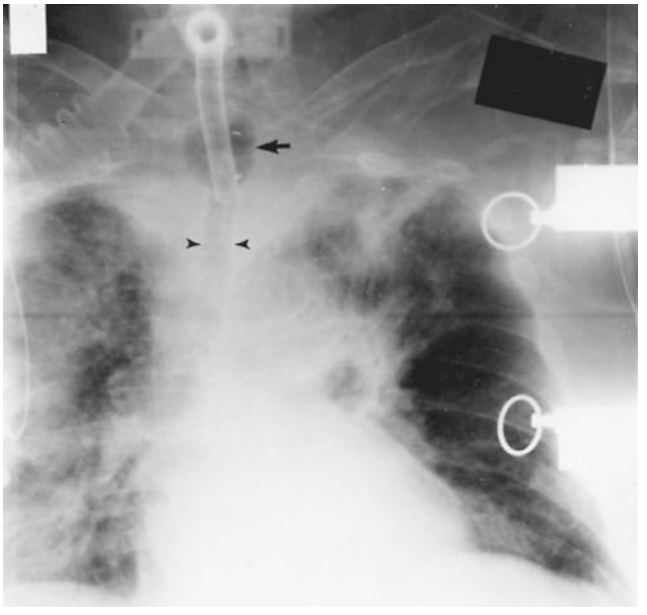

FIGURE 63.2. Overdistended tracheostomy tube cuff. Portable examination, anteroposterior view, in a patient with diffuse parenchymal infiltrates from acute respiratory distress syndrome with a tracheostomy tube. Lucent circular area (*arrow*) surrounding the tracheostomy tube is a distended cuff. It markedly exceeds normal tracheal diameter (*arrowheads*). This patient has tracheomalacia and has had the cuff reinflated to this size persistently after deflation and reinflation to the minimal leak level.

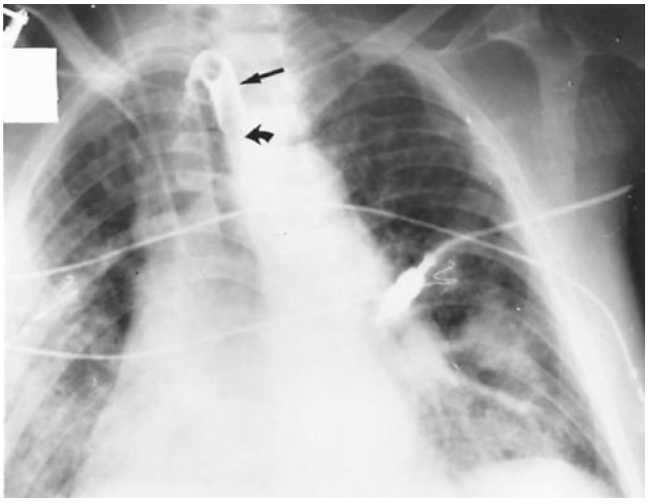

FIGURE 63.3. Tracheostomy tube lateral to shadow of trachea. Portable anteroposterior view of a patient with pulmonary edema, with the left lateral edge of the tracheostomy tube (*straight arrow*) lying to the left of the tracheal wall (*curved arrow*). The patient had a history of nasogastric tube feedings being recovered from the tracheostomy tube, which eroded the trachea into the esophagus.

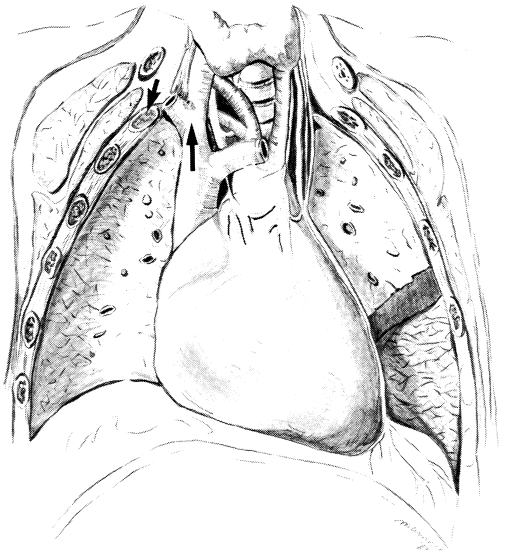

FIGURE 63.4. Junction of internal jugular vein and right subclavian vein. Veins shown in relation to the first rib. The junction of the internal jugular and right subclavian veins (*long arrow*) occurs at approximately the level of the first rib (*short arrow*). The central venous pressure line should be at or beyond this point to measure true venous pressure. (Drawing by Mary Cunnion.)

Tracheostomy Tubes

The tip of the tracheostomy tube should be located one-half to two-thirds of the way between the stoma and the carina. Unlike the endotracheal tube, the tracheostomy tube does not change position with flexion and extension of the neck. The tracheostomy tube should be evaluated to determine its inner diameter (which should be two-thirds that of the tracheal lumen); its long axis (which should parallel the tracheal lumen); the location of its distal end (Fig. 63.3) (which should not abut the tracheal wall laterally, anteriorly, or posteriorly); and for development of increasing pneumothorax, pneumomediastinum, or subcutaneous emphysema, which may require immediate attention.

Central Venous Catheters

Central venous catheters should be evaluated to ensure that the true central venous pressure is measured. The catheter should be located beyond the venous valves, the most proximal of which is just distal to the junction of the internal jugular vein and the subclavian veins. This is found at approximately the level of the first anterior rib [10] (Fig. 63.4) (see Chapter 2).

Brandt et al. [11] found that the distance to the junction of the superior vena cava and the right atrium is usually the total of the distance from the cutdown site to the suprasternal notch plus one-third the distance from the suprasternal notch to the xiphoid process. Complications of central venous catheter lines include vascular perforation or dissection (Fig. 63.5A,B) and cardiac perforation, leading to cardiac tamponade (Fig. 63.5C), embolization, and infection.

Swan–Ganz Catheters

Swan–Ganz catheters are used to perform right heart catheterizations [12]. Ideally, the tip of the Swan–Ganz catheter should be located in the right or left branch of the pulmonary artery. Occasionally, the tip may be malpositioned (Fig. 63.6); a film should be routinely taken to check its position. If it is more distal to the above location, the catheter may produce pulmonary infarction (Fig. 63.7) by blocking the artery directly or from a clot in or around the tip. Other rare complications include perforation of the pulmonary artery, the resulting focal hemorrhage leading to formation of "traumatic pseudoaneurysm" (Fig. 63.7D), balloon rupture, and pulmonary artery–bronchial tree fistulas.

Intra-Aortic Counterpulsation Balloons

The intra-aortic counterpulsation balloon (IACB) was designed to improve cardiac function in a setting of cardiogenic shock [13], and this remains the major indication for its use. Ideally, the tip of the IACB should be positioned at the level of the aortic arch just distal to the origin of the left subclavian artery to augment coronary perfusion maximally without occluding the subclavian and cerebral vessels (Fig. 63.8). Complications from IACBs are major vessel obstruction, embolization from a clot formed in or around the catheter, and aortic dissection with balloon rupture.

As with endotracheal tubes, the position of the IACB changes with a change in patient position, moving cephalad 1.0 to 4.5 cm when the patient moves from a recumbent to a sitting position [14]. The position, therefore, should be checked periodically.

Chest Tubes

Chest tubes (thoracostomy or pleural drainage tubes) are used to drain either fluid or air from the pleural space (see Chapter 8). If placed for a pneumothorax, the tube should be seen in the anterosuperior position as the air collects beneath the sternum; if placed to drain a pleural effusion, the tube should be seen in the posteroinferior position. To ascertain that the tube is in the pleural space, one must see opaque and nonopaque sides

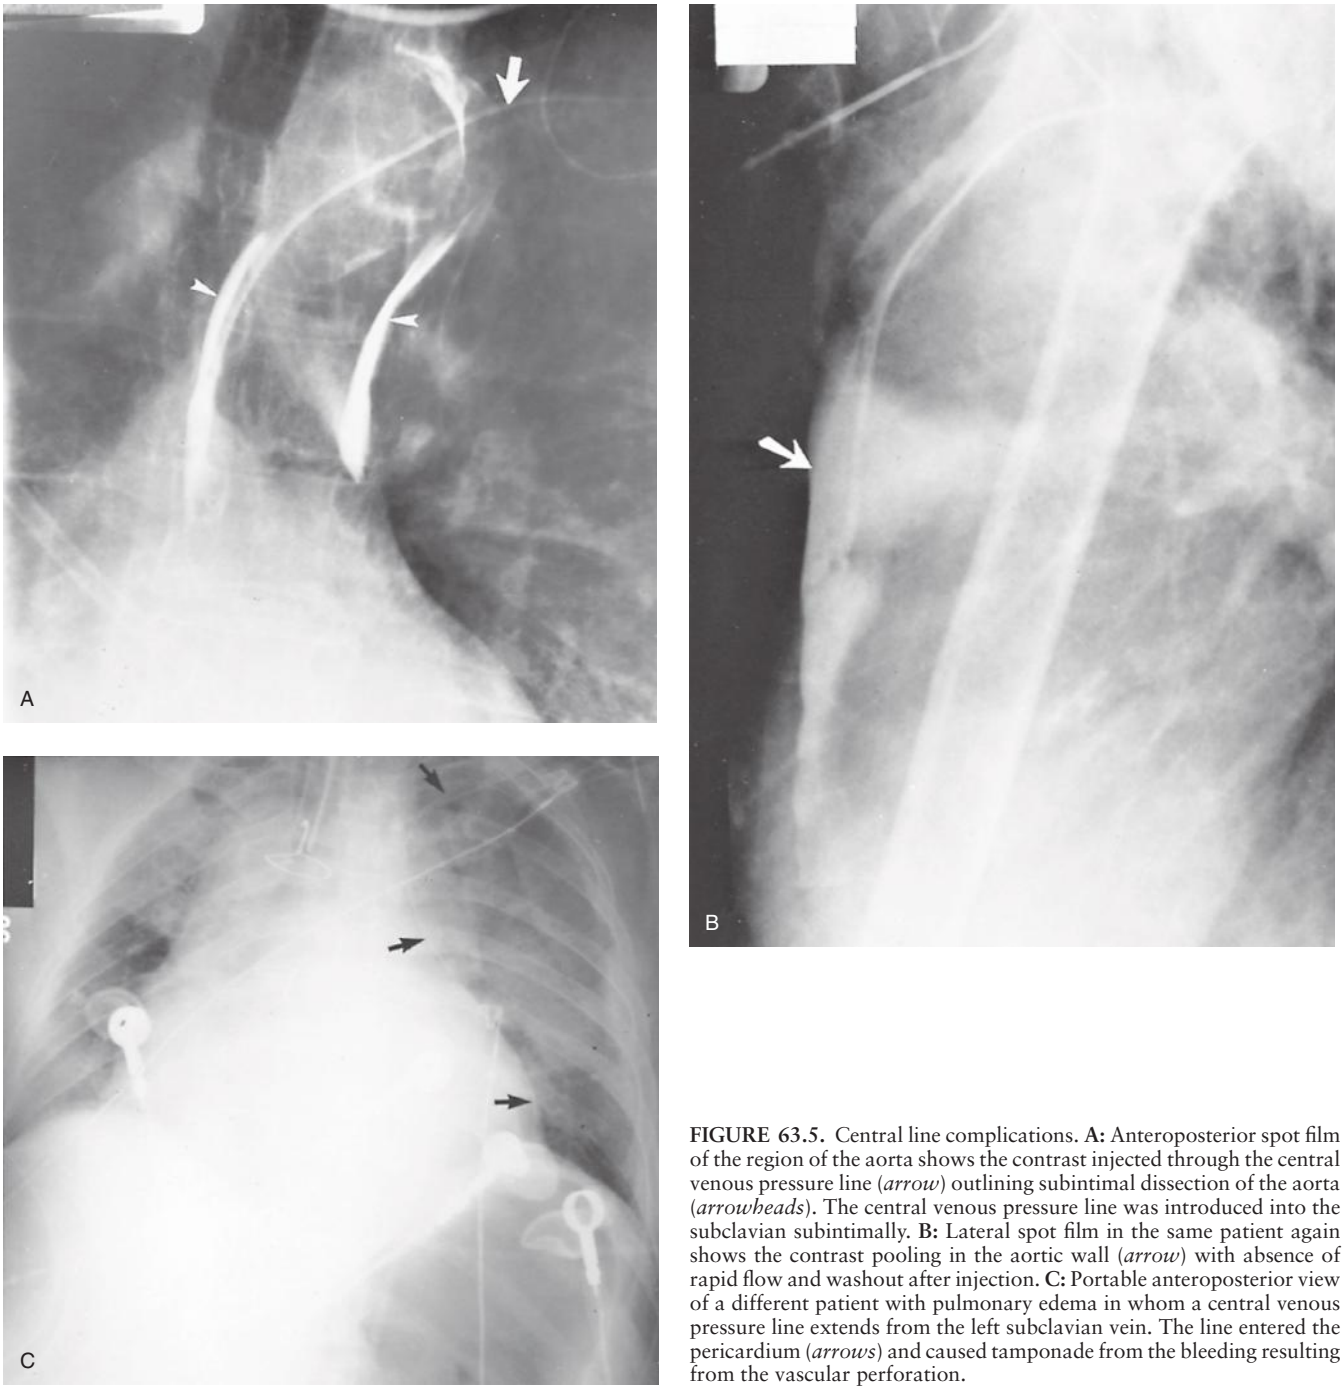

FIGURE 63.5. Central line complications. **A:** Anteroposterior spot film of the region of the aorta shows the contrast injected through the central venous pressure line (*arrow*) outlining subintimal dissection of the aorta (*arrowheads*). The central venous pressure line was introduced into the subclavian subintimally. **B:** Lateral spot film in the same patient again shows the contrast pooling in the aortic wall (*arrow*) with absence of rapid flow and washout after injection. **C:** Portable anteroposterior view of a different patient with pulmonary edema in whom a central venous pressure line extends from the left subclavian vein. The line entered the pericardium (*arrows*) and caused tamponade from the bleeding resulting from the vascular perforation.

of the tube. When the nonopaque side is not seen, it is because the subcutaneous tissue, which is similar to the tube in density, has silhouetted this nonopaque border and the tube is outside the pleural space [15]. The side hole of the tube (where there is a break in the opaque marker) also should be seen within the pleural space.

Nasogastric Tubes

The tip of the nasogastric tube and the side hole should be visible below the diaphragm within the gastric lumen. A malpositioned NG tube can be identified by its characteristic side hole (Fig. 63.9A,B).

Transvenous Pacemakers

The pacemaker is passed under fluoroscopic guidance to the apex of the right ventricle (see Chapter 5). Films should be checked for breaks or fractures in the wire (Fig. 63.10). A lateral view should be obtained to ascertain that the pacemaker tip is directed anteriorly 3 to 4 mm beneath the epicardial fat stripe [16]. A posteriorly directed tip in the lateral view, coupled with a cephalad direction in the anteroposterior (AP) view,

FIGURE 63.6. Swan–Ganz catheter looped in inferior vena cava and reentering right atrium. Anteroposterior close-up view shows the Swan–Ganz catheter through the superior vena cava (*long arrow*) and right atrium (*short arrow*), looping in the inferior vena cava (*arrowheads*) and reentering the right atrium (*curved arrow*).

suggests that the pacer is in the coronary sinus [17]. Projection of the pacemaker tip anterior to the epicardial fat stripe suggests myocardial perforation [16]. Air entrapment in the pulse generator pocket can produce a system malfunction with unipolar pulse generators; this should be kept in mind when examining patients with subcutaneous emphysema [18].

EVALUATION OF THE LUNG PARENCHYMA, PLEURA, MEDIASTINUM, AND DIAPHRAGM

Densities of the Lung Parenchyma

Pulmonary parenchymal densities in the critically ill patient may be caused either by infectious or noninfectious conditions, such as atelectasis, cardiogenic pulmonary edema, acute respiratory distress syndrome (ARDS), pulmonary infarction, or contusion. Radiologic evaluation to determine whether parenchymal densities are secondary to pulmonary edema, other causes, or a combination of edema and other causes is often necessary to complement or initiate a clinical search for pneumonia so that proper therapy can be started.

In 1973, Leeming [19] observed gravitational displacement of edema fluid to the dependent lung. He suggested that pulmonary edema could be differentiated from other causes by a positional shift in the infiltrate. In 1982, Zimmerman et al. [20] evaluated the gravitational shift test and concluded that it is a simple noninvasive method for detecting mobilizable lung water, useful even in the presence of pulmonary damage or an inflammatory process.

After baseline films are obtained, the gravitational shift test is performed, using bedside frontal films. The patient is maintained in a lateral decubitus position for 2 to 3 hours before the films are taken. The hemithorax with fewer parenchymal densities is placed in the dependent position. In 85% of their patients with pulmonary edema, Zimmerman et al. [20] found that the densities in the up lung shifted toward the dependent lung, whereas in 78% of patients with inflammatory disease, no shift was seen.

Evaluation of densities in the retrocardiac area may require an overpenetrated film (Fig. 63.11), a 15- to 30-degree left anterior oblique film, or a right lateral decubitus view. The latter position provides better aeration of the left lung and allows greater visualization of the retrocardiac area. In the presence of pleural effusion, a decubitus view may be necessary to displace the pleural fluid and allow better visualization of the parenchyma.

Congestive Failure and Pulmonary Edema Due to Pulmonary Venous Hypertension

Elevation of pulmonary venous pressure, irrespective of cause, produces a sequence of radiologic findings. When pulmonary venous pressures rise above normal, pulmonary vascular gravitational redistribution occurs [21], producing distention of the upper lobe vessels with a concomitant decrease in caliber of those in the lower lobe in the upright patient. In patients in the supine position, the equivalents of the upper lobe vessels are the anterior or ventral pulmonary vessels and the equivalents of the lower lobe vessels are the posterior or dorsal vessels. The change in caliber of the vessels in the supine position is discernible in a good cross-table lateral film of the chest. These changes are also visible with computed tomography (CT); on a CT, the dorsal vessels become progressively narrower as venous pressure increases.

At pulmonary capillary wedge pressures of 20 to 25 mm Hg, lymphatic drainage is exceeded and the alveolar interstitium, bronchovascular interstitium, interlobular septa, and subpleural tissues become distended with edema fluid. The visible radiologic changes at these pressures are:

1. Thickening of the interlobular septa (Kerley A and B lines) (Fig. 63.12)
2. Peribronchial cuffing, in which hairline, well-defined bronchial walls seen on end increase in thickness and lose their sharp definition (Fig. 63.13A,B)
3. Blurring or haziness of the perivascular outlines (Fig. 63.13A,B)
4. Thickening of the interlobular fissures (Fig. 63.13A,B)
5. Widening of the pleural layer over the convexity of the lungs secondary to the presence of fluid in the subpleural space
6. Pulmonary vascular redistribution (Fig. 63.13C)

Interstitial edema can clear rather rapidly after therapy (Fig. 63.13D). At pulmonary capillary wedge pressures of 25 to 40 mm Hg, edema fluid pours into the alveolar spaces and air space or alveolar edema is seen. The air space consolidation may extend to the subpleural zone, or the more characteristic butterfly or bat-wing edema pattern may be seen (Fig. 63.14).

Unilateral pulmonary edema is probably positional, related primarily to a gravitational shift of mobilizable fluids to the dependent lung [19]. It is postulated that asymmetric edema is often right sided because of cardiac enlargement that impedes

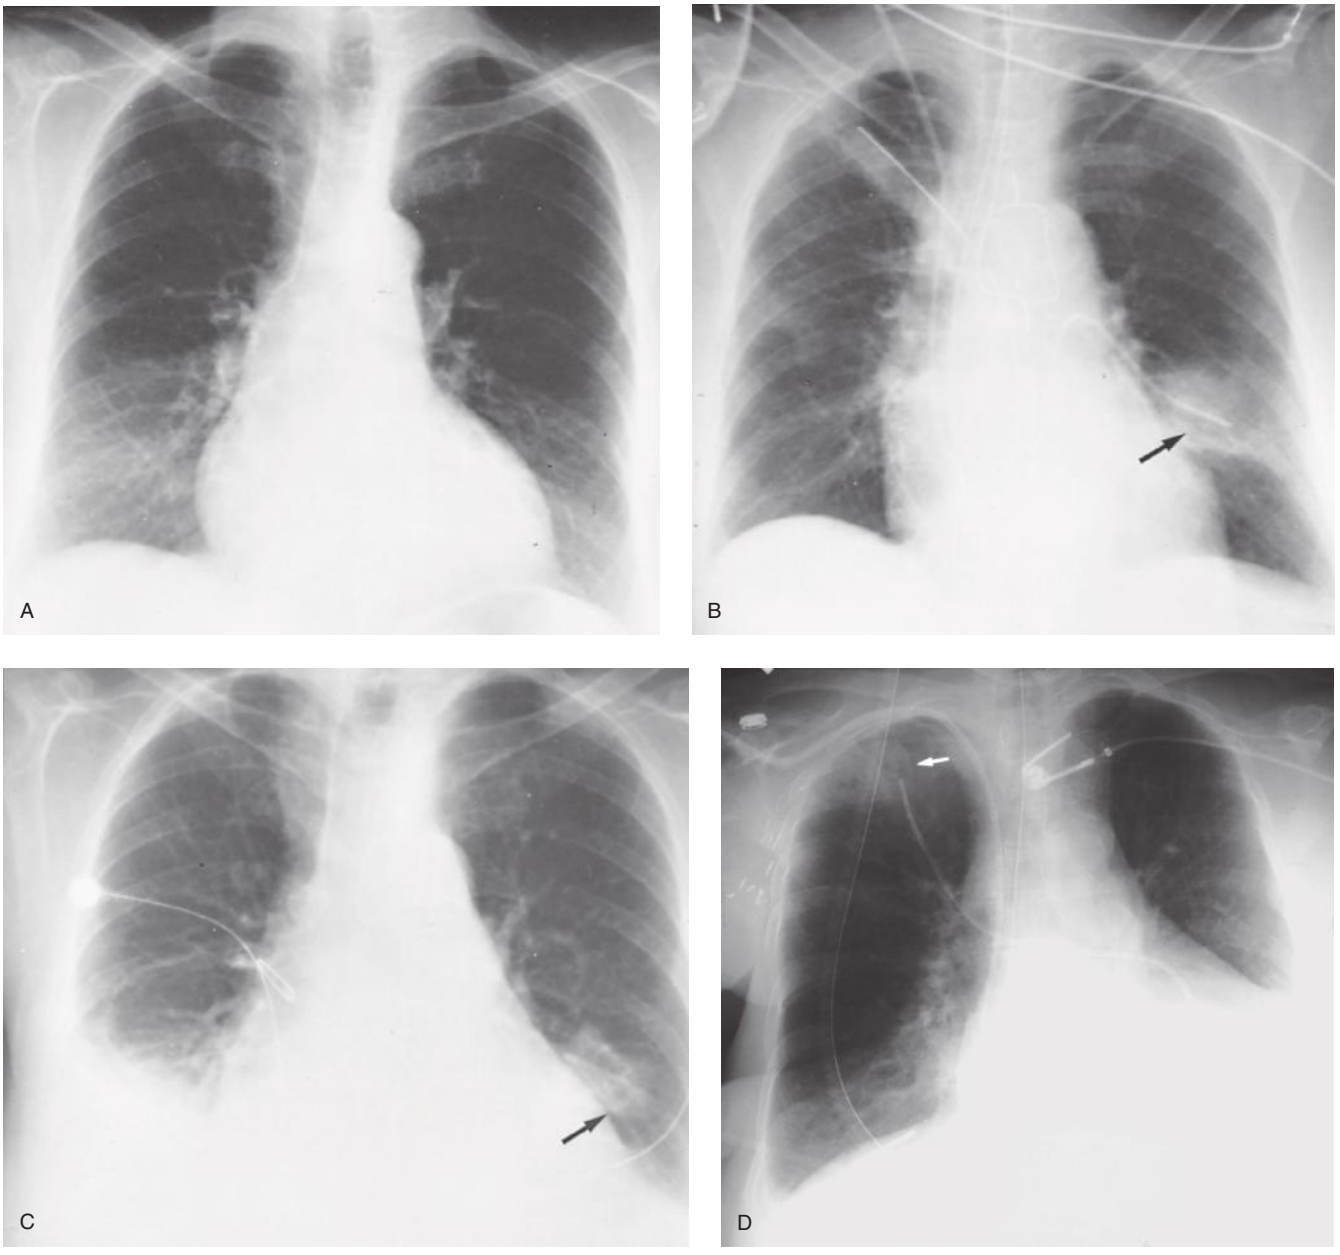

FIGURE 63.7. Infarction caused by Swan–Ganz catheter. **A:** Preoperative posteroanterior view of the chest shows bilaterally clear lung parenchyma. **B:** Postoperative posteroanterior view of the chest shows overly distal position of the Swan–Ganz catheter. An area of density (*arrow*) surrounds the tip of the catheter, representing a pulmonary infarct in the area supplied by the occluded artery. **C:** Posteroanterior film after 5 days shows a persistent left lower lobe density (*arrow*)—the resolving infarct. Right pleural effusion is also present. **D:** Note tip of Swan–Ganz catheter line at periphery of right upper lobe pulmonary artery and showing a round opacity representing "traumatic pseudoaneurysm" (*arrow*).

blood flow in the left pulmonary arterial system, thereby reducing capillary volume. Unilateral diminution in pulmonary blood flow, as seen in Swyer–James syndrome, right or left pulmonary artery thromboembolism, and surgical corrections of congenital heart disease (e.g., shunts for tetralogy of Fallot) are other causes of unilateral edema (Fig. 63.15).

Atypical patterns of congestive failure and pulmonary edema were described by Hublitz and Shapiro [22] in patients with chronic pulmonary disease. Of the four basic patterns they described, two differ in appearance from pulmonary edema in patients with normal lung compliance and vascularity. An asymmetric regional pattern, in which edema occurs only in zones with adequate vascularity, occurs in these patients. The extent of involvement varies greatly from one segment of the lung to another relative to the state of the vascular bed. Another pattern seen is the miliary nodular pattern. Hublitz and Shapiro [22] postulated that the thick-walled spaces in which thickened fibrous septa replace normal alveolar walls impair collateral ventilation and prevent dispersion of edema fluid throughout the lungs. Fluid is then trapped in relatively larger spaces that have replaced normal alveoli. Shadows produced do not coalesce, and the images are seen on radiographs as miliary nodular patterns. The other two patterns, interstitial and reticular, are also seen without chronic lung disease.

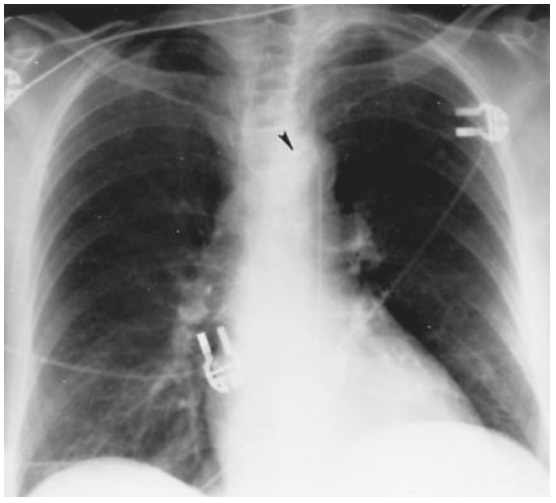

FIGURE 63.8. Intra-aortic counterpulsation balloon occluding left carotid and subclavian arteries. Posteroanterior view shows the tip of the intra-aortic counterpulsation balloon (*arrowhead*) positioned too proximally in the aortic arch, at about the level of the takeoff of the left carotid and left subclavian arteries. When inflated during systole, the balloon occludes these vessels. The tip of the intra-aortic counterpulsation balloon should be distal to the origin of the left subclavian artery.

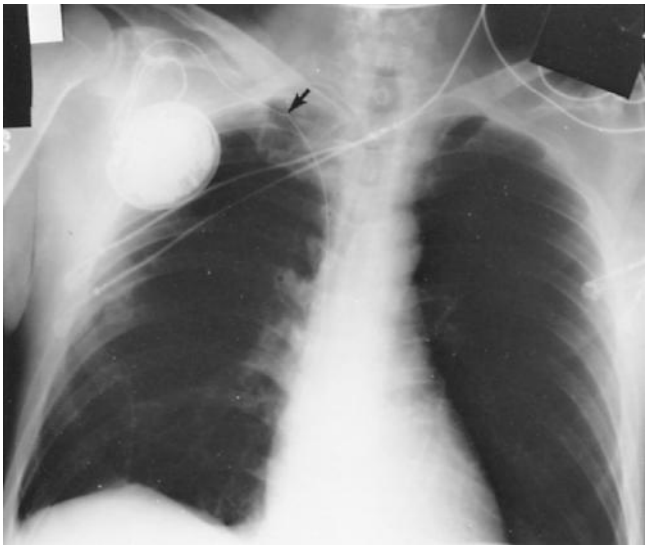

FIGURE 63.10. Posteroanterior view of the chest in a patient with a malfunctioning pacemaker. A break in the pacer wire (*arrow*) caused the malfunction.

Pulmonary edema can be due to cardiac or noncardiac causes. Different radiologic indices distinguish between hydrostatic (cardiac) edema, overhydration pulmonary edema, and edema secondary to increased capillary permeability (see the section Acute Respiratory Distress Syndrome) [23]. In overhydration edema (e.g., edema secondary to renal failure), the cardiac output is large, and, consequently, pulmonary blood flow is large. All vessels are recruited, and no redistribution of flow occurs. Because blood volume is also increased, the

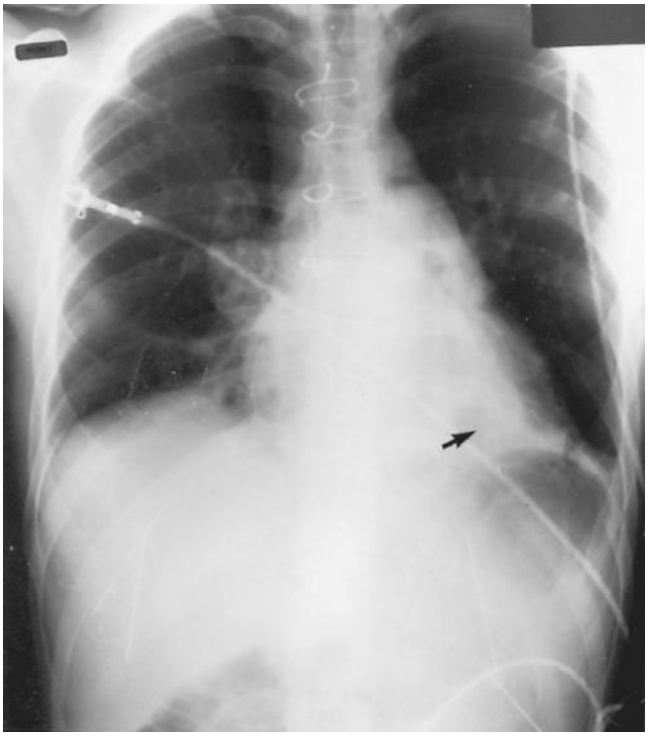

FIGURE 63.11. Left lower lobe atelectasis. Overpenetrated posteroanterior film demonstrates the presence of a retrocardiac density (*arrow*) secondary to atelectasis in a patient who had coronary artery bypass surgery.

FIGURE 63.12. Congestive heart failure. **A:** Posteroanterior view of a patient in congestive heart failure. The heart size is at the upper limit of normal. Vascular redistribution and Kerley B lines (*arrow*) are present. **B:** Enlargement of a posteroanterior film of a different patient shows Kerley B lines (*arrowheads*) perpendicular to the lateral chest wall. **C:** Posteroanterior view of the first patient after therapy shows that pulmonary vascular redistribution is no longer present and Kerley B lines have disappeared. **D:** Posteroanterior view of a different patient in congestive failure shows cardiomegaly with left ventricular enlargement, numerous Kerley B lines on the right, and a pleural density (*arrowhead*), probably representing subpleural edema (density parallel to the right lower ribs).

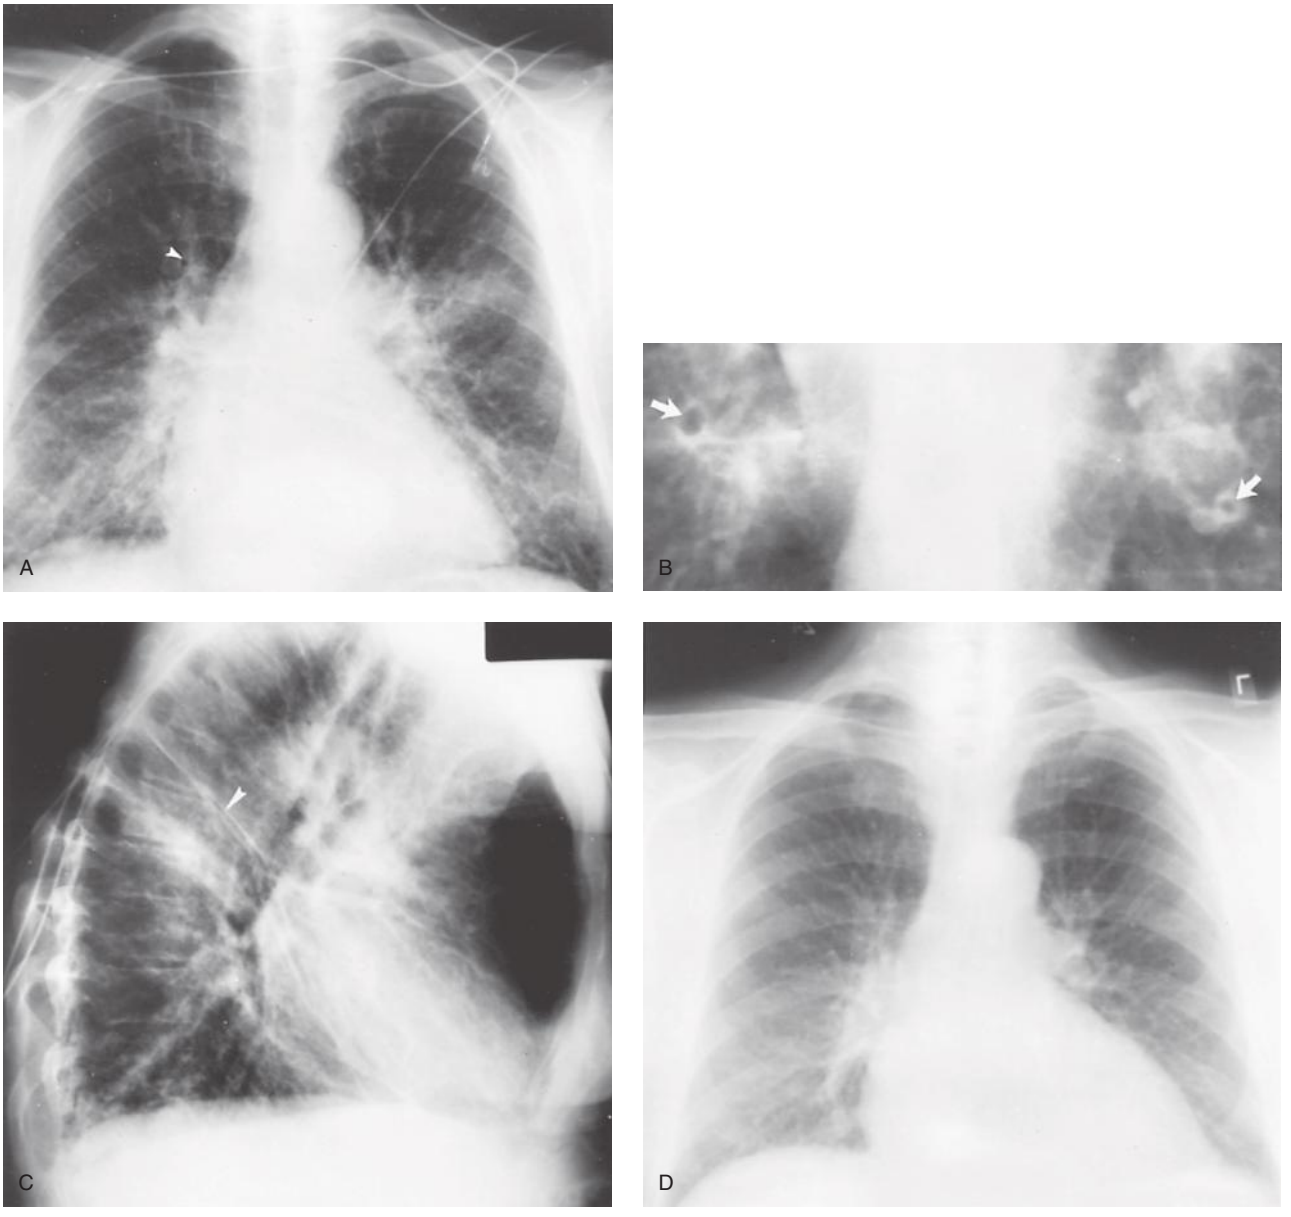

FIGURE 63.13. Interstitial edema. **A:** Posteroanterior film of a patient with congestive heart failure shows cardiomegaly, increased interstitial markings, and right-sided peribronchial cuffing (*arrowhead*) secondary to interstitial edema. **B:** Enlargement of a posteroanterior film of a different patient shows bilateral peribronchial cuffing (*arrows*). **C:** Lateral view of the first patient shows a small amount of fluid in the fissures (*arrowhead*). **D:** Follow-up film of the same patient after 6.5 weeks. Resolution of the congestive heart failure and interstitial edema has occurred. The size of the vessels in the upper lobes is greater than that of the vessels in the bases, suggesting that redistribution is still present.

vascular pedicle, azygos vein, and hilar vessels are large. In pure capillary permeability edema, there is no increase in blood volume, and therefore the vascular pedicle and azygos vein remain normal in size; no signs of pulmonary venous hypertension are present, and heart size is also normal. When different types of edema coexist, edema may occur at lower left atrial pressures, and wedge pressure readings may be low or only slightly elevated [24].

Acute Respiratory Distress Syndrome

Numerous factors can be responsible for ARDS, but the common denominator is always an acute injury to the alveolocapillary unit. The pathologic alterations with corresponding radiologic changes occur 12 to 24 hours after the first appearance of respiratory symptoms. Insidious accumulation of edema fluid in the extravascular space occurs. This appears to be confined to the true unrestricted interstitial space, in which the basal laminae of the epithelium and endothelium are separated, and does not appear in the restricted interstitial space with fused basal laminae [25].

The corresponding radiologic picture is a perihilar, perivascular haziness with peribronchial cuffing. Only occasionally are Kerley A and B lines seen; in one series, they were noted in only 5 of 75 cases [26]. During the acute stage, the alveoli also become nonhomogeneously filled with a proteinaceous and often hemorrhagic cell-containing fluid. Hyaline membranes form in

FIGURE 63.14. Alveolar pulmonary edema. Butterfly pattern of pulmonary edema can be seen in the perihilar areas.

the alveoli and sometimes in the alveolar ducts. The radiologic picture is one of patchy, ill-defined, confluent miliary nodular or alveolar densities that are not rapidly reversible (Fig. 63.16).

The course of ARDS is highly variable. In some patients, reabsorption of the exudates is complete within a few days, thereby producing radiologic clearing of the densities. In some, there is a delayed clearing of the exudates, with a corresponding delay in clearing of the radiologic picture. In a third group, progressive fibrosing alveolitis follows. The progression of fibrosis and the degree of tissue derangement do not correlate with the duration of the disease. Radiologically, this phase presents a diffuse, fibrotic pattern.

After the first week, the radiologist's main concern is the recognition of superimposed complications, such as pulmonary infections, oxygen toxicity, barotrauma, and pulmonary embolism with infarction. When clinical signs and symptoms of infection are present and the radiographic picture deteriorates, pneumonia should be suspected. Development of cavities and a change in the character of the densities should lead to suspicion of superimposed abscess, infarction, or cardiac failure. Unger et al. [27] showed that only direct hemodynamic measurements of the pulmonary capillary wedge pressure provide a dependable means of detecting superimposed failure in cases of

FIGURE 63.15. Asymmetric pulmonary edema. **A:** Preoperative posteroanterior film shows a right upper lobe pulmonary nodule (*arrowhead*). **B:** Anteroposterior film shows changes secondary to the right upper lobe lobectomy. A right pulmonary embolism developed after the film was taken. **C:** Asymmetric pulmonary edema is seen developing in the left side only, presumably due to the lack of perfusion in the right side.

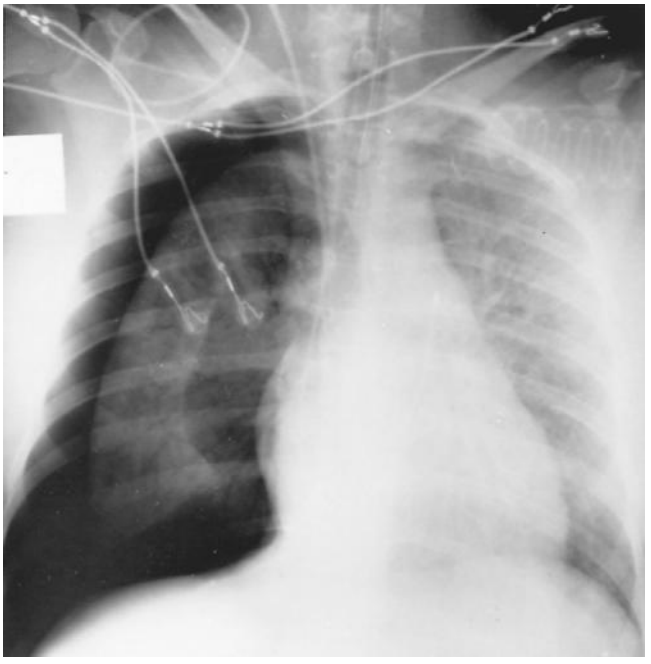

FIGURE 63.16. Acute respiratory distress syndrome with pneumothorax. Portable anteroposterior film shows bilateral alveolar densities. Air bronchograms are seen bilaterally. Note pattern of collapse of the relatively stiff lung when pneumothorax occurred.

ARDS. Pulmonary embolism, with or without infarction, can be verified with a pulmonary arteriogram using the Swan–Ganz catheter, already in place in most cases, to inject the contrast material.

Atelectasis and Pneumonia

Atelectasis is easily diagnosed when a characteristic linear density or large densities are seen with accompanying signs suggestive of volume loss (shift of fissures or mediastinal and diaphragmatic elevation, or both). Densities that fall between these categories, however, such as patchy infiltrates, are often indistinguishable from pneumonia on a single study.

In the presence of opacities that are not readily diagnosed as atelectasis, pneumonia should be strongly considered. Aspirates for culture should be obtained from the lung periphery, with care to bypass the upper airway because the central airways become readily colonized after placement of a tracheostomy or endotracheal tube [28]. Open lung biopsy is sometimes necessary for diagnosis (Fig. 63.17).

Chemical Aspiration Pneumonia

The extent and severity of pulmonary injury after aspiration of gastric contents depend on the volume and character of the aspirated material (see Chapter 54) [29–34] (Fig. 63.18). Pathologically, the lungs show areas of atelectasis within minutes; up to 1 hour after aspiration, however, only mild microscopic abnormalities are present (interstitial edema with capillary congestion). These progress to complete desquamation of the bronchial epithelium and polymorphonuclear leukocyte

FIGURE 63.17. *Pneumocystis jiroveci* pneumonia. **A:** Posteroanterior view baseline film shows diffuse interstitial infiltrates secondary to Wegener's granulomatosis. (Patient was medicated with cyclophosphamide [Cytoxan] and prednisone.) **B:** Follow-up film after increasing dyspnea and interstitial infiltrates developed. Appearance of lung parenchyma is indistinguishable from that of pulmonary edema. Open lung biopsy revealed *P. jiroveci* pneumonia.

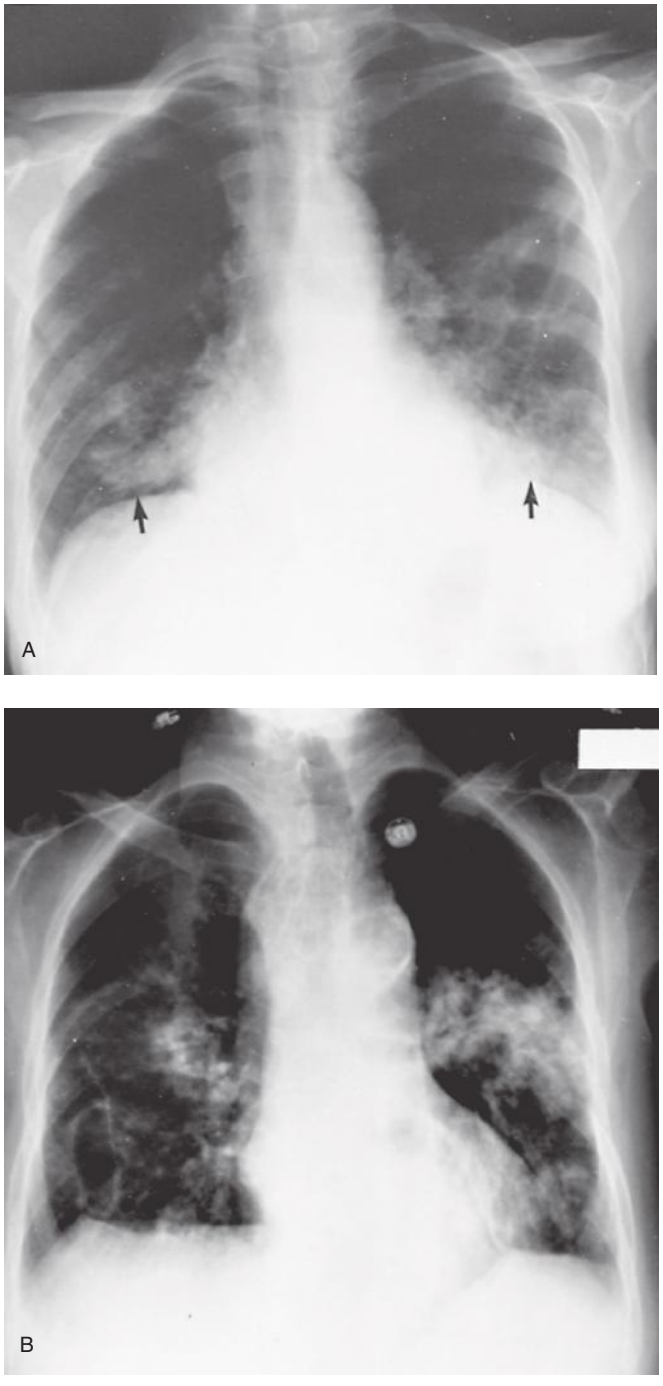

FIGURE 63.18. Aspiration pneumonia. **A:** Posteroanterior view of the chest shows bilateral basal densities (*arrows*) in a patient with aspiration pneumonia. **B,C:** Posteroanterior and lateral views in another patient show patchy densities scattered in both lungs from aspiration pneumonia.

infiltration of the area (bronchiolitis). Alveolar spaces fill with edema fluid, red blood cells, and polymorphonuclear leukocytes (alveolar infiltrates), progressing to consolidation in 24 to 48 hours. Formation of hyaline membranes occurs by 48 hours and organization or resolution within 72 hours. Complete resolution, focal parenchymal scars, or bronchiolitis obliterans may follow.

From the preceding discussion, it is clear that after aspiration, the chest film may show any finding or changes, ranging from interstitial edema or opacities simulating pneumonia to changes of ARDS. In ICU patients who aspirate, the incidence of complications is increased. In 75% of young patients without underlying medical disease, aspiration pneumonia follows an uncomplicated course, and the chest radiograph clears after 7 to 10 days. However, ICU patients are particularly prone to development of infectious complications, such as pneumonia, abscess formation, ARDS, and bronchiolitis, after aspiration of gastric contents.

Pulmonary Contusion, Hematoma, and Traumatic Lung Cyst

Pulmonary contusion is a frequent cause of posttraumatic pulmonary opacification (Fig. 63.19). It is often seen without evidence of rib or sternal fractures. Radiologically, it is seen as an area of increased density or a large area of consolidation with poorly defined margins that do not conform to the shape of the lobes or lung segments. The lack of sharp demarcation

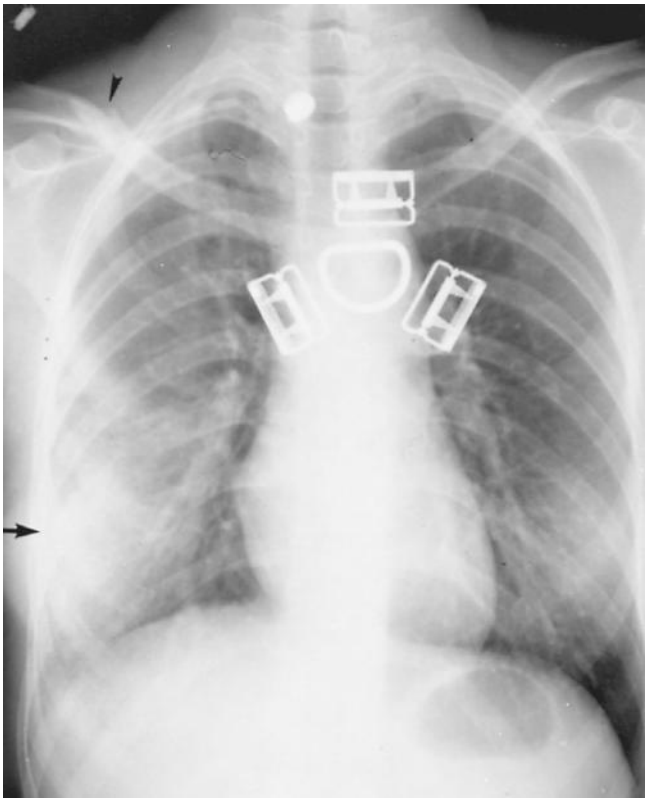

FIGURE 63.19. Pulmonary contusion. Opacification (*arrow*) of the right lower lobe after trauma secondary to lung contusion. Note fracture of the right clavicle (*arrowhead*).

of the margins is due to seepage of blood or edema fluid into the alveoli and probably into the interstitial tissues. The area of increased density or consolidation is usually seen within the first 6 hours. Improvement of the lesion is rapid, occurring within 24 to 48 hours. Complete clearing is usually seen in 3 to 10 days. Secondary infection leads to liquefaction of dead tissues and bronchial communication, producing an air-filled cavity with or without an associated fluid level.

When laceration or tearing of a lung occurs, commonly as a result of a penetrating injury or surgical resection, a pulmonary hematoma (a collection of blood within a space in the lung) forms. The cavity formed by retraction of the torn elastic tissues may be completely dense or partially air filled if bronchial communication occurs. The lesion may progressively increase in size in the next few days because of edema or seepage of blood. This is in contrast to a contusion, which regresses in size. The lesion may take weeks or months to clear. Occasionally, a clot may form and simulate an intracavitary fungus ball. Resolution may be incomplete, resulting in a pulmonary nodule.

Traumatic lung cysts also may occur after trauma. They may appear immediately after blunt trauma or may form after several hours or days. Single, multiple, or multilocular thin-walled, oval to spheric cystic spaces may be seen in the lung periphery or subpleurally. Bleeding into the cyst from ruptured capillaries may occur. The lung cysts persist for long periods, often more than 4 months, but progressively decrease in size during this period.

Pulmonary Thromboembolism and Infarction

Episodes of pulmonary thromboembolism usually show some changes on plain chest radiographs, such as linear atelectasis, elevation of a hemidiaphragm, or pleural effusion. Most embolic occlusions occur in the lower lobes, the right more often than the left, probably as a result of hemodynamic flow patterns (see Chapter 52).

The radiographic changes can be divided into two categories: those with increased radiographic density (with hemorrhagic consolidation or infarction, or both) and those without. Changes without associated hemorrhagic consolidation or infarction are seen only when the thromboembolism is massive. These changes consist of the following:

1. An area of increased radiolucency (local oligemia) of the lung within the distribution of the occluded artery (Westermark sign) [35]. This is seen within the first 36 hours after the thromboembolic episode.
2. Enlargement of a major hilar vessel secondary to distention of the vessel by the bulk of the thrombus.
3. Signs of volume loss, such as displacement of the hemidiaphragm or fissures, or both. Volume loss is probably caused by a deficit in pulmonary surfactant, resulting from loss of perfusion. It is more frequent in cases accompanied by pulmonary infarction.
4. Cor pulmonale, recognized when right ventricular cardiac enlargement, main pulmonary artery enlargement, increased size of the major hilar vessels with sudden tapering of the vessels, and dilatation of the azygos vein and superior vena cava are seen. These changes occur with widespread multiple peripheral embolism or massive central embolization.

Thromboembolism with increased density or infarction shows the same changes as thromboembolism without increased density, except for the sign of peripheral oligemia. The area of oligemia is replaced by parenchymal consolidation from tissue necrosis or hemorrhage and edema. The density is almost always pleurally based. Hampton's hump, a homogeneous, wedge-shaped density with its base contiguous to the pleural surface and apex toward the hilum, is rarely seen but is highly suggestive of pulmonary infarction.

The consolidations vary in size, but most are 3 to 5 cm in diameter (Fig. 63.20). Air bronchograms are rarely present; cavitation is unusual and, if present, suggests septic embolization. If the consolidation is secondary to hemorrhage and edema, it clears in 4 to 7 days without residua; if the infarction leads to necrosis, resolution averages 20 days and may take as long as 5 weeks. This sequence of events is more common in patients with underlying cardiac disease. Linear densities (line shadows) representing plate-like atelectasis, parenchymal scarring, or thrombosed vessels or line shadows of pleural origin (fibrous pleural thickening or interlobular fissure thickening) are also seen radiographically in cases of thromboembolism, but all of these findings are nonspecific. Pleural effusion is at least as common as parenchymal consolidation; the amount of fluid is frequently small, and the fluid is often unilateral.

The frequent presence of underlying chest disorders, such as ARDS, pulmonary edema, associated pneumonia, or chronic obstructive lung changes, often makes the radiologic diagnosis of pulmonary embolism virtually impossible on plain chest radiographs in the ICU patient. Radioisotopic scanning provides distinctive patterns for pulmonary embolism, congestive heart failure, and emphysema. Ventilation-perfusion scans should be performed whenever pulmonary embolism is suspected in patients with normal chest films. The clearest distinguishing feature of embolism is its focal segmental or local wedge-shaped configuration. An irregular, moth-eaten pattern, nonsegmental in nature, is seen in pulmonary congestion and chronic obstructive pulmonary disease. A nonmatched area on a scan (a combination of normal ventilation and abnormal perfusion) in the correct temporal setting is highly suggestive of embolism. Scans provide guidelines as to the probability of emboli and serve as

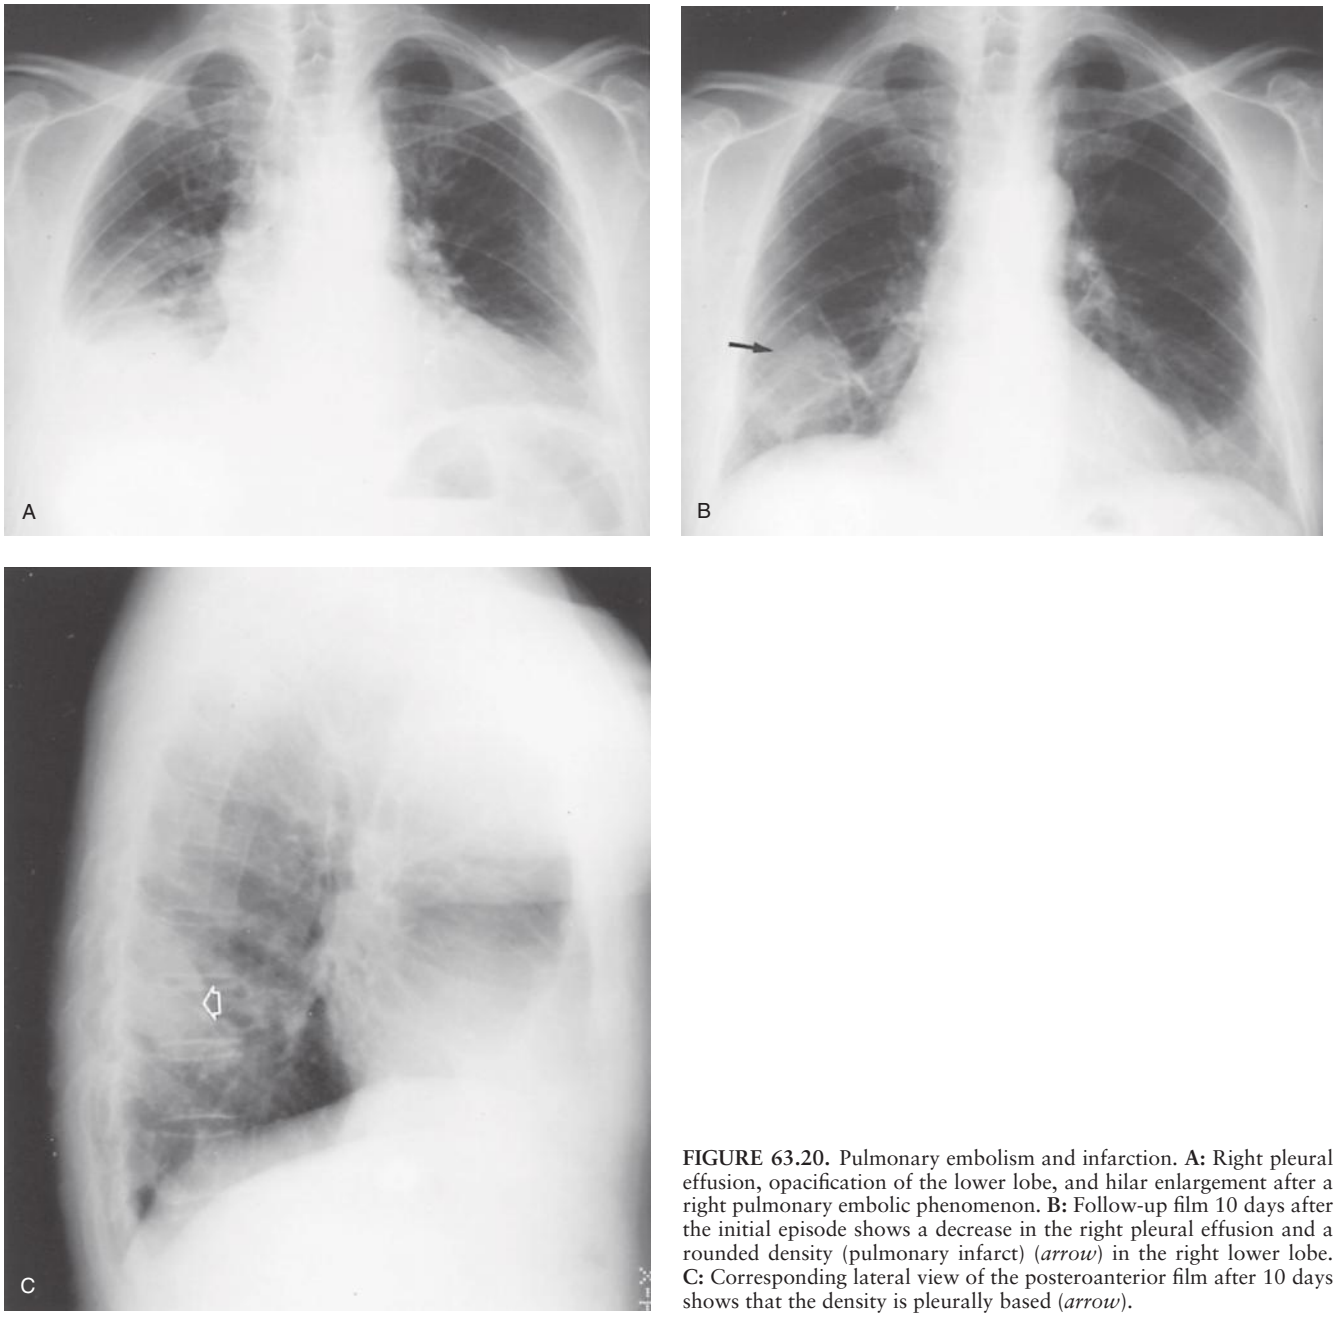

FIGURE 63.20. Pulmonary embolism and infarction. **A:** Right pleural effusion, opacification of the lower lobe, and hilar enlargement after a right pulmonary embolic phenomenon. **B:** Follow-up film 10 days after the initial episode shows a decrease in the right pleural effusion and a rounded density (pulmonary infarct) (*arrow*) in the right lower lobe. **C:** Corresponding lateral view of the posteroanterior film after 10 days shows that the density is pleurally based (*arrow*).

an excellent road map for pulmonary arteriography. They also serve as a baseline for future evaluation (see Chapter 52).

In patients with abnormalities on their chest films, multidetector CT angiography is the examination of choice [36]. And although there is a slight increase in diagnostic accuracy for pulmonary embolism by addition of CT venography, it does not appear to improve the diagnostic yield of CT pulmonary angiography enough to justify the additional radiation [37]. They can show intravascular filling defect(s) produced by the embolus/emboli up to the segmental artery level (Fig. 63.21). The gold standard for the diagnosis of thromboembolism is multidetector CT angiography.

Fat Embolism

Fat embolism usually follows trauma with associated fracture, but conditions such as severe burns, diabetes mellitus, fatty liver, pancreatitis, steroid therapy, sickle cell anemia, surgery for prosthetic hip placement, and acute osteomyelitis can also result in fat embolism. Most of the fat is believed to originate as neutral fats released from the marrow, entering the circulation via torn veins in the injured area and, to a lesser extent, through the lymphatic system. Fats are then transported to the lungs in the form of neutral triglycerides. Mechanical occlusion of small vessels occurs, but no significant physiologic abnormality results unless large amounts of fat embolize a great number of vessels. In the lungs, hydrolysis of fat occurs through the action of lipase, converting the triglycerides to unsaturated chemically toxic fatty acids. Congestion, edema, intra-alveolar hemorrhage, and loss of surfactant occur. The fat globules also appear to induce platelet and erythrocyte aggregation and stimulation of intravascular coagulation.

Another probable source of fat is the body fat deposits. Free fatty acids are mobilized and released into the blood after stress. Chylomicrons coalesce into larger fat globules; these

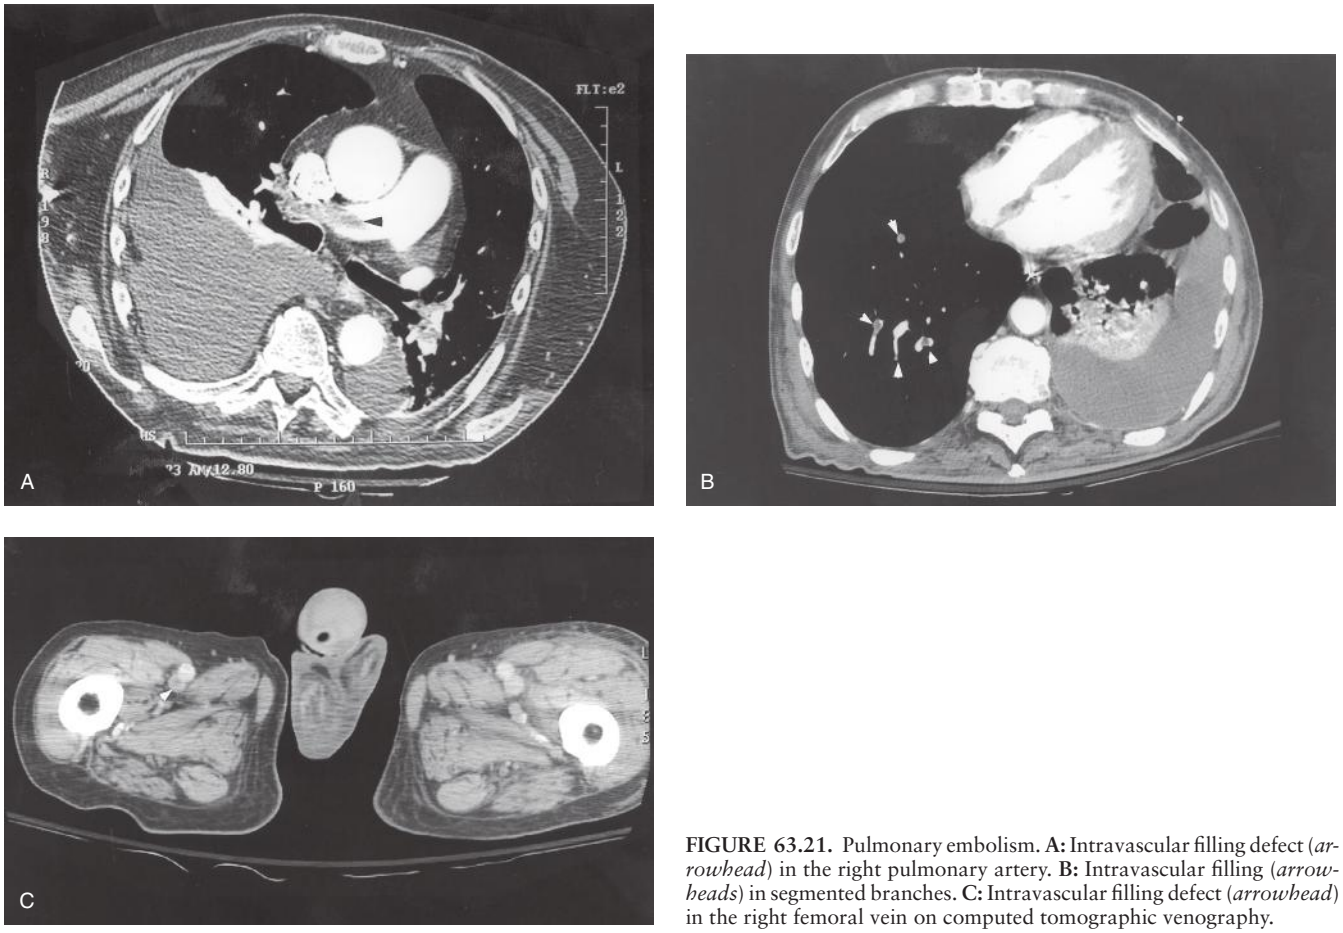

FIGURE 63.21. Pulmonary embolism. **A:** Intravascular filling defect (*arrowhead*) in the right pulmonary artery. **B:** Intravascular filling (*arrowheads*) in segmented branches. **C:** Intravascular filling defect (*arrowhead*) in the right femoral vein on computed tomographic venography.

fat droplets are then carried into the lungs, where they are hydrolyzed by lipase into the chemically active fatty acids.

Continuous fat embolization, conversion of triglycerides to fatty acids, and intravascular coagulation occur as an ongoing process. Usually within 1 to 3 days, the changes are sufficient to produce the full-blown picture of the syndrome. Emboli pass from the pulmonary circulation into the systemic circulation and lodge in different organs, notably the brain, kidney, and skin.

The chest radiograph is normal in 87.5% of patients in whom the diagnosis of fat embolism is made based on lipiduria [38]. In those with positive chest findings, widespread or patchy areas of air space consolidation are noted, due to alveolar hemorrhage and edema distributed predominantly in the peripheral and basal areas. The densities clear in 7 to 10 days but may take 4 weeks to resolve completely. Acute cor pulmonale with cardiac failure also may be seen.

ABNORMALITIES OF THE PLEURA, MEDIASTINUM, AND DIAPHRAGM

Pleural Effusion

The appearance of fluid in the pleural space is the same whether the fluid is serous, chylous, purulent, or sanguineous. The degree of opacity of the shadow depends on the amount of fluid and presence or absence of underlying pulmonary disease. Radiologically, pleural fluid is seen as a density that is free from lung markings, displaces the lung, and most often (if free) is located in the dependent portion of the thorax. It is easily identifiable when tangent to the radiograph beam; seen *en face*, the fluid appears as a homogeneous area of increased density in the thorax. If the amount is not too large or there is no associated parenchymal consolidation, vascular markings may be seen through the area of increased density when the effusion is seen *en face*.

Free pleural fluid is not confined to any portion of the thoracic cavity, and the distribution changes with patient position. Distribution is influenced by gravity, capillary action, and resistance of the underlying lung to expansion. In the upright position, the fluid collects first in the posterior costophrenic sulcus and subsequently in the lateral costophrenic sulcus. The typical meniscal configuration of pleural fluid (Fig. 63.22) is attributed to several factors, including capillary attraction drawing the fluid superiorly between the visceral and parietal pleural surfaces, the relation of the fluid collection to the radiograph beam, the greater retractility of the lung periphery, and the tendency of the lung to preserve its shape while recoiling from the chest.

Subpulmonary collection of pleural fluid is the typical pattern of free fluid collection in the upright position if no pleural adhesions are present [39]. Radiologically, the fluid presents as an opaque density, parallel to the diaphragm and simulating an elevated hemidiaphragm (Fig. 63.23). Subpulmonic effusion is recognized in the posteroanterior (PA) film when the apex of the pseudodiaphragmatic shadow peaks more laterally than usual. The pulmonary vessels in the lung posterior to the subpulmonic collection cannot be seen through the pseudodiaphragmatic contour because of the greater density of the fluid collection. On the left side, there is increased distance

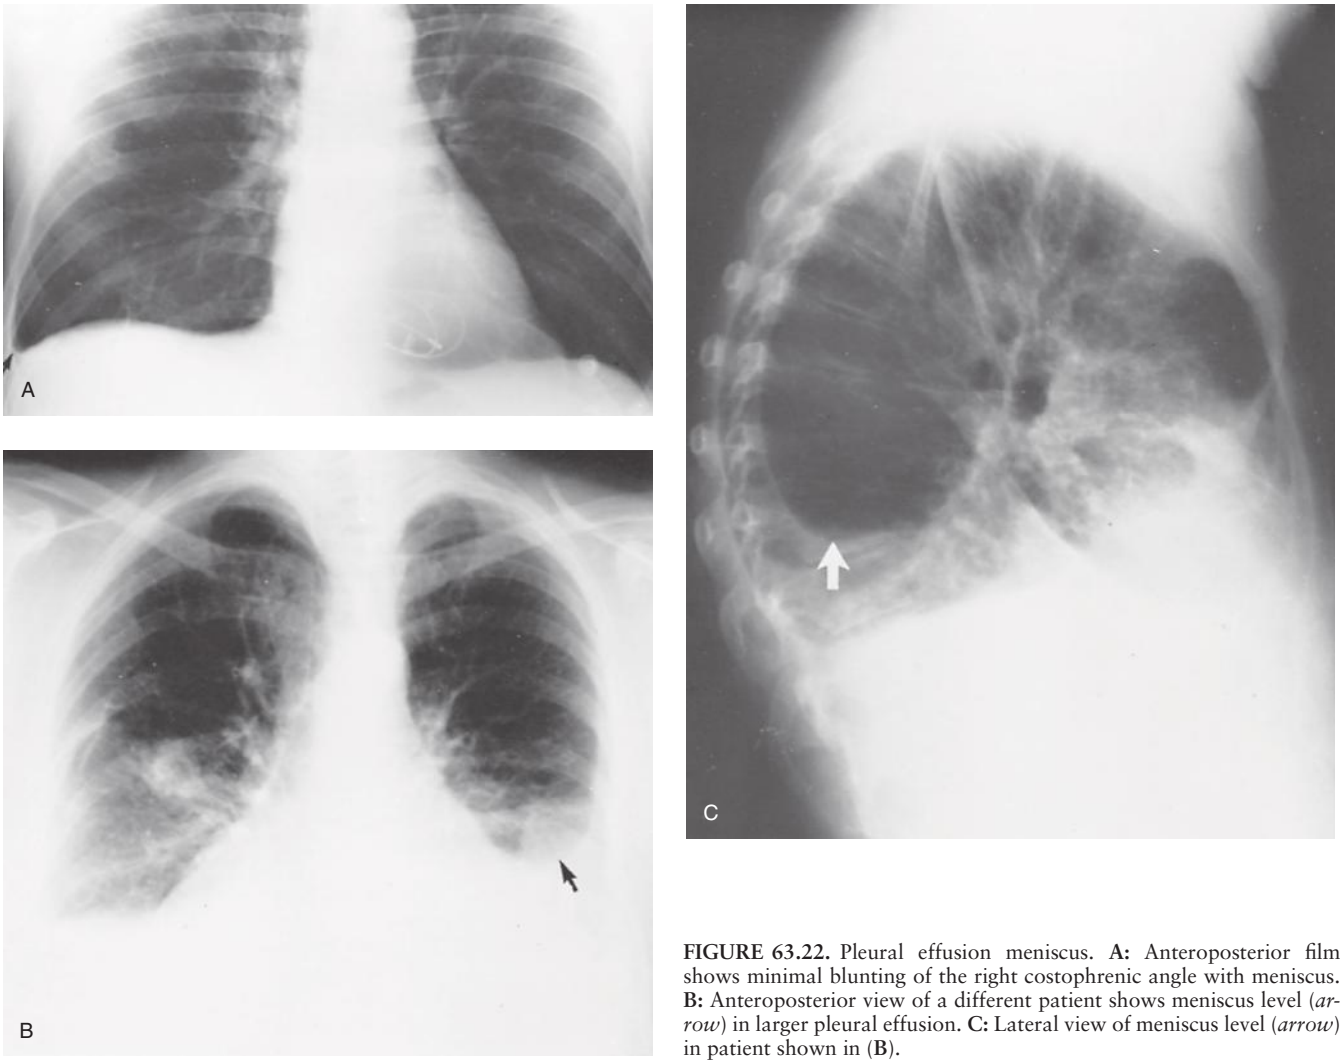

FIGURE 63.22. Pleural effusion meniscus. **A:** Anteroposterior film shows minimal blunting of the right costophrenic angle with meniscus. **B:** Anteroposterior view of a different patient shows meniscus level (*arrow*) in larger pleural effusion. **C:** Lateral view of meniscus level (*arrow*) in patient shown in (**B**).

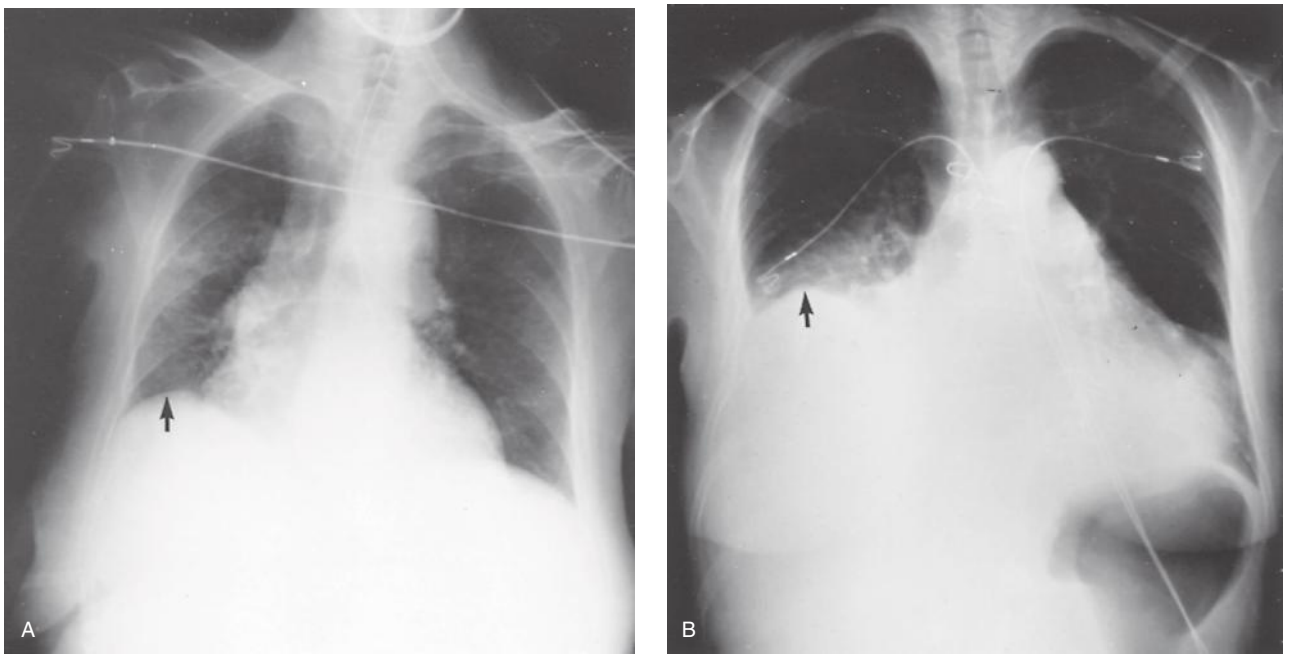

FIGURE 63.23. Subpulmonic effusion. Anteroposterior views of two different patients (**A,B**) with the subpulmonic effusion simulating elevated hemidiaphragms, with a more lateral than usual peak (*arrows*).

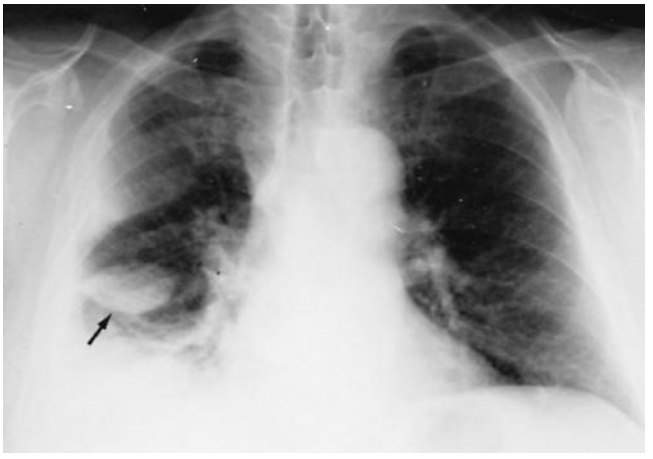
between the gastric bubble and the base of the lung. Often, the costophrenic sulcus is blunted.

The appearance of interlobar fluid depends on the shape and orientation of the fissure, location of fluid within the fissure, and direction of the radiograph beam. Often, an elliptic or rounded, sharply marginated density is identified on PA or lateral films (Fig. 63.24). A middle lobe step, or step-off appearance, may be seen when the fissures are incomplete laterally [40]. In the supine position, fluid layers may be seen posteriorly, producing a hazy density over the hemithorax. These layers also may produce an apical cap [41] (Fig. 63.25A) or widening of the paravertebral pleural line [42].

A lateral decubitus view can be obtained to confirm the presence of pleural effusion, rule out a parenchymal process coexisting with an effusion, or quantify grossly the amount of fluid in the pleural cavity. In the lateral decubitus view, fluid forms a shadow parallel to the thoracic wall (Fig. 63.25B,C). When a decubitus view cannot be obtained for a completely immobile patient, an ultrasonographic evaluation can be performed. Sonographically guided thoracentesis enhances the likelihood of a successful tap in these cases and when the fluid is loculated.

Pleural effusion occurs quite frequently in the first week after thoracic or abdominal surgery (Fig. 63.26). After



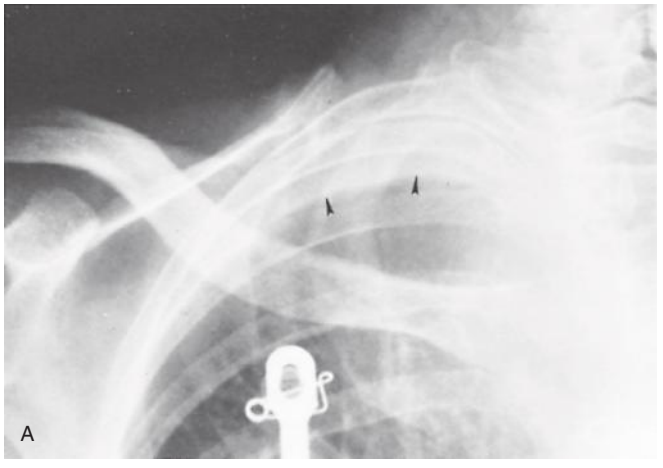


FIGURE 63.24. Interlobar effusion. Pseudotumor appearance of fluid (*arrow*) within the minor fissure.

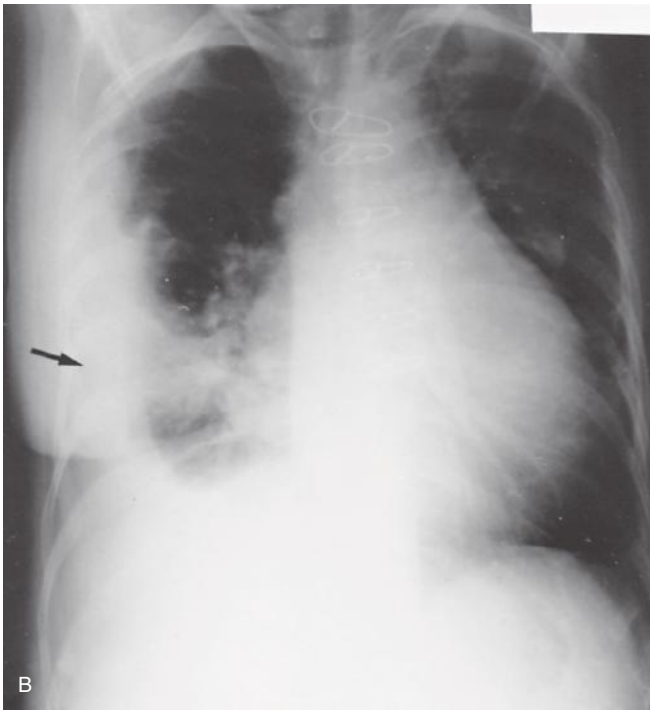

FIGURE 63.25. Pleural fluid in recumbency. **A:** Arrowheads show fluid tracking over the lung apex (apical cap) in the recumbent position. **B:** Right lateral decubitus view (right side down) shows layering of the pleural fluid (*arrow*). **C:** Right lateral decubitus view shows layering of pleural fluid and tracking into the minor fissure (*arrows*). Note bilateral apical caps (*arrowheads*).

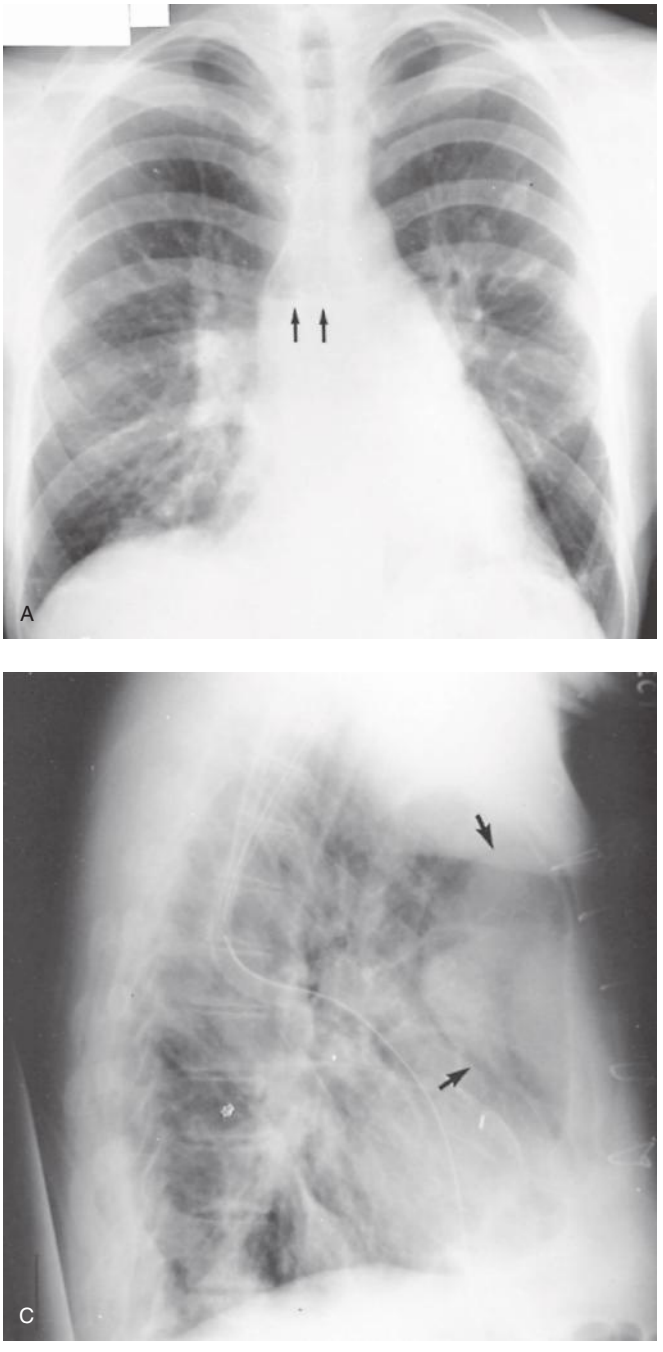

FIGURE 63.26. Fluid collections after surgery. **A:** Posteroanterior film of a patient several weeks after coronary artery bypass graft surgery shows an air-fluid level (*arrows*) superimposed on the shadow of the base of the heart. **B:** Lateral film of the same patient shows the air-fluid level (*arrows*) in the anterior mediastinum. **C:** Lateral film of a different patient outlines a semicircular soft tissue density (*arrows*) in the anterior mediastinum, representing a loculated fluid collection after surgery.

pneumonectomy, increasing amounts of fluid are noted to accumulate in the thorax. This accumulation may be rapid or may occur over a period of 1.5 to 2.0 months after surgery, eventually becoming organized.

Empyema and Peripheral Lung Abscess

An intrathoracic fluid-containing cavitary lesion adjacent to the chest wall may represent either a lung abscess (Fig. 63.26) or an empyema. By conventional radiography, visualization of the three-dimensional shape of the pleural lesion as oblong, flattened, and conforming to the shape of the thorax helps differentiate between the two lesions. A discrepancy in the width of the air-fluid levels between two 90-degree projections (i.e., when a wider level is apparent on AP than on lateral view, or vice versa) also suggests a pleural location. Abscesses are more spheric than empyemas and show no significant discrepancy in width on the two projections.

Often, however, one cannot distinguish between abscesses and empyemas by conventional radiography. In these cases, CT should be considered for adequate localization because there is a radical difference between the appropriate methods of treatment. Empyemas must be drained with a thoracostomy tube, whereas abscesses can be treated medically. Pugatch et al. [43] and Baber et al. [44] showed the usefulness of CT in differentiating between empyemas and abscesses. The former group showed that with CT, abscesses appear thick walled and irregular in shape, with an undulating or ragged inner wall. They often have multiple loculations, and their shape is unaltered by a change in patient position from supine or prone to decubitus. In contrast, empyemas appear more regular in shape and have smooth inner walls of uniform width. Their margins are sharply defined, with no loculi, and the shape of the cavity

often changes with a change in patient position from supine or prone to decubitus.

Postpneumonectomy Space and Bronchopleural Fistula

After a pulmonary resection, air is seen in the pleural space from small air leaks in the cut surface of the lung. Small amounts of fluid also may be present. Air is usually reabsorbed gradually and continuously, followed by reabsorption of fluid, and both may be completely gone within the first 24 to 48 hours. Prolonged persistence of air and fluid may require drainage. Residual spaces may remain indefinitely without untoward effects and do not necessarily suggest bronchopleural fistula. Malamed et al. [45] stated that in 86% of cases, these residual spaces are obliterated within a year.

Air and fluid are always apparent in the basilar zone of the hemithorax after a pneumonectomy and may be loculated in some cases. The rate of fluid accumulation is variable, but the space left by a pneumonectomy is usually completely obliterated within 3 weeks to 7 months. If the fluid level decreases rather than increases, one must differentiate between a benign decrease in fluid and a bronchopleural fistula with loss of the fluid through the tracheobronchial tree.

A bronchopleural fistula displaces the mediastinum to the opposite side because of an increase in the amount of air on the operated side. Benign descent in fluid level without a fistula shows no associated mediastinal shift. Total clearing of fluid from the space and coughing up of fluid and blood suggest a bronchopleural fistula. Sudden reappearance of air in an obliterated space suggests either a bronchopleural fistula or a gas-forming infectious process.

A bronchopleural fistula can occur any time during the postoperative period but more often occurs within 8 to 12 days after surgery. If seen within the first 4 postoperative days, it is probably secondary to a mechanical failure of closure of the stump and requires reexploration and reclosure. A bronchopleural fistula also may occur after a suppurative pneumonia or massive pulmonary infarction, or even spontaneously.

Extremely rapid filling of a space with fluid suggests infection, hemorrhage, or malignant effusion. If secondary to infection, the rapid increase in height of the fluid level is usually associated with fever and leukocytosis. Empyema may occur alone or may be associated with a bronchopleural fistula. On the other hand, a bronchopleural fistula can occur without associated empyema, and the fluid in the pleural space in these cases is sterile.

Several methods have been used to diagnose bronchopleural fistulas, including the instillation of methylene blue into the pleural space [46], sinography, and bronchography [47]. Zelefsky et al. [48] demonstrated small leaks using xenon-133 in a gaseous state in a ventilation study. In the presence of a fistula, the xenon-133 activity accumulated in the pleural space and remained trapped within the pleural space on the washout study. The simplicity and reliability of this procedure make it a useful diagnostic tool.

Pericardial Effusion, Hemopericardium, and Tamponade

Fluid or blood in the pericardial cavity is suspected when an enlargement of the cardiac silhouette with a water-bottle configuration is noted; this typical configuration is not often seen. Fluoroscopy demonstrating diminished pulsations is frequently helpful but not diagnostic. In 1955, Kremens [49] and Torrance [50], using laminography, described the relation of the epicardial fat line to pericardial effusion. In 1968, Lane and Carsky [51,52] added the epicardial fat pad sign, as seen in the lateral radiograph, as a diagnostic aid. Several authors subsequently described the epicardial fat pad sign in the frontal projection [52,53]. This sign is seen as a strip of soft tissue greater than 2 mm interposed between the anterior mediastinal fat and the epicardial fat (Fig. 63.27).

Chen et al. [54] also described widening of the tracheal bifurcation angle in the presence of pericardial effusion on plain films. However, CT and ultrasound remain the definitive tools for the diagnosis of pericardial effusion, and ultrasound can be performed at the bedside.

Laceration of the Thoracic Aorta and Brachiocephalic Arteries

The initial diagnosis of injury to the thoracic aorta (Fig. 63.28A) and the brachiocephalic arteries may be suspected on the basis of clinical signs. The presence of fractures of the first and second ribs suggests the possibility of associated vascular injuries. Confirmation by diagnostic imaging is recommended, regardless of a normal radiologic appearance on plain chest films, if the mechanism of injury could potentially affect the thoracic aorta and brachiocephalic vessels.

Laceration of the aorta and brachiocephalic vessels most frequently follows rapid deceleration in vehicular accidents or falls. The differences in the degree of fixation of the different segments of the aorta may cause sufficient stresses between segments in forceful deceleration to cause closed rupture. Flexion stress and a sudden increase in intraluminal pressure also may be the cause of injury.

In 69% to 89% of cases, injury to the aorta occurs at the isthmus, the area between the origin of the left subclavian artery and the attachment of the ductus arteriosus. In the remaining cases, injury is equally divided among the ascending aorta, aortic arch, and descending aorta [55]. Tear is almost always transverse and may involve only one or all layers. When all layers are involved, exsanguination occurs; if the tear is only through the intima or the intima and media, the adventitia and the mediastinal pleura can contain the blood at least temporarily. Parmley et al. [47] emphasized that if the diagnosis is missed, up to 90% of those who survive the initial impact will die within 4 months. Therefore, the diagnosis must be very aggressively pursued.

In an adequately obtained plain film of the chest, mediastinal widening appears to be the most useful sign suggesting a mediastinal hematoma [56,57]. A perfectly normal aortic outline without mediastinal widening makes the diagnosis of aortic or brachiocephalic vessel injury very unlikely.

Aortic and brachiocephalic injuries should be confirmed [58,59]. Magnetic resonance imaging (MRI), transesophageal color-flow Doppler echocardiography, contrast-enhanced CT [60], and aortography all have high sensitivities. (See Chapter 36 for a complete discussion of the circumstances under which each method is preferred.) If static filming is performed during aortography, two angiographic series must be obtained, with the right posterior oblique projection as the acceptable standard and the frontal or AP projection as the second view (Fig. 63.28B,C).

Traumatic Diaphragmatic Hernia

Severe diaphragmatic injury after blunt or penetrating trauma to the thoracoabdominal area may allow escape of abdominal contents into the thorax. The presence of a gas-containing viscus within the thoracic cavity is the hallmark of traumatic

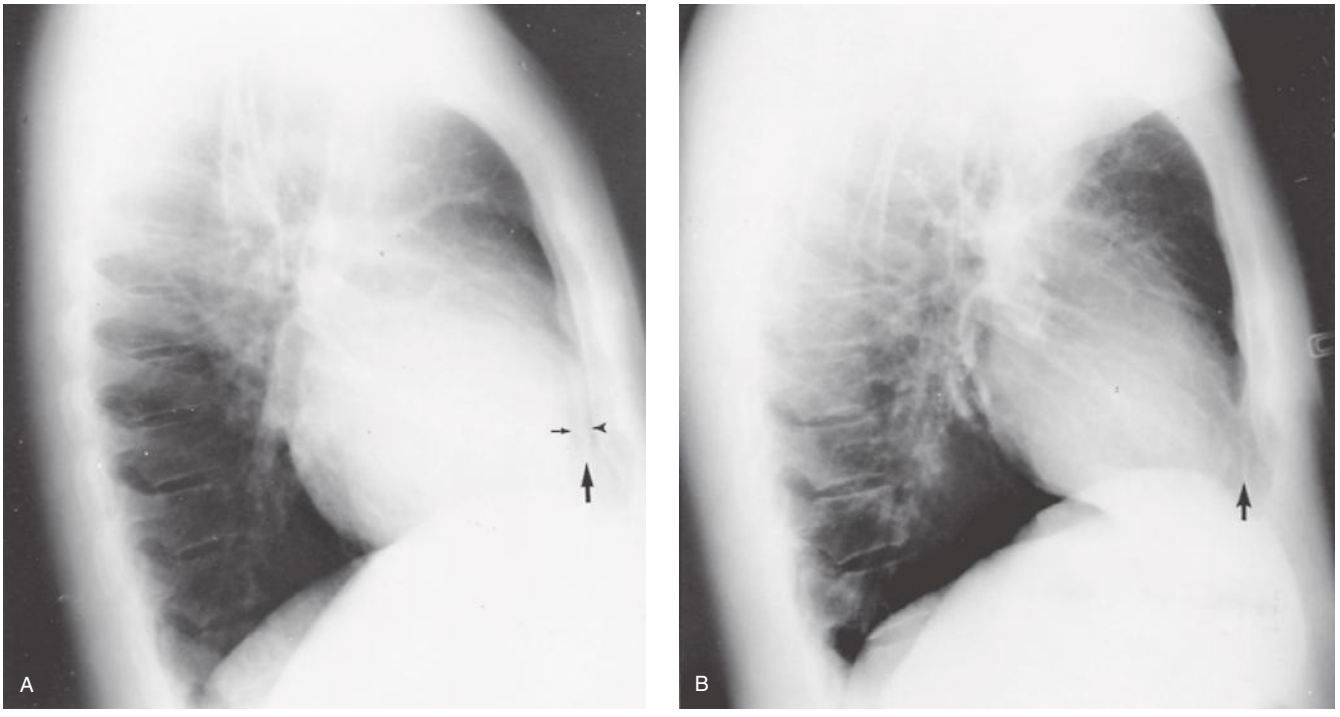

FIGURE 63.27. Pericardial effusion. **A:** Lateral view of the chest shows the pericardial effusion as a strip of density (*long arrow*) sandwiched between two strips of lucency. The posterior strip of lucency represents epicardial fat (*short arrow*), and the anterior strip represents mediastinal fat (*arrowhead*). An increase of the density to greater than 2 mm suggests pericardial fluid (effusion or hemopericardium). **B:** Follow-up lateral view of the same patient after resolution of the pericardial effusion. The cardiac size is smaller, and the width of the strip of density (*arrow*) has returned to normal.

diaphragmatic rupture with an associated hernia. Most hernias occur on the left side, because the liver acts as a buffer on the right. Very often, the condition may be overlooked during the initial phase (the first 14 days). During the latent period, which varies considerably, patients may have vague chronic symptoms or no symptoms at all. Symptomatic patients may be subjected to numerous diagnostic procedures in an attempt to unravel their vague abdominal complaints, which probably are due to intermittent incarceration of the herniated viscus. The obstructive phase may occur at any time, the obstruction being secondary to incarceration or strangulation.

Radiologic findings on plain chest films vary from what appears to be merely an arched or elevated diaphragm (with or without platelike atelectasis in the adjacent lung) to visualization of a hollow viscus above the diaphragm with a marked shift in the heart and mediastinum. Ball et al. [61] suggested that the chest film is the most reliable means of determining the correct diagnosis. Additional diagnostic aids include contrast studies with barium to demonstrate the presence of a viscus above the diaphragm, diagnostic pneumoperitoneum to outline the defect with free passage of air from the peritoneum into the pleural or pericardial cavity, and introduction of contrast into the pleural space to demonstrate free passage from the pleura into the peritoneal cavity. Lung and liver–spleen scans also have been used, as has ultrasound.

Toombs et al. [62] and Heiberg et al. [63] demonstrated the usefulness of CT in recognizing traumatic rupture of the diaphragm. CT identifies parts of the diaphragm as a separate structure, and a discontinuity in its contour can be recognized. The posterolateral portions of the diaphragm are well demonstrated, and tears are easy to see in these areas. Dynamic CT is particularly helpful. We found direct coronal sections (whenever the patient can be appropriately positioned in the CT gantry) to be extremely useful in diagnosing diaphragmatic tears with herniation. MRI is the definitive diagnostic imaging modality. It is able to image the muscles of the diaphragm, the defect or rent, and the bowel herniating through it.

EXTRA-ALVEOLAR AIR AND SIGNS OF BAROTRAUMA

Pneumothorax

The diagnosis of pneumothorax is made when air is seen superior, inferior, lateral, or anterior to the lung and the visceral pleural line is identified. The air creates a zone of radiolucency devoid of lung markings between the lung and the thoracic wall. The lung partially (Fig. 63.29A) or wholly (Fig. 63.29B) collapses and drops to the most dependent position, slung by its fixed attachment at the pulmonary ligament. The density of the partially collapsed lung may not increase when compared with the opposite side because blood flow through it diminishes correspondingly, the degree of diminution of flow progressing with increasing collapse. Thus, the ratio of air to blood is maintained and the lung density remains unaltered [64].

As air accumulates in the pleura, the mediastinum tends to shift to the opposite side. This is best seen in a film taken during the expiratory phase of respiration. For the mediastinum to shift, the intrapleural pressure must become merely less negative, not necessarily positive, on the side of the pneumothorax. If the mediastinum is not fixed, the diminished negative pressure on the side of the pneumothorax creates sufficient imbalance between the pleural pressures of the two sides to cause mediastinal displacement during the expiratory phase of

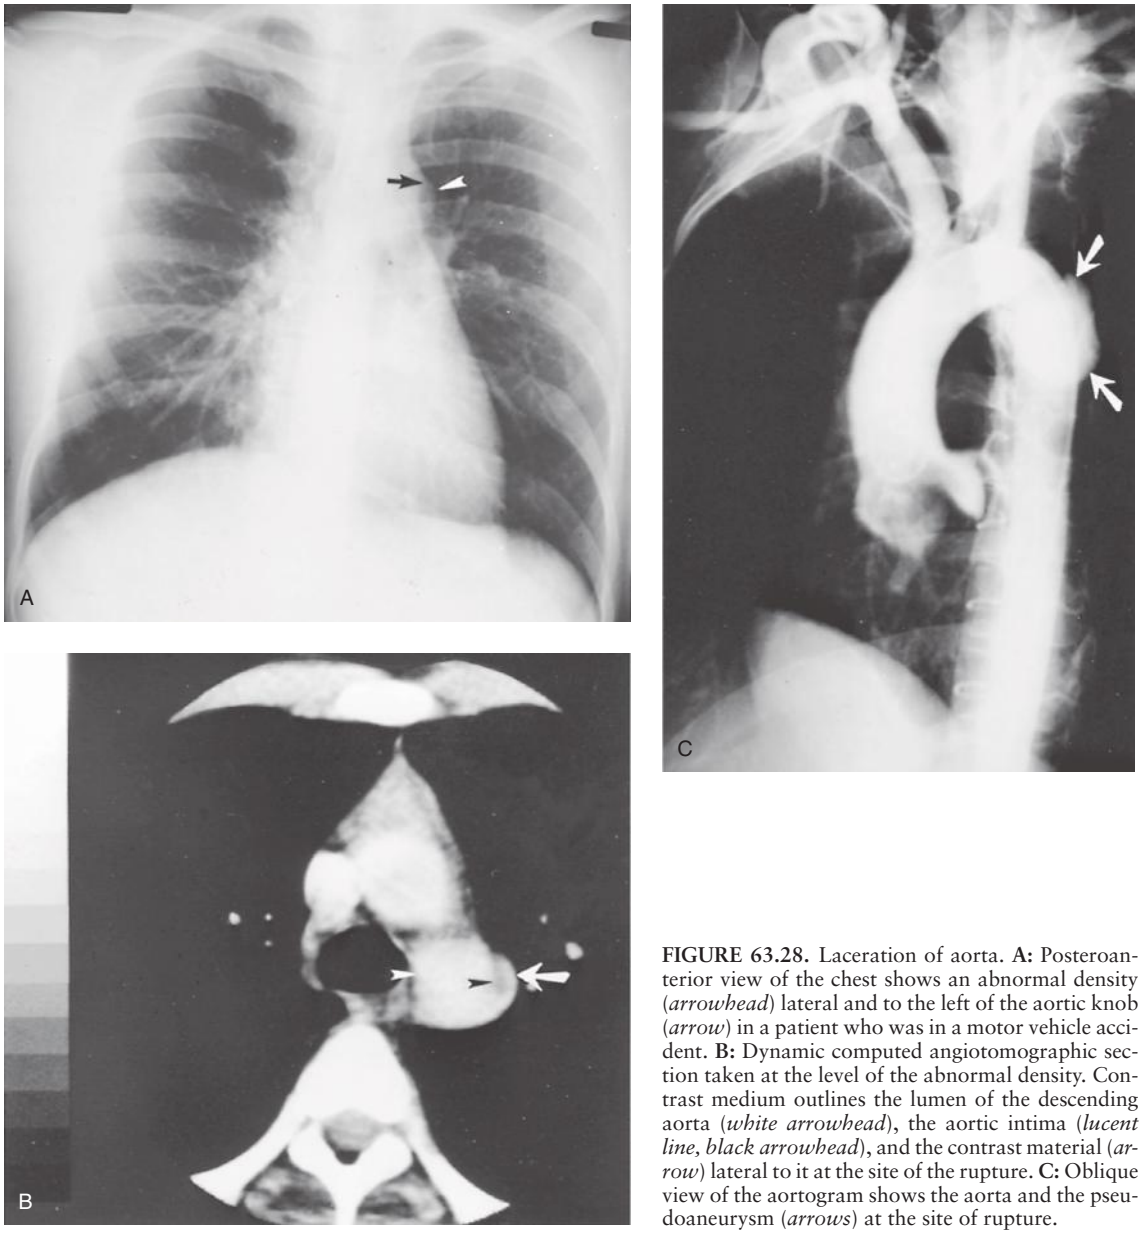

FIGURE 63.28. Laceration of aorta. **A:** Posteroanterior view of the chest shows an abnormal density (*arrowhead*) lateral and to the left of the aortic knob (*arrow*) in a patient who was in a motor vehicle accident. **B:** Dynamic computed angiotomographic section taken at the level of the abnormal density. Contrast medium outlines the lumen of the descending aorta (*white arrowhead*), the aortic intima (*lucent line, black arrowhead*), and the contrast material (*arrow*) lateral to it at the site of the rupture. **C:** Oblique view of the aortogram shows the aorta and the pseudoaneurysm (*arrows*) at the site of rupture.

respiration. If the mediastinum is not fixed, tension pneumothorax causes a shift of the mediastinum to the opposite side during inspiratory and expiratory phases of respiration. In addition, flattening, with progression to reversal of the normal curve of the hemidiaphragm, occurs in tension pneumothorax. Rhea et al. [65] described a simple reproducible means of measuring the percentage of pneumothorax present in upright PA and lateral films. The percentage of pneumothorax is calculated by means of an average interpleural distance, using the total lung volume of the partially collapsed lung and the total hemithoracic volume as parameters. Pneumothorax size can be predicted using a nomogram based on average interpleural distance.

The distribution of air in the pleural cavity is affected by pleural adhesions and by disease of the underlying lung. Adhesions prevent lung retraction; therefore, extensive adhesions may lead to a loculated pneumothorax. A diseased lung, especially one with scarring or atelectasis secondary to bronchial obstruction, tends to retract to a greater degree than the adjacent lung. Obstructive emphysema, consolidation, and interstitial emphysema make the lung rigid and interfere with retraction, keeping the lung or the involved segment expanded. The distribution of air is also influenced by patient position, because air rises to the nondependent portion of the thorax.

Early recognition of a pneumothorax is mandatory in ICU patients, especially those on respirators or those who are prone to barotrauma or rapid progression to tension pneumothorax. The presence of lower lobe disease, with the lobes resisting reaeration, causes air to collect in the subpulmonic region, simulating a pneumoperitoneum [66]. Thus, in ICU patients, the subpulmonic area must be carefully examined, even if the film is obtained in the upright position, because lower lobe disease, consolidation due to ARDS, and pneumonia are frequently present. In the supine patient, air collects in the anterior portion of the thorax, between the medial portion of the lung and the anterior mediastinum, or in the subpulmonic area (Fig. 63.30).

Subpulmonic pneumothorax is seen as a lucent area outlining the anterior costophrenic sulcus projected over the right or left upper quadrant [67] or only as a deep lateral costophrenic

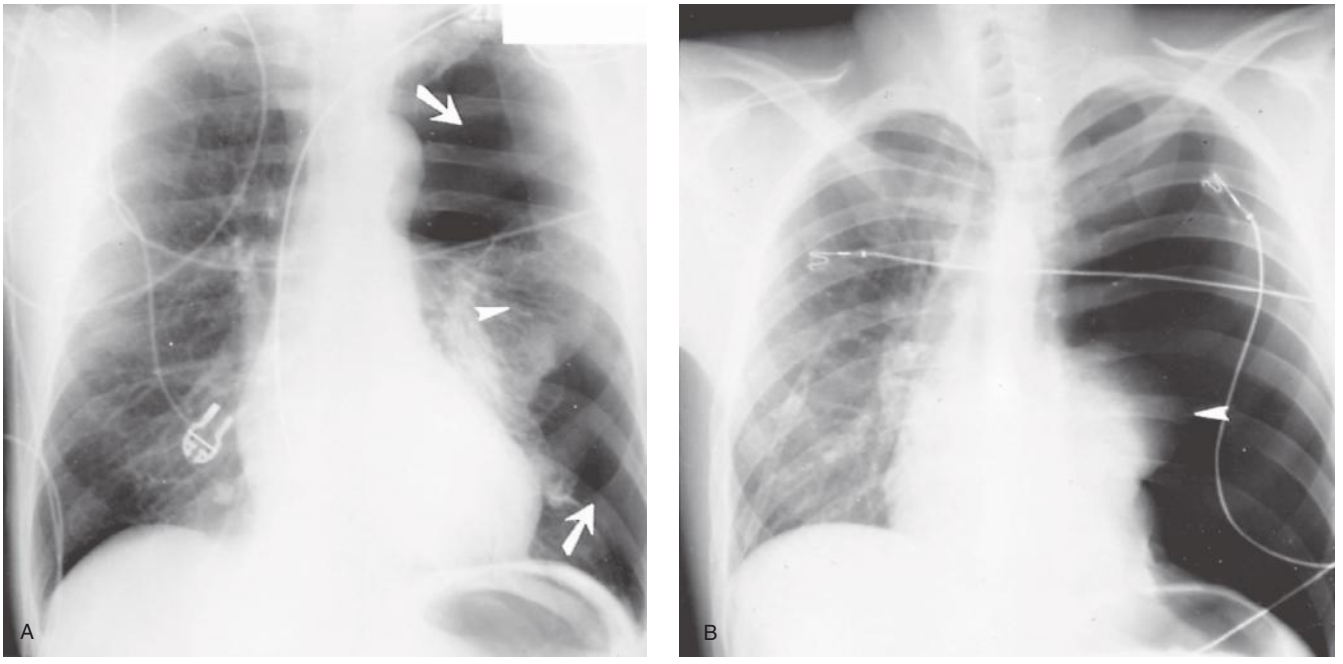

FIGURE 63.29. Pneumothorax. **A:** Posteroanterior film of a patient with left pneumothorax. Air in the pleural space (*arrows*) is differentiated from the aerated lung by the absence of bronchovascular markings. Note lack of increased density of the lateral aspect of the partially collapsed lung (*arrowhead*). **B:** Total collapse of the lung against the mediastinum (*arrowhead*) seen in another patient. Note increase in size of the left hemithorax and slight shift of the mediastinum to the contralateral side.

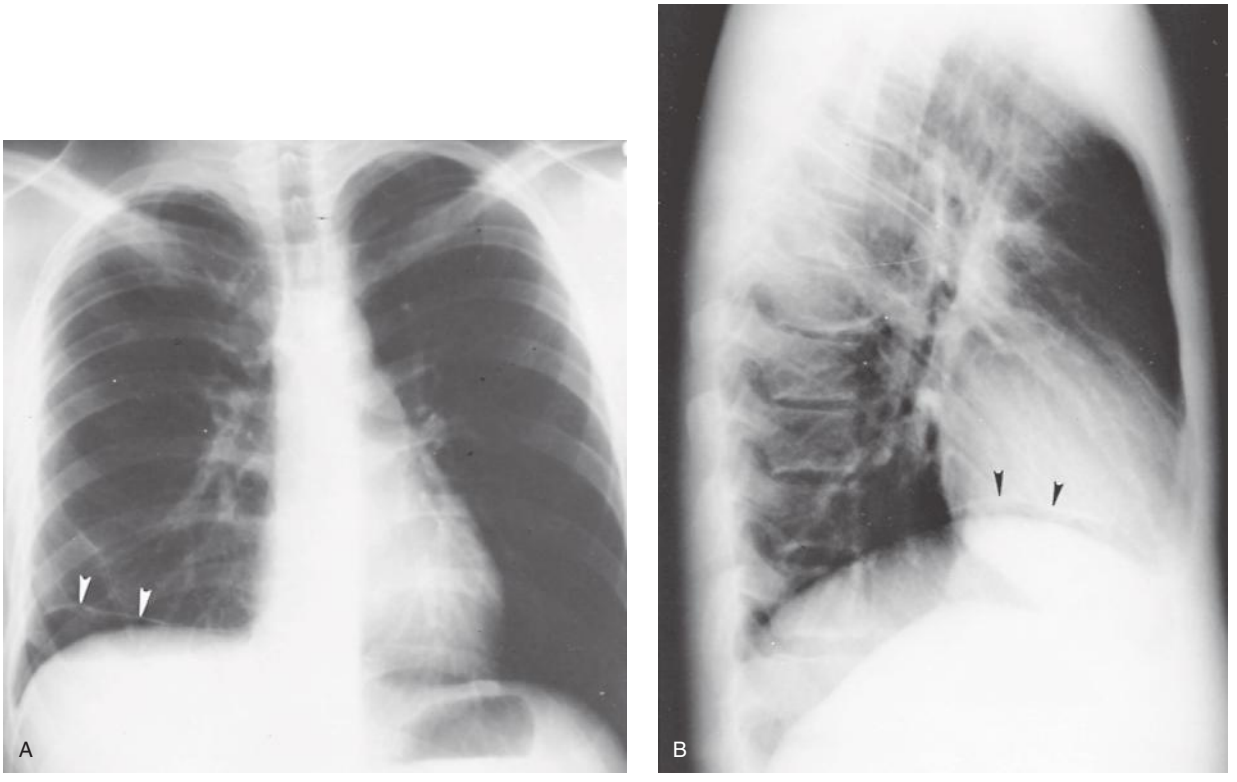

FIGURE 63.30. Subpulmonic pneumothorax. **A:** Posteroanterior view of the chest shows a linear density (*arrowheads*) representing the visceral pleura displaced superiorly by the collection of pleural air (subpulmonic pneumothorax) beneath it. **B:** Lateral view shows the same linear density (*arrowheads*) and subpulmonic pneumothorax.

FIGURE 63.31. Pulmonary interstitial emphysema (PIE). Anteroposterior film of a patient with acute respiratory distress syndrome and PIE shows the irregular lucent mottling, especially in the medial aspect of both lungs. Pneumothorax (*arrow*) is also seen in the right lower hemithorax.

sulcus on the involved side [68]. Even with progression to a tension pneumothorax, in a patient with ARDS, it is possible for the only finding to be a flattening of the cardiac border or a lateral depression of the hemidiaphragm [69]. These findings should be recognized as signs of tension, because severe cardiovascular and pulmonary compromise can develop rapidly in these patients.

Pulmonary Interstitial Emphysema

Pulmonary interstitial emphysema (PIE) results from a rupture of the alveolar wall when the pressure within the alveoli exceeds that within the adjacent vascular bed and perivascular connective tissue. As a result, air dissects along the interstitium of the lungs. Histologically, PIE is seen as spaces produced by the dissection of air into the perivascular connective tissues, the interlobular septa, and the subpleural connective tissue, most extensively around the pulmonary veins [70].

Radiologically, these spaces are seen as irregular radiolucent mottling in the medial one-half to two-thirds of the lungs or as discrete areas of radiolucency (Fig. 63.31). They are 2 cm or more in diameter (blebs or pneumatoceles) and are best seen at the lung bases. PIE also may appear as radiolucent streaks radiating toward the hila or as a lucent halo around vessels on end. Subpleural blebs may be present, most frequently around the hilar areas.

Interstitial emphysema changes rapidly, decreasing in size and disappearing completely in a matter of days. Differentiation of interstitial emphysema from necrotizing bronchopneumonia is sometimes difficult or impossible. Extensive PIE makes the lung appear better aerated than it actually is. PIE may progress to pneumothorax; infradiaphragmatic dissection; or mediastinal, cervical, or subcutaneous emphysema [71].

Subcutaneous Emphysema

Air in the subcutaneous tissues is seen as linear streaks of lucency outlining tissue planes or as bubbles of lucency within the soft tissues (Fig. 63.32). Localized subcutaneous emphysema

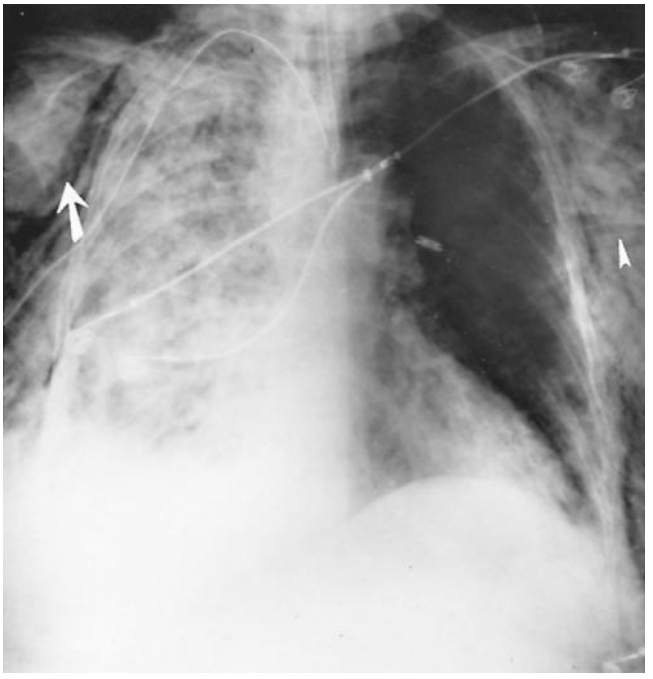

FIGURE 63.32. Subcutaneous emphysema. Anteroposterior film of a patient with right lung opacification from pneumonia with an endotracheal tube and right chest tube in place. The radiating lucencies in the left hemithorax (*arrowhead*) outline the pectoralis muscles. Other air collections (*arrow*) are in the subcutaneous tissues.

usually follows thoracostomy tube insertions, tracheostomies, and transtracheal aspirations and usually is of no significance. It may also be the earliest sign of pulmonary barotrauma. Extensive air in the subcutaneous tissues may occur in patients on ventilators, those with malfunctioning chest tubes, or those with bronchopleural fistulas.

Pneumomediastinum

Pneumomediastinum is manifested radiologically as vertical streaks of lucency just lateral to the borders of the heart, with the parietal and visceral pleura reflected by the lucent stripe (Fig. 63.33A). Although this condition can be seen in the PA view, the lateral view (Fig. 63.33B), specifically the cross-table lateral view, is more diagnostically useful.

Air can enter the mediastinum from a ruptured bronchus, trachea, or esophagus; from the neck (especially during the course of tracheostomy or line placement, when the negative pressure of the thorax draws air in through the incision); from the retroperitoneum; and from the lungs in association with interstitial emphysema. Small amounts of pneumomediastinum should be distinguished from the normal lucency of a kinetic halo around the heart. This artifactual halo is produced by normal cardiac motion; it is only moderately lucent and does not outline the pleural reflection. When air extends into the soft tissues of the neck or into the retroperitoneum, it is most likely secondary to a pneumomediastinum.

Pneumopericardium

Radiologic diagnosis of a pneumopericardium is made when a lucent stripe is seen around the heart extending to, but not beyond, the proximal pulmonary artery and outlining a thickened pericardium (Fig. 63.34). It may be difficult to differentiate

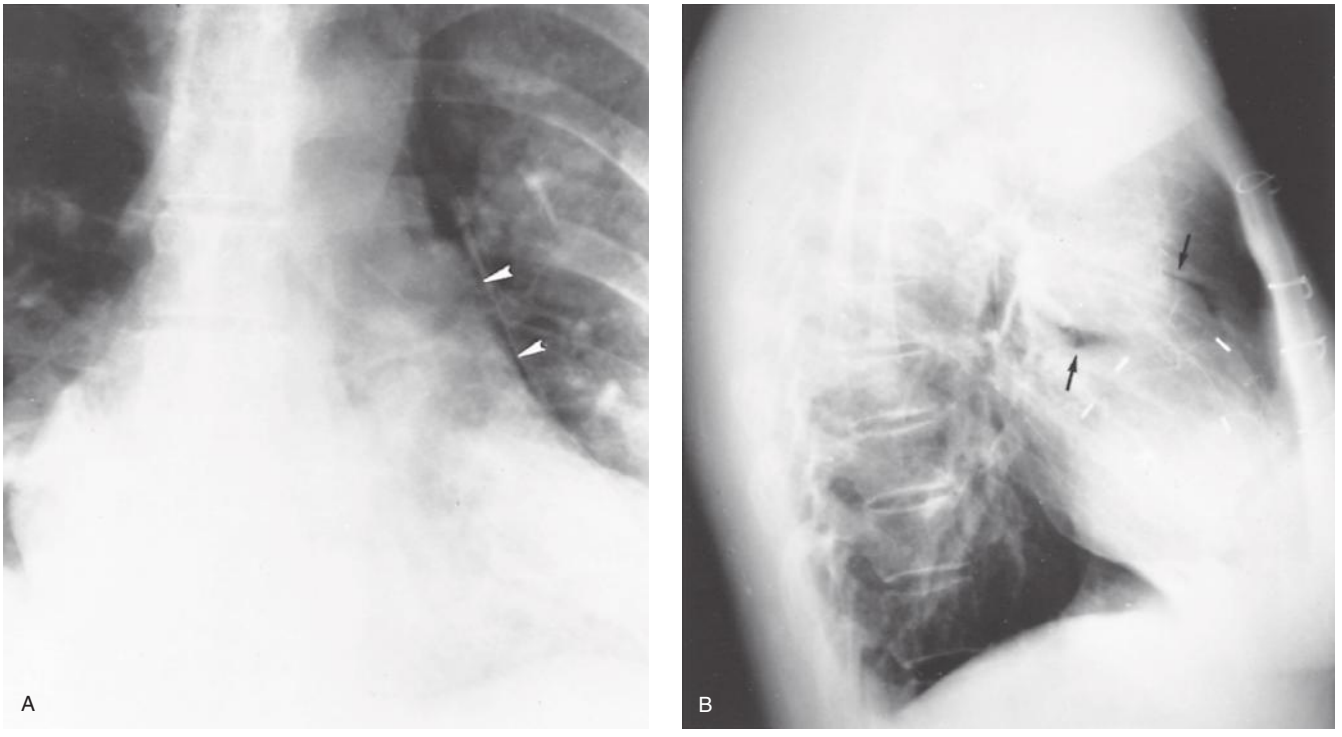

FIGURE 63.33. Pneumomediastinum. **A:** Posteroanterior view of the chest shows air in the mediastinum (*arrowheads*). **B:** Lateral view of chest in a different patient shows lucent areas (*arrows*) representing pneumomediastinum outlining the main pulmonary artery. The patient had previous coronary artery bypass surgery.

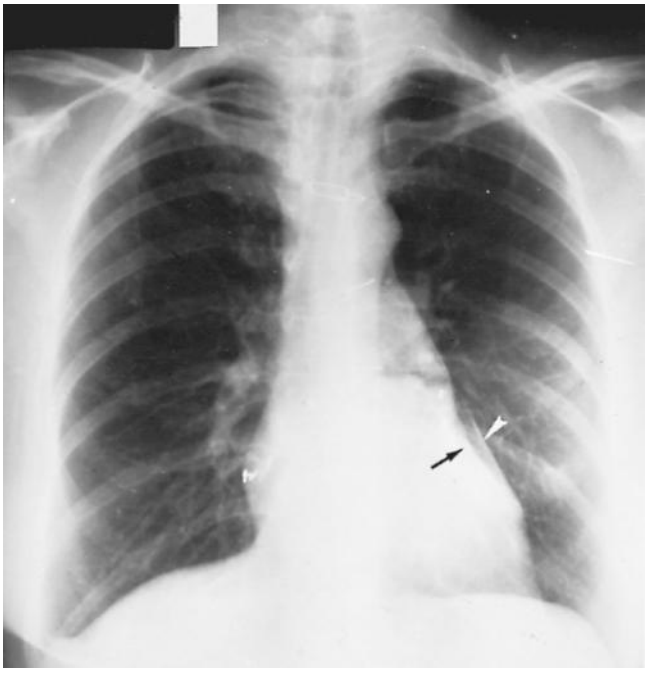

FIGURE 63.34. Pneumopericardium. Posteroanterior view of the chest shows a lucent area (pneumopericardium) lateral to the cardiac shadow (*arrow*) and medial to a strip of density of the pericardium (*arrowhead*). Slight blunting of the right costophrenic sulcus from a small pleural effusion is also present. The patient had previous coronary artery bypass surgery.

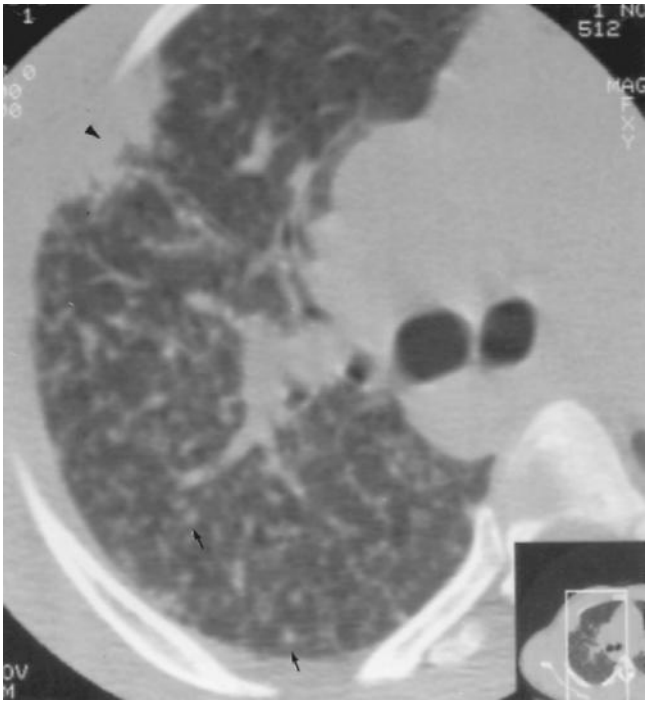

FIGURE 63.35. *Arrows* point to miliary nodules that are hardly visible on plain films but well seen by high-resolution computed tomography in a patient with miliary tuberculosis. *Arrowhead* points to an area of tuberculous consolidation.

FIGURE 63.36. *Arrowheads* point to faint areas of alveolar opacification in a patient with *Pneumocystis jiroveci* pneumonia who had a totally negative chest film.

from a pneumothorax or pneumomediastinum; a cross-table lateral film may be necessary. Pneumopericardium is almost always the result of surgery but also may follow trauma or infection.

Extrapulmonary Structures

Evaluation of the chest radiograph is never complete unless the extrapulmonary, extrapleural, and extracardiac structures (extrathoracic soft tissues and bony thorax) are carefully assessed

FIGURE 63.37. *Arrows* point to emphysematous areas of lung in a patient with normal chest radiograph.

for possible pathology. It is not the purpose of this chapter to deal with these pathologic processes in depth; suffice it to say that one should look for masses, calcifications, and abnormal air collections such as abscesses in the cervical and thoracic soft tissues and subphrenic areas. The bony structures also may provide clues to disease of a systemic nature (e.g., H-shaped vertebrae and bone infarcts in sickle cell anemia) or to metastases in the form of lytic or blastic bone lesions. Fractures after trauma, and occasionally rib fractures from resuscitation procedures after cardiac arrest, may be seen on the chest radiograph.

Additional Imaging

As previously stated, many patients cannot be moved from the ICU and CCU areas. For the patient who can be moved

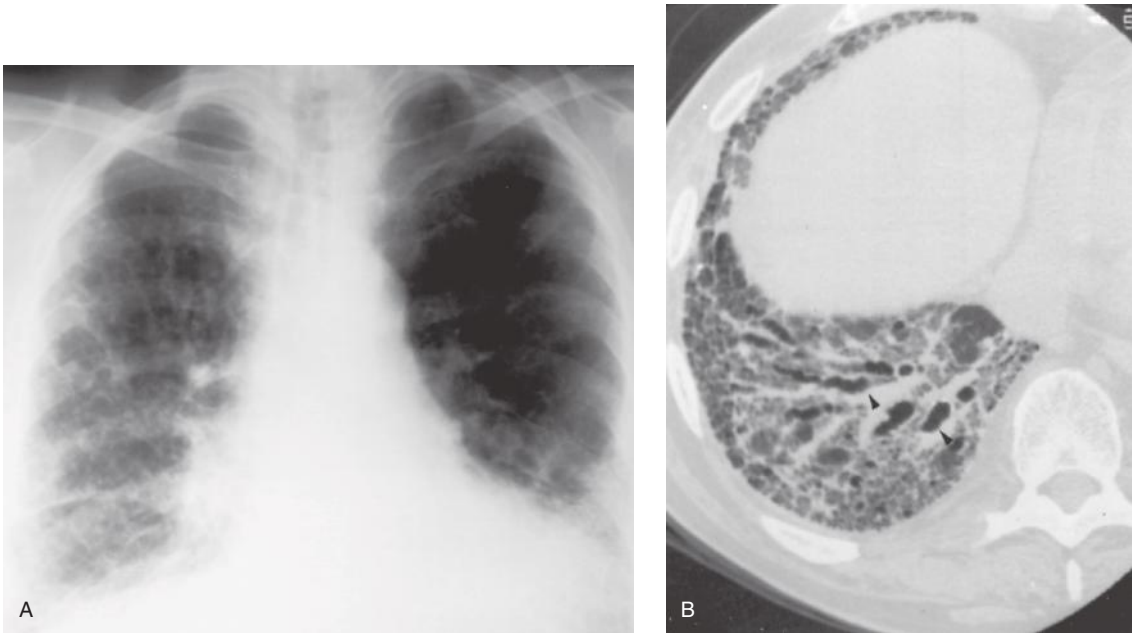

FIGURE 63.38. A: Patient with interstitial opacities in both lower lobes. **B:** High-resolution computed tomography shows extremely well the reticular interstitial opacities and the bronchiectasis (*arrowheads*) from the patient's idiopathic pulmonary fibrosis.

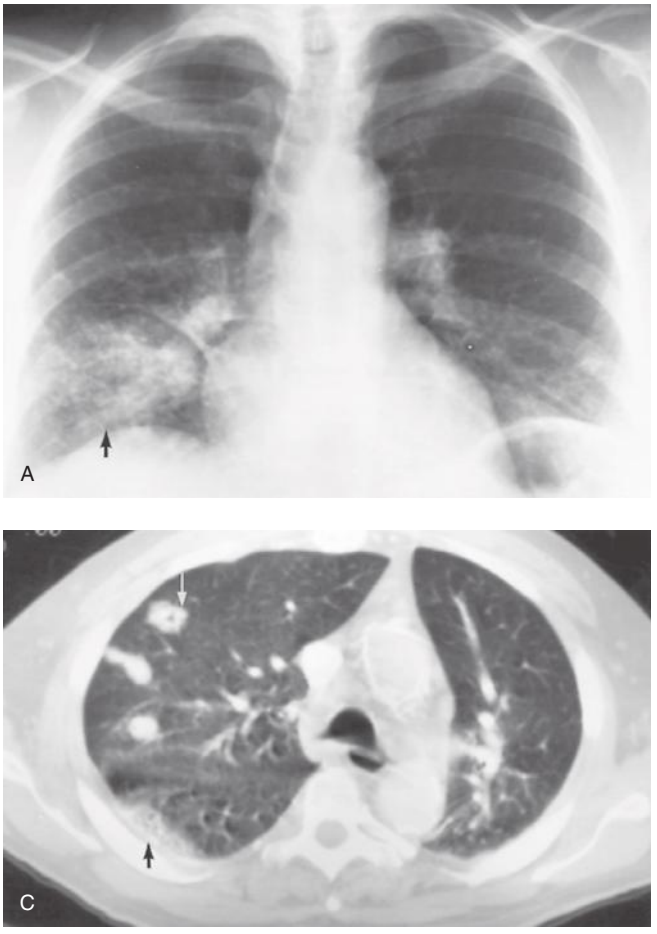

FIGURE 63.39. A: Posteroanterior film shows confluent opacity (*arrow*) in the right lower lobe and two nodular opacities in the left lower lobe. **B,C:** Computed tomography shows the multiple nodular opacities (*white arrows*) obscured by the pneumonia (*black arrows*), one of which (*white arrow* in **C**) shows a cavity. The patient is a drug addict with pneumonia and septic emboli.

and whose clinical conditions demand additional radiologic workup for diagnostic elucidation or therapeutic intervention, other modalities are available. CT pulmonary arteriography, CT venography, digital subtraction angiography, interventional procedures (e.g., catheter placement for pharmacotherapy and drainage of obstructed areas), ultrasonographically guided drainage of abscesses and pleural or pericardial effusions, positron emission tomography, and nuclear magnetic resonance are either available now or will be soon in the armamentarium of radiology departments.

CT, MRI, and ultrasound now form the armamentarium of imaging modalities in addition to plain films available to clinicians for thoracic imaging. The clinical problem to be solved dictates the modality to be used.

The modality of choice for imaging of the lung parenchyma is CT. High-resolution CT (1.5-mm sections at small fields of view and using edge-enhancement techniques) gives a very detailed look at the lung parenchyma, allowing early abnormalities of the lungs to be seen before they are visible on plain films (Figs. 63.35 and 63.36), assessment of the degree of emphysematous destruction of lung (Fig. 63.37), better characterization of parenchymal and interstitial abnormalities (Figs. 63.38 through 63.40), and even the ability to see through the diffuse opacification of the hemithoraces seen on plain films (Fig. 63.41).

The pleura is better assessed by CT than by plain film (Figs. 63.42 through 63.45). Differentiation between pleural and parenchymal abnormalities is easier using CT (Fig. 63.46). CT is the best modality to use when looking for calcification in a lesion, whether it be in lung, mediastinum, or pleura. Small amounts of air are also best seen using CT (Fig. 63.47).

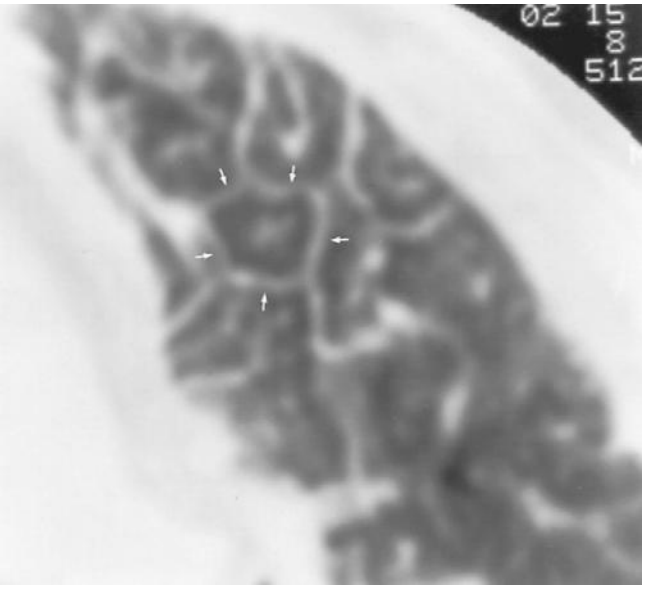

FIGURE 63.40. Enlargement of section of high-resolution computed tomography in a patient with lymphangitic metastasis from breast carcinoma. *Arrows* point to the distended interlobular septae forming the polygonal outline of a secondary lobule. Central density within the secondary lobule represents an arteriole.

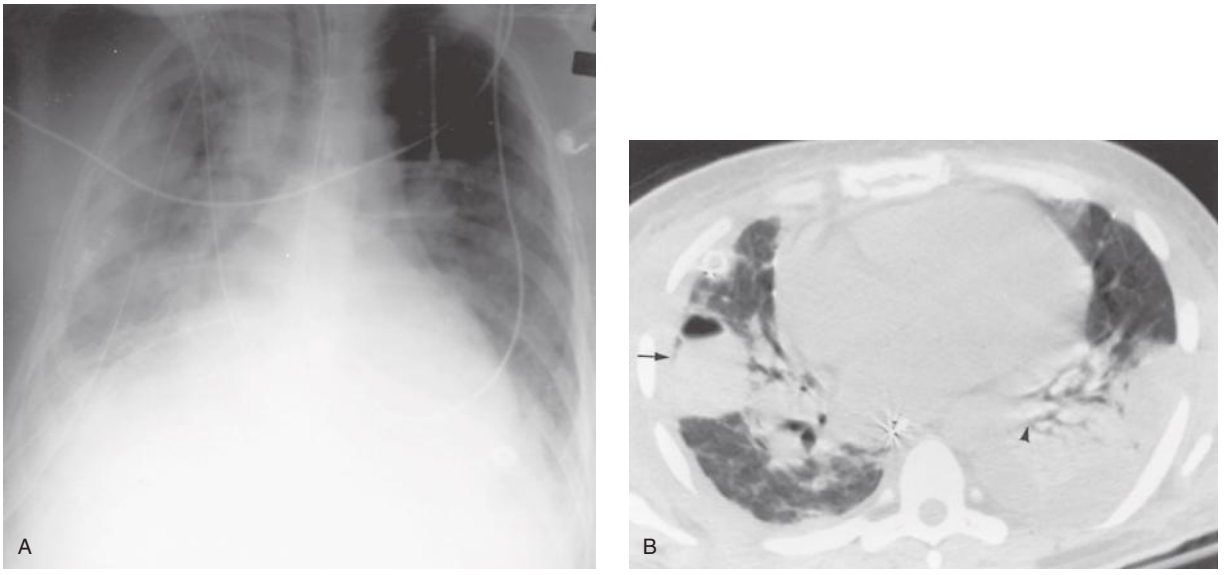

FIGURE 63.41. A: Posteroanterior film shows bilateral parenchymal opacification with greater involvement of the right side. **B:** Computed tomography shows the right lung abscess with air-fluid level (*arrow*) and the pneumonia with air bronchograms (*arrowhead*) in the left, defining better the pathology producing the areas of opacification in the posteroanterior film.

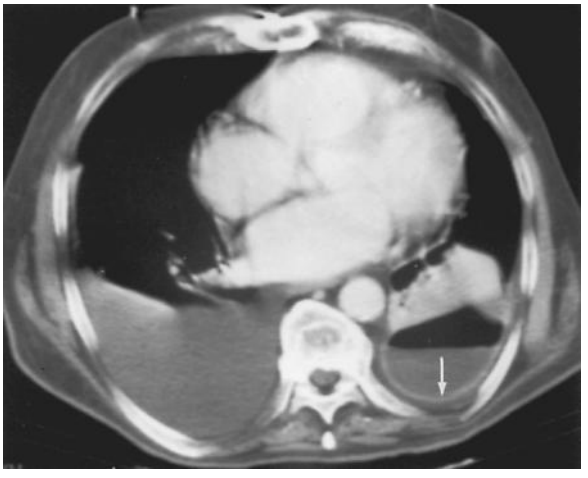

FIGURE 63.42. Contrast-enhanced computed tomography distinguishes between a pleural effusion on the right and an empyema on the left by visualization of an enhancing pleura (curvilinear white line, *arrow*).

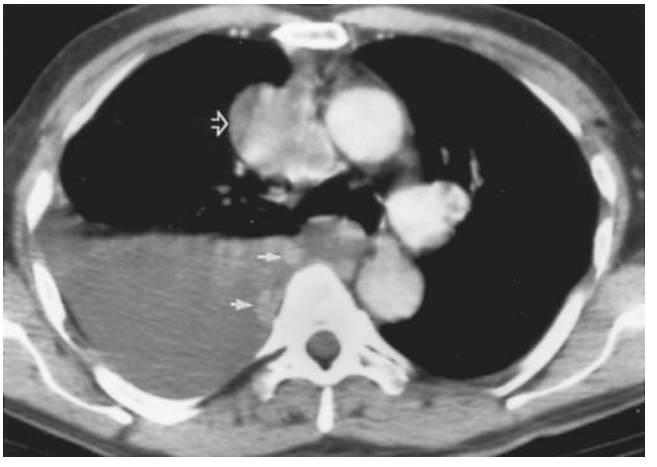

FIGURE 63.43. Patient with bronchogenic carcinoma (*open arrow*) with pleural effusion. White arrows point to metastatic pleural deposits that are not visible on plain films.

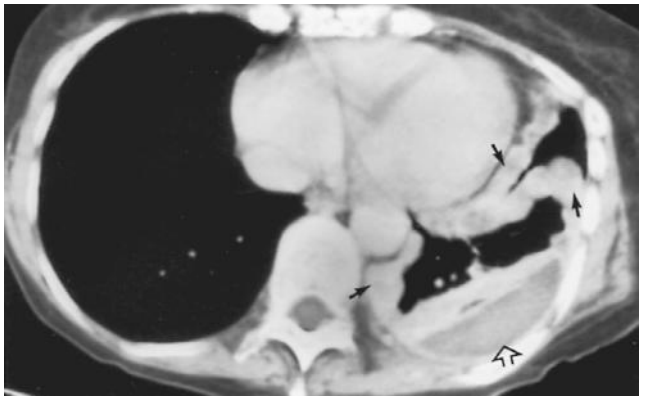

FIGURE 63.44. Patient with a densely opacified left hemithorax. Computed tomography shows the lobulated pleural thickening (*arrows*) and pleural effusion (*open arrow*) secondary to mesothelioma.

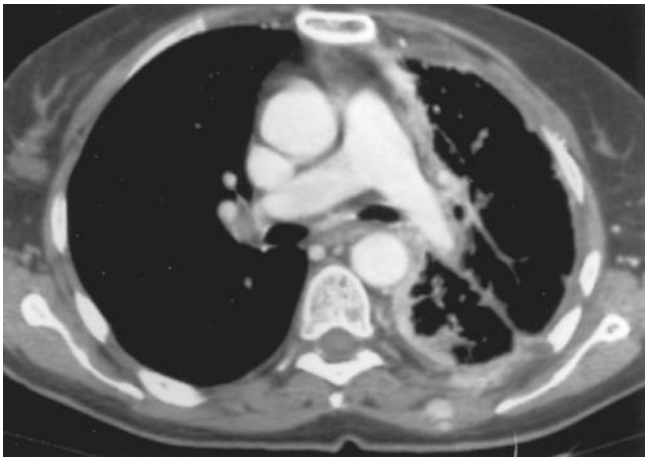

FIGURE 63.45. Irregular pleural opacity in the left pleural space from metastatic adenocarcinoma.

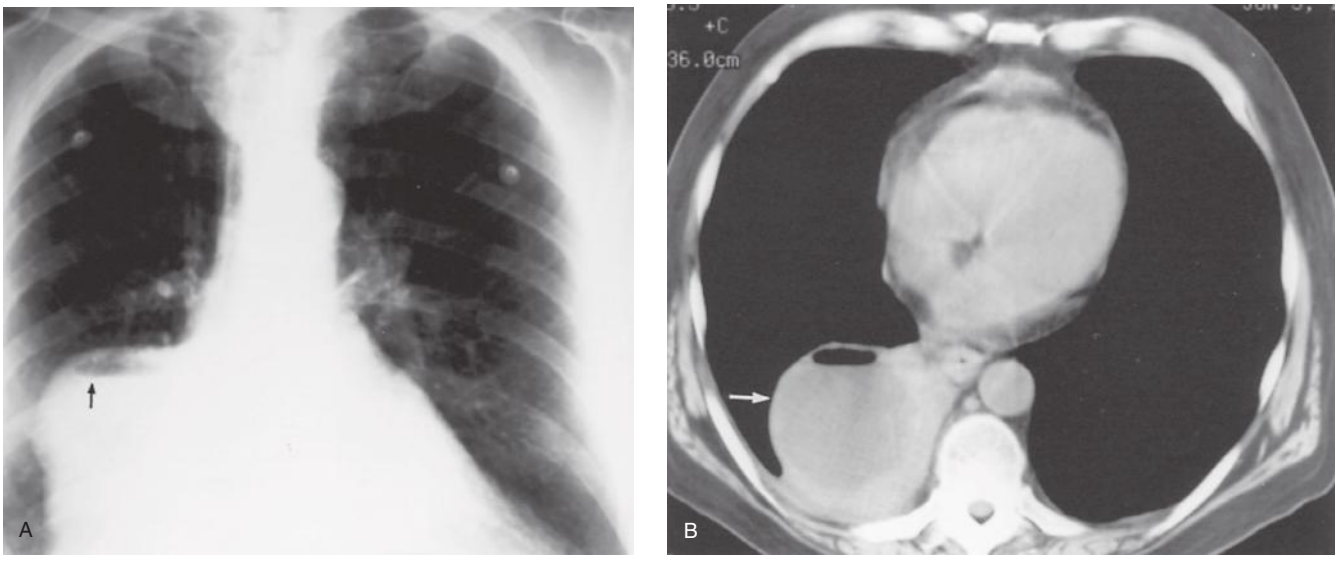

FIGURE 63.46. Mass opacity with air-fluid level on the posteroanterior view (*black arrow*) (**A**), clearly imaged by computed tomography (*white arrow*) (**B**), and shown to be a lung abscess.

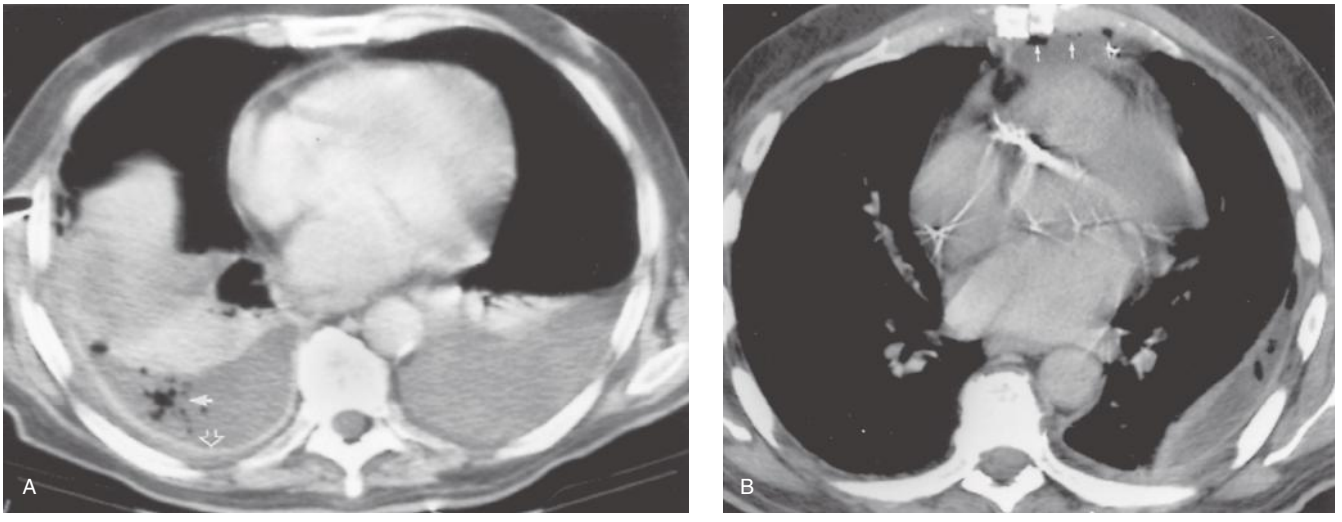

FIGURE 63.47. A: Patient with bilateral effusions. Computed tomography (CT) shows air within the effusion (*arrow*) and pleura enhancement (*open arrow*), allowing the diagnosis of an empyema. **B:** Patient who had coronary bypass surgery several weeks before this CT shows mediastinitis with air (*arrows*) in the retrosternal area. Empyema is also noted in the posterior left hemithorax.

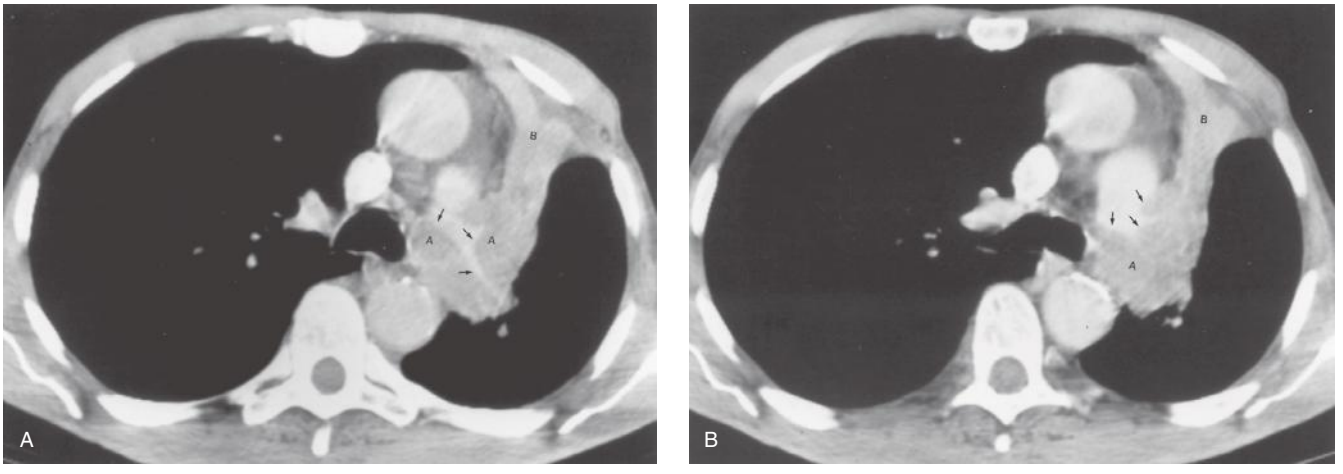

FIGURE 63.48. A,B: Contiguous computed tomography sections show the contrast-enhanced pulmonary artery (*arrows*) encased by and obstructed by the bronchogenic carcinoma (**A**), which has also produced postobstructive atelectasis (**B**). The mass and atelectasis, but not the pulmonary artery's involvement, could be seen on plain films.

FIGURE 63.49. In a patient who had a lobectomy, computed tomography shows a filling defect (*arrow*) representing a thrombus within the contrast-enhanced pulmonary vein.

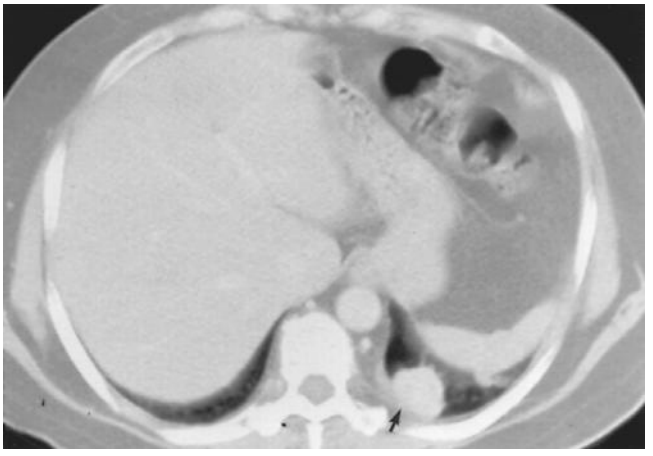

FIGURE 63.50. An adenocarcinoma seen only by computed tomography (*arrow*). It was not seen on routine films because it overlies the shadows of the vertebral body on lateral view and is obscured by the spleen and stomach and aorta on the posteroanterior chest film.

Involvement of the arteries and veins most often not identifiable on plain films can be seen using CT (Figs. 63.48 and 63.49). Abnormalities hidden by overlying structures in PA and lateral views can be seen in CT cross-sectional images (Fig. 63.50).

Mediastinal abnormalities can be imaged using CT, MRI, or ultrasonography. To determine the size of mediastinal nodes, CT's resolution would make it superior to MRI; CT can delineate the borders of small nodes lying close to each other or matted together, whereas MRI may make them appear as larger, pathologic-sized nodes. Posterior mediastinal lesions are probably best imaged using MRI to show their relation to an involvement of the spinal canal and spinal cord.

On the other hand, MRI is like CT in imaging vascular structures well. It is not within the scope of this chapter to discuss the principles and physics behind MRI. Suffice it to say that using spin-echo technique, flowing blood appears as a signal void (black) and as high-signal intensity (white) on gradient recall images. The latter provides an angiographic image similar to that achieved using angiography.

The cardiac chambers can be imaged equally well with MRI and ultrasonography but not as well with CT (Fig. 63.51). In the evaluation of the cardiac muscles, however, MRI is superior to CT or ultrasonography.

Aneurysms and dissecting aneurysms of the aorta can be imaged using all five modalities: contrast-enhanced CT, angiography, echocardiography for the root of the ascending aorta, transesophageal echocardiography for the descending aorta, and MRI. The advantage of ultrasonography is that it can be done at the bedside if necessary. However, MRI is superior

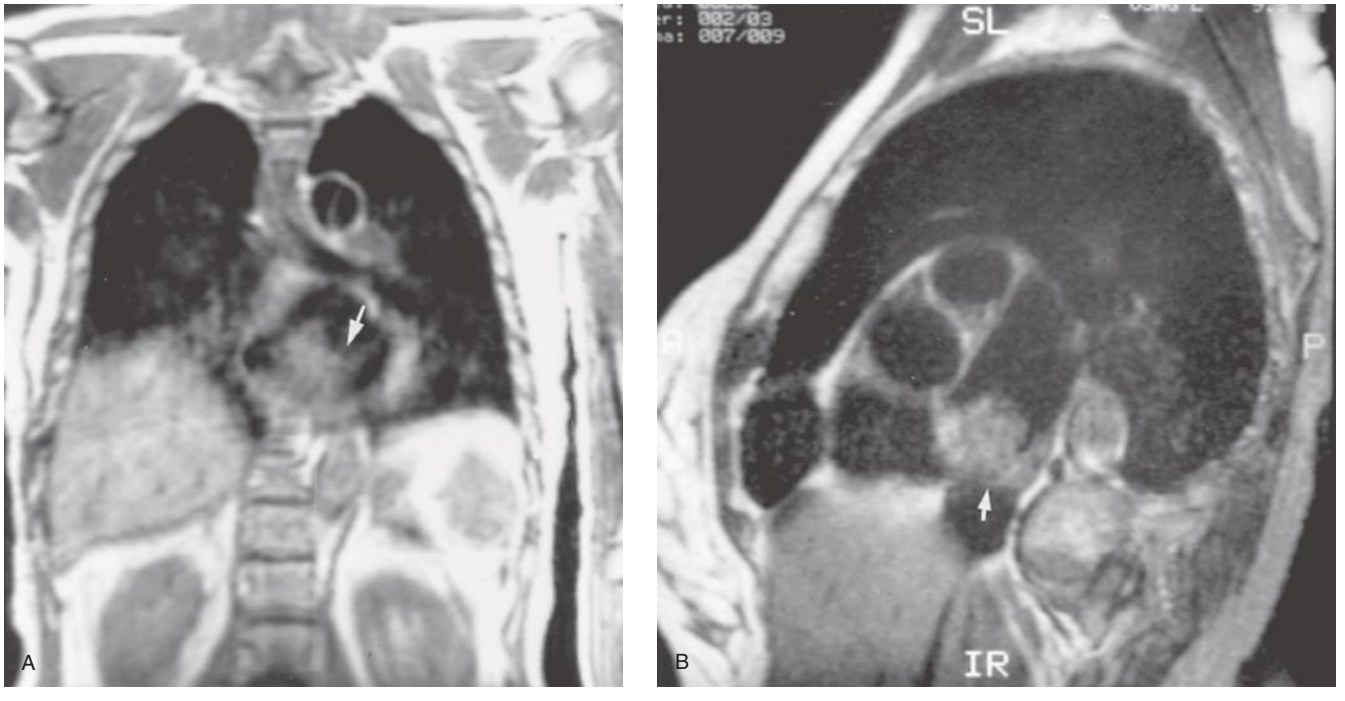

FIGURE 63.51. A,B: Coronal and sagittal plains on magnetic resonance imaging. *Arrows* point to an atrial myxoma. Echocardiography demonstrated this lesion also.

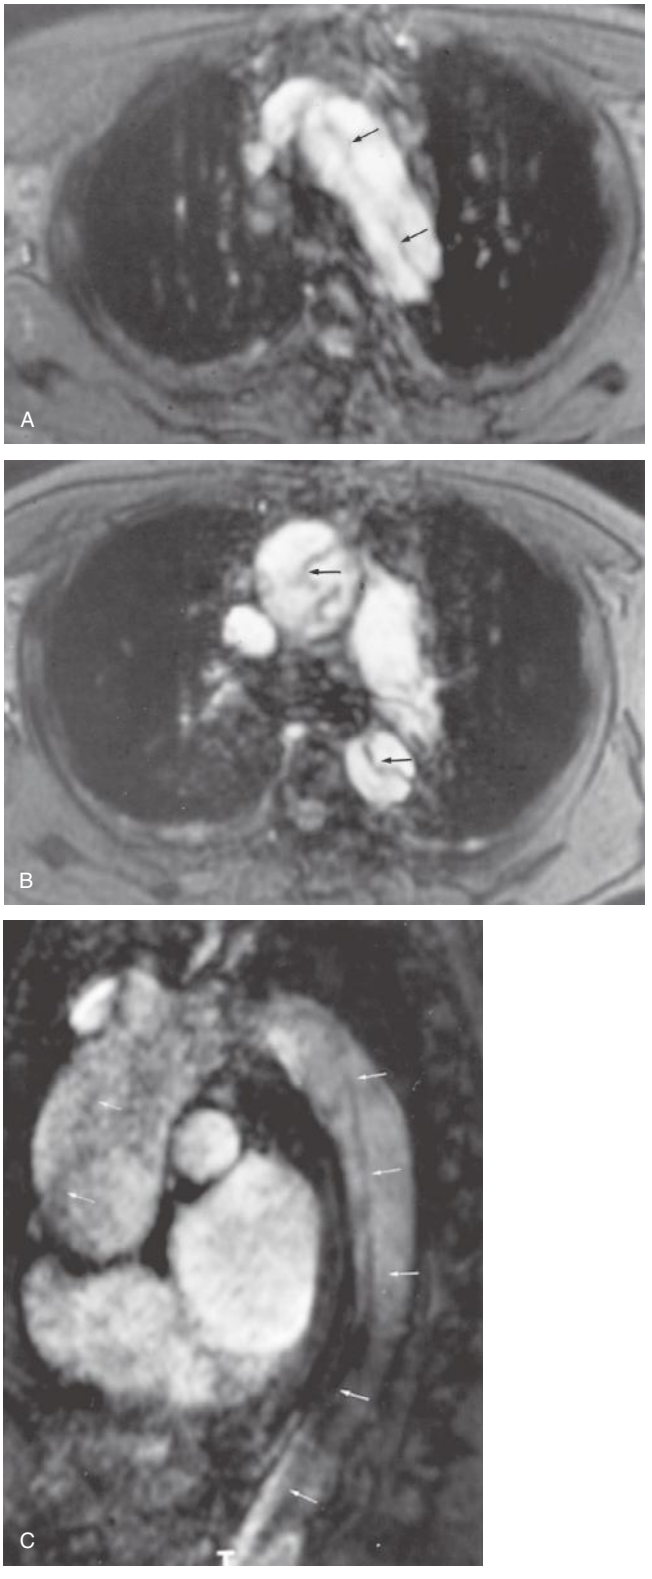

FIGURE 63.52. A–C: *Arrows* point to the flap in a dissecting aneurysm. Magnetic resonance images well the dissection and its extent in multiple planes.

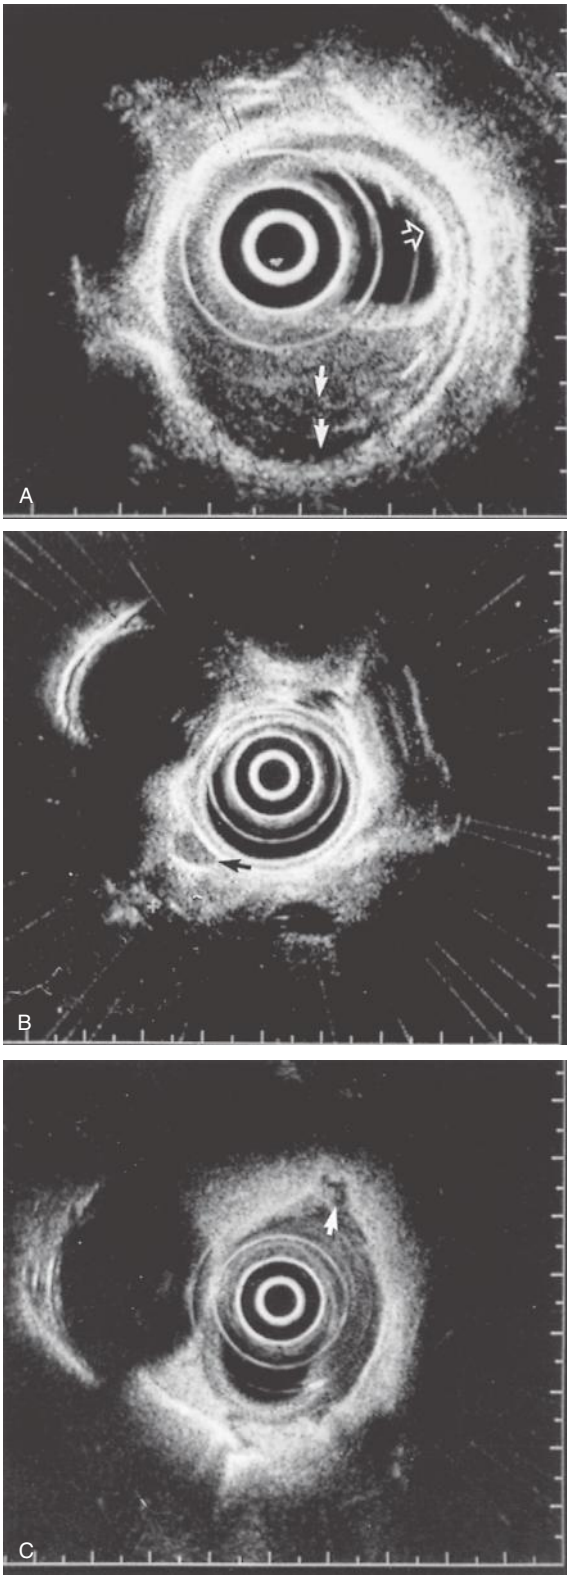

FIGURE 63.53. Esophageal endosonography in a patient with esophageal carcinoma. Open *arrow* shows normal thickness of the esophageal wall. White *arrows* in (**A**) and (**C**) show the extension of the lesion into the adventitia. Black *arrow* in (**B**) shows metastatic lymphadenopathy.

to either CT or ultrasonography because of the ability to do multiplane imaging and delineate the entire extent of the abnormality (Fig. 63.52) noninvasively.

Esophageal mucosal lesions are best assessed by barium swallow. Submucosal, mural, and serosal lesions and lesions extrinsic to the esophagus can be assessed using CT, ultrasonography, or MRI. Ultrasonography and MRI are probably superior to CT in delineating the layers of esophagus involved. Transesophageal ultrasonography is the least costly and most efficient modality to use, because the gastroenterologists would probably use a scope anyway in the presence of any esophageal problem. Transesophageal endosonography is superior to CT for staging a tumor and evaluating depth of tumor infiltration, especially in the early stages (Fig. 63.53). Severe stenosis is the main limiting factor to the use of transesophageal endosonography. The availability of the various imaging modalities provides clinicians with useful tools in addition to their clinical acumen and laboratory results for diagnostic problem solving in the ICU patient.

CHAPTER 64 ■ ACUTE INHALATION INJURY

DAVID J. PREZANT, DORSETT D. SMITH AND LAWRENCE C. MOHR JR

OVERVIEW

Chemicals with potential toxicity are regularly used and produced in a variety of industrial processes. If inhaled, many have the potential to cause asphyxiation or life-threatening acute lung injury. Although recent events have increased concern that toxic gases may be used as weapons of mass destruction, accidental exposures remain the greatest health threat [1]. Individuals may be exposed to the accidental release of toxic gases in the workplace [2] or in the general environment, including the home [1].

Smoke inhalation is another major cause of acute inhalation injury [3]. Thousands of individuals become smoke inhalation victims each year, having been exposed to toxic gases and airborne particulate matter from the burning of a variety of materials [4]. Smoke inhalation most commonly occurs as a result of industrial or residential fires, where large amounts of carbon monoxide, hydrogen cyanide (HCN), hydrogen chloride, acrolein, sulfur dioxide, phosgene, and other toxic, irritant gases are produced (Table 64.1). It remains the primary cause of death in approximately 80% of burn injury victims in the United States.

Toxic agents can be inhaled in several different physical states. A gas is a substance that, at standard temperature and pressure, has the ability for its molecules to diffuse freely and be distributed uniformly throughout any container. A gas in the atmosphere has the capability of infinite expansion. The density of a gas is expressed relative to air. The denser the gas, the heavier it is. Gases that are denser than air will typically gravitate to low areas. Cold gases are denser than the same gas at higher temperatures. A vapor is a substance in the gaseous state that normally exists as a liquid or solid and is formed when a substance is heated above its critical temperature, which is the temperature at which it cannot be liquefied regardless of the amount of pressure applied. A fog is a liquid aerosol formed by a condensation of a substance from a gaseous state to a liquid state. Dusts are fine particles of a solid organic or inorganic material that are small enough to be airborne, typically ranging from 0.1 to 25.0 μm in diameter. Fumes are extremely fine solid particles that are dispersed into the air by the combustion or melting of solid materials, particularly metals. Fumes usually consist of particles that range from 0.001 to 1.0 μm in diameter. Smoke consists of airborne particles resulting from the incomplete combustion of organic materials. These particles either contain or are coated with multiple chemical substances resulting from combustion and range in size from less than 0.3 μm to greater than 10 μm in diameter.

The nature of acute injury that an individual sustains after the inhalation of a toxic substance will depend on the chemical and physical properties of the inhaled toxicant, the pathophysiological mechanism by which the toxicant causes injury, the dose received, and whether prior pulmonary disease exists. This chapter will focus on the diagnosis and treatment of acute inhalation injury resulting from asphyxiant gases, toxic irritant gases, and smoke.

TABLE 64.1

TOXIC PRODUCTS OF COMBUSTION IN RESIDENTIAL FIRES

Acetaldehyde	Hydrogen fluoride
Acrolein	Hydrogen sulfide
Ammonia	Isocyanates
Carbon monoxide	Metals (Pb, Zn, Mn, Cd, Co)
Chlorine	Oxides of nitrogen
Hydrogen chloride	Phosgene
Hydrogen cyanide	Sulfur dioxide

ASPHYXIANT GASES

Background

Asphyxiants are gases that cause tissue hypoxia. They are classified as either *simple asphyxiants* or *chemical asphyxiants*

TABLE 64.2

SIMPLE ASPHYXIANTS

Heavier than air	Lighter than air
Argon	Acetylene
Butane	Ethylene
Carbon dioxide	Methane
Ethane	Neon
Natural gas	Nitrogen
Propane	

based on their mechanism of toxicity. Simple asphyxiants displace or dilute oxygen in the ambient atmospheric air causing a decrease in the fraction of oxygen in inspired air (FIO_2). Chemical asphyxiants, on the other hand, interfere with physiological processes associated with the uptake, transport, or utilization of oxygen. Simple asphyxiants include common gases such as carbon dioxide, natural gas, propane, methane, nitrogen, and acetylene. They may be lighter or heavier than air (Table 64.2). Simple asphyxiants that are lighter than air accumulate and displace oxygen in higher areas first, whereas those that are heavier than air accumulate and displace oxygen in low-lying areas first. Chemical asphyxiants can be further characterized as those that decrease oxygen-carrying capacity, such as carbon monoxide, and those that inhibit oxygen utilization by cells, such as HCN (Table 64.3). Medical problems related to the inhalation of the most common asphyxiants are discussed in the sections that follow.

Carbon Dioxide

Pathophysiology

Carbon dioxide (CO_2) is the most common simple asphyxiant. It is produced by aerobic metabolism and is exhaled into the atmosphere by humans and other animals. It is also a byproduct of carbohydrate fermentation, the combustion of carbonaceous material, and the oxidation of coal contaminants in coal mines. It exists in the frozen form as dry ice. CO_2 is heaver than air and reduces FIO_2 simply by diluting and displacing oxygen in ambient air. Most deaths from CO_2 asphyxiation result from the confinement of an individual in enclosed or poorly ventilated space. Such closed-space confinement prevents air with a normal FIO_2 from entering while exhaled CO_2 is accumulating and displacing oxygen inside. Simple asphyxiation from CO_2 has also been reported from environmental exposures. In 1986, for example, simple asphyxiation caused approximately 1,700 deaths from a cloudy mist of CO_2 and water droplets that rose suddenly from a lake in Cameroon [5]. Asphyxiation from CO_2 has also been reported by off-gassing from dry ice in a confined space [6].

TABLE 64.3

CHEMICAL ASPHYXIANTS

  - Hydrogen cyanide
  - Hydrogen sulfide

In general, once the ambient CO_2 increases to the point where the FIO_2 has decreased to 0.15, acute signs and symptoms of hypoxia begin to appear within minutes. These include dyspnea, tachypnea, tachycardia, confusion, incoordination, and dizziness. As the FIO_2 decreases below 0.10, lethargy or coma may develop as a result of cerebral edema, and cardiopulmonary arrest may occur. Brain damage sustained as a result of extensive cerebral edema or prolonged hypoxia may be permanent in individuals with these conditions who are resuscitated and survive. It is unlikely that life can be sustained for more than several minutes with a FIO_2 less than 0.06 [7].

Diagnosis and Management

CO_2 asphyxiation should be considered in any patient who presents with clinical signs of hypoxia, is unconscious, or is found to be in cardiopulmonary arrest after removal from an enclosed space or another source of potential CO_2 exposure. Clinical signs are nonspecific and related to the magnitude of hypoxia, as indicated earlier. Arterial blood gases, serum electrolytes, and measurement of the anion gap should be obtained. During and shortly after CO_2 asphyxiation, arterial blood gas analysis would be expected to show decreased arterial oxygen tension (PaO_2) and elevated carbon dioxide tension ($PaCO_2$). However, both PaO_2 and $PaCO_2$ typically return to normal shortly after the patient is removed from the source of CO_2 exposure. Once the patient breathes oxygenated air, CO_2 is rapidly excreted by hyperventilation. Most patients will be acidotic at the time of presentation as a result of respiratory acidosis from CO_2 retention and concurrent lactic acidosis from hypoxia. Lactic acidosis will cause an elevated anion gap. The respiratory acidosis typically resolves shortly after removal from the source of CO_2 exposure. The lactic acidosis will resolve once tissue oxygenation returns to normal but usually takes longer to resolve than the respiratory acidosis. The hypoxia caused by CO_2 asphyxiation can cause cardiac dysrhythmias and myocardial infarction, especially in individuals with underlying heart disease. Therefore, it is recommended that an electrocardiogram and serial cardiac biomarkers be obtained on all patients.

Removal from the source of exposure and administration of oxygen are the only specific therapies for CO_2 asphyxiation. If the patient is alert, has spontaneous respirations, and has a patent airway, it is recommended that high-flow oxygen be administered by a nonrebreather mask. Endotracheal intubation will be required if adequate oxygenation cannot be achieved by the use of a face mask or the patient has suffered mental status changes or cardiopulmonary arrest. Additional supportive care, such as cardiopulmonary resuscitation, hemodynamic support, manual ventilation, and mechanical ventilation should be used as required by the patient's overall condition. Cardiac dysrhythmias and myocardial infarction should be aggressively treated. Most victims of CO_2 asphyxiation will recover completely if removed from the source of CO_2 exposure prior to cardiopulmonary arrest and given medical treatment as soon as possible. Individuals who have experienced a prolonged period of hypoxia, however, may have irreversible brain damage and chronic neurological sequelae if they are successfully resuscitated.

Carbon Monoxide

Pathophysiology

Carbon monoxide (CO) is a colorless, odorless, tasteless, nonirritating gas. It is the most common chemical asphyxiant and the

second most common atmospheric pollutant after carbon dioxide. CO is produced in a variety of ways, including incomplete combustion from fires, faulty heating systems, internal combustion engines (including gas-powered generators placed in poorly ventilated areas during electrical failures), wood stoves, charcoal grills, volcanic eruptions, and a variety of industrial processes. In vivo hepatic production of CO occurs in poisoning from methylene chloride that is commonly found in paint thinners and is easily absorbed through the skin.

More than 5,000 deaths are attributed to CO poisoning in the United States each year [8]. Most are intentional from exposures to motor vehicle exhaust. The minority are accidental and due to fires or the use of poorly ventilated generators following storms, blackouts, or other disasters [9]. CO poisoning is responsible for 80% of fatalities related to smoke inhalation [10,11]. Twenty-five percent of fatalities from CO poisoning occur in persons with underlying cardiopulmonary disease [11,12].

Upon inhalation, CO easily diffuses across alveolar-capillary membranes in the lung and is rapidly taken up by erythrocytes in the pulmonary capillary blood. It binds to the iron moiety of hemoglobin with an affinity that is approximately 240 times greater than the affinity of hemoglobin for oxygen. Thus, CO competes with oxygen for hemoglobin binding sites and, as a result of its greater affinity, displaces oxygen from hemoglobin. The binding of CO to the iron moiety also creates an allosteric change in the hemoglobin molecule that inhibits the off-loading of oxygen in the peripheral tissues and causes a shift of the oxyhemoglobin dissociation curve to the left. CO also interferes with intracellular oxygen utilization by inactivating intracellular respiratory enzymes, such as cytochrome oxidase [13]. Thus, the cumulative effect on peripheral oxygen delivery and utilization is greater than that expected from decreased oxygen transport alone [14]. Reoxygenation injury of the brain has also been described [15]. One mechanism for reoxygenation injury appears to be lipid peroxidation of the brain by xanthine oxidase that is generated by peroxidases and reactive oxygen species produced by activated neutrophils that become sequestered in the microvasculature of the brain following, but not during, CO poisoning [16]. In summary, CO toxicity involves four pathophysiological mechanisms: (a) a decrease in the oxygen-carrying capacity of blood; (b) decreased oxygen delivery to peripheral tissues as a result of the left shift in the oxyhemoglobin dissociation curve; (c) mitochondrial dysfunction and impairment of cellular respiration by inhibition of cytochrome oxidase activity; and (d) lipid peroxidation of the brain during reoxygenation. It has been suggested that an immunological response to myelin basic protein may also be involved in the delayed neurological dysfunction that is seen in over half of those with serious CO poisoning between 3 days and 4 weeks after exposure [17].

The clinical presentation of individuals with CO poisoning is highly variable with nonspecific symptoms and signs that are loosely correlated to carboxyhemoglobin levels (Table 64.4). Early symptoms of CO poisoning include headache, dizziness, sore throat, nausea, shortness of breath, and fatigue. These symptoms can mimic those of a nonspecific viral syndrome, especially when an entire family is affected from CO exposure related to a faulty home heating system during the winter months. Impaired ability to concentrate occurs in more than half of affected individuals, and 6% have been reported to experience loss of consciousness. The severity of symptoms appears to correlate better with duration of exposure than with carboxyhemoglobin levels [18]. The brain and heart are very sensitive to CO intoxication, and both neurologic and cardiovascular impairment predominate with prolonged exposures. Mental status changes, and seizures, loss of consciousness, tachypnea, tachycardia, cardiac dysrhythmias, hypotension, and myocardial ischemia are likely to occur when the carboxyhemoglobin concentration exceeds 20%. Loss of consciousness may then occur rapidly and without warning. Cardiovascular disorders may occur at lower concentrations in subjects with preexisting cardiopulmonary diseases. Evidence of myocardial ischemia has been observed in one third of individuals with moderate-to-severe CO intoxication, and it has recently been reported that myocardial injury, as determined by elevation of serial cardiac biomarkers, is an independent predictor of mortality from CO poisoning [12,19,20]. Metabolic acidosis, as a result of increased lactate production from anaerobic metabolism, is a common consequence of tissue hypoxia. Rhabdomyolysis can occur as a consequence of impaired aerobic metabolism in skeletal muscle cells. Renal failure can develop as a consequence of rhabdomyolysis, but this occurs infrequently [21]. Carbon monoxide poisoning is almost always fatal when the carboxyhemoglobin concentration exceeds 60% [10,22].

TABLE 64.4

CARBON MONOXIDE TOXICITY

HBCO level %	Clinical manifestations of carbon monoxide intoxication
0–5	Normal nonsmoker
5–10	Mild headache, shortness of breath with exertion, decreased exercise tolerance, decreased angina threshold
10–20	Moderate headache, fatigue, dizziness, blurred vision, nausea, decreasing threshold for exertional shortness of breath with possibly shortness of breath at rest
20–30	Severe headache, confusion and impaired judgment, vomiting, shortness of breath at rest, decreased cardiac arrhythmia threshold
30–40	Muscle weakness, incapacitation, cardiac arrhythmias, decreased seizure threshold
40–50	Seizures, syncope, cardiac arrest
50–60	Fatal

Fetal hemoglobin has a much greater affinity for CO than adult hemoglobin. Therefore, during pregnancy, the fetus may be more susceptible to CO poisoning than the mother. Once the mother is removed from the source of CO, clearance of carboxyhemoglobin may take four to five times longer in the fetus than it did in the mother [23]. Thus, the effective duration of CO exposure is considerably longer for the fetus than it is for the mother. It has been reported that severe CO toxicity in pregnant women can produce ischemic brain damage to the fetus and increase the risk of stillbirth [24,25].

Carbon monoxide poisoning can result in a delayed neuropsychiatric syndrome that may present at any time between 3 days and 4 months after apparent recovery from acute effects [10,26]. The syndrome has been reported to occur in 10% to 30% of individuals who survive CO poisoning. Symptoms include cognitive impairment, personality changes, parkinsonism, incontinence, focal neurological deficits, dementia, and psychosis. There is poor correlation between the development of the delayed neuropsychiatric syndrome and carboxyhemoglobin levels. Loss of consciousness during the acute illness phase, carboxyhemoglobin 25% or more, duration of exposure, and age appear to be significant risk factors (18). Brain imaging studies have shown that the areas most affected are the globus pallidus and deep white matter [10]. The exact mechanism for the development of this syndrome is unclear, but it is thought to be associated with reoxygenation brain injury, as discussed earlier. Most affected individuals recover within 1 year, although some may have chronic, long-term neurological or psychiatric impairment [10].

Diagnosis and Management

Because CO poisoning can present with a variety of nonspecific signs and symptoms, a high index of suspicion is needed to make the diagnosis. Cherry-red lips, cyanosis, and retinal hemorrhages have been reported in some cases of high-dose CO poisoning, but these signs occur infrequently and diagnosis depends on clinical history substantiated by increased levels of carboxyhemoglobin in arterial or venous blood [10]. Carboxyhemoglobin is most accurately measured by cooximetry because routine pulse oximetry cannot distinguish between carboxyhemoglobin and oxyhemoglobin. PaO_2 is also of little value, since in the absence of coexistent lung injury it is normal. This is due to the fact that a CO partial pressure of only 1 mm Hg in arterial blood can saturate more than 50% of hemoglobin without affecting gas exchange or the amount of dissolved oxygen.

Recently, noninvasive cooximetry has become commercially available. Studies show that it has a high degree of specificity but poor sensitivity [27,28]. Using a cutoff of 15% carboxyhemoglobin, noninvasive cooximetry had a poor sensitivity of 48% (correctly identified only 11 of 23 patients with elevated levels) but an excellent specificity of 99% (correctly identify 96 of 97 patients with levels below 15%) [28]. Until further studies are done, this would suggest that its primary value is ruling out the diagnosis when there are no symptoms. It is probably most useful in environments where it is difficult or not possible to obtain blood measurement such as by Emergency Medical Service (EMS) units in the prehospital environment [29].

The evaluation of patients with CO poisoning should also include a thorough examination for evidence of thermal injury to the skin or airways. If CO poisoning is the result of a suicide attempt, a drug screen and serum ethanol, salicylate, and acetaminophen levels should be obtained. Another advantage of measuring the arterial carboxyhemoglobin level is that it also allows for simultaneous measurement of arterial pH. The pH can be used in conjunction with the anion gap and the serum lactate level to assess the degree of metabolic acidosis which when elevated is an independent predictor of poor prognosis [10]. $PaCO_2$ is only helpful in assessing the ventilatory response to hypoxia and ventilatory compensation for lactic acidosis and should be obtained when mental status is abnormal or there is a prior history of chronic pulmonary disease. The serum creatine kinase level will be elevated if rhabdomyolysis has occurred. An electrocardiogram and serial cardiac biomarkers should be obtained in all patients to evaluate the possibility of myocardial ischemia or infarction. Because CO lowers the threshold for the development of ventricular dysrhythmias, patients should be carefully monitored until they are discharged from the emergency department or hospital [30]. The chest radiograph is usually normal, but signs of noncardiogenic pulmonary edema can rarely be seen in cases of severe CO poisoning [22], especially if there is coexistent smoke inhalation. Computed tomography (CT) of the head is useful if there is a need to rule out other causes of neurological impairment in this acute setting.

The initial treatment of CO poisoning is prompt removal from the source of exposure and administration of 100% oxygen via a nonrebreather mask to reduce the half-life of carboxyhemoglobin from 4 to 6 hours to 40 to 80 minutes [10,31]. Patients who are unconscious or have cardiopulmonary compromise should be intubated and receive 100% oxygen by mechanical ventilation and hyperbaric oxygen therapy (HBOT) be considered (see later). Oxygen should be administered until the carboxyhemoglobin level returns to normal. Pregnant women typically require oxygen for a longer period of time, because it takes longer for CO to be excreted from the fetus as a result of the greater affinity of fetal hemoglobin for CO [23].

Most patients with mild-to-moderate CO poisoning can be treated in the emergency department and discharged after the carboxyhemoglobin level has returned to normal and all abnormal signs and symptoms have resolved. Patients with severe CO poisoning, coexistent smoke inhalation, serious underlying diseases, neurologic or cardiopulmonary instability, or whose poisoning was an intentional suicide attempt should be admitted to the hospital for treatment and close observation.

HBOT has been used to treat patients with either extreme levels of CO poisoning ($\geq$25% carboxyhemoglobin) or end-organ sensitivity to CO at elevated but lower levels. Examples of this might include neurologic abnormalities or hemodynamic instability that was felt to be caused by CO poisoning. HBOT is performed by placing the patient in a chamber that is highly pressurized with 100% oxygen. HBOT produces a large increase in the amount of dissolved oxygen in blood that in turn greatly increases the partial pressure of oxygen in the blood. The half-life of carboxyhemoglobin decreases as the partial pressure of oxygen in the blood increases. HBOT with 100% oxygen at a pressure of 2.5 to 3.0 atmosphere will reduce the half-life of carboxyhemoglobin from 4 to 6 hours to approximately 20 minutes [10,22,31].

Several animal studies suggest that HBOT may attenuate the development of delayed neuropsychiatric symptoms following CO exposure [32]. Although, the efficacy of HBOT for preventing the development of the delayed neuropsychiatric syndrome in humans following CO poisoning has not been conclusively established [33], many experts argue for its use when levels exceed 20% to 25% [33,34]. HBOT will, however, hasten the resolution of symptoms and when available is currently recommended for patients with CO poisoning meeting any of the following criteria: any period of unconsciousness, coma, or persistent neurologic abnormalities; carboxyhemoglobin level of 25% or more; metabolic lactic acidosis; or cardiac dysrhythmias [10,12,18,26,35–37]. If myocardial ischemia is present, most experts believe cardiac catheterization with stenting of the blocked vessel to be the urgently required procedure. In a pregnant patient, fetal distress even at lower percentage of carboxyhemoglobin elevations would prompt consideration for HBOT if available.

The clearance of CO can also be accelerated by use of normocapnic hyperoxic hyperpnea. In this technique, the patient breathes a hyperoxic gas mixture that contains an FIO_2 of 95.2% to 95.5% and a small amount of CO_2, in the range of 4.5% to 4.8%, through a nonrebreathing circuit. The resulting increase in minute ventilation increases the partial pressure gradient for oxygen and CO between pulmonary capillary blood and alveolar gas but does not increase the partial pressure gradient for CO_2. In a clinical study, normocapnic hyperoxic hyperpnea reduced the half-life of carboxyhemoglobin to 31 minutes in comparison with 78 minutes in individuals treated with 100% oxygen at normal minute ventilation [38]. CO-poisoned patients in hospitals without access to hyperbaric chambers might benefit from this technique.

In addition to controversy concerning which patients with CO intoxication might benefit most from HBOT, there also exists controversy surrounding the need to treat for HCN toxicity (see later) in patients suffering severe CO poisoning from smoke inhalation. The likelihood for cyanide toxicity in smoke inhalation victims increases with increasing carboxyhemoglobin levels and increasing acidosis [39].

Hydrogen Cyanide

Pathophysiology

Hydrogen cyanide (HCN) is a chemical asphyxiant produced by the combustion of nitrogen-containing polymers during fires [39–41]. It is also part of jewelry making and various manufacturing processes (metal plating) and in the reclamation of

silver from photographic and radiographic film. It has the potential to be used as a chemical agent in terrorist attacks [42]. It is a colorless, volatile liquid at room temperature but readily vaporizes into a gas. The gaseous form of HCN easily diffuses across the alveolar membrane after inhalation. Inhaled HCN is lethal in high doses, and its inhalation during a fire can contribute to the mortality of smoke inhalation victims [39–41]. The inhalation of lethal doses of HCN may also occur following accidental releases at industrial facilities or from its use in a terrorist attack.

After inhalation, HCN is rapidly distributed to tissues throughout the body. At the cellular level, HCN molecules bind to iron-containing sites on cytochrome a_3 in mitochondria that inhibits the enzyme's activity toxicity and decreases the cellular utilization of oxygen [39,42]. Cytochrome a_3 is a key enzyme in the cytochrome oxidase system that is important for carrying out and sustaining aerobic metabolism within cells. Inhibition of cytochrome a_3 by HCN will stop cellular respiration and oxidative phosphorylation, forcing affected cells into anaerobic metabolism. The binding of HCN to cytochrome a_3, and the resulting inhibition of cellular respiration, can occur very rapidly after HCN is inhaled, with clinical signs and symptoms typically occurring within 15 seconds after inhalation.

The clinical effects of HCN intoxication are directly related to its ability to stop cellular respiration. They are nonspecific and identical to the signs and symptoms typically seen during hypoxia. Hyperpnea, dyspnea, tachycardia, agitation, anxiety, dizziness, headache, confusion, nausea, muscle weakness, and trembling are common. Lactic acidosis occurs as a result of anaerobic metabolism and may be severe. Hypotension, flushing, seizures, and Parkinson-like symptoms may occur in cases of severe intoxication. Coma, apnea, and cardiac dysrhythmias are poor prognostic signs unless prompt treatment is given [42,43].

Diagnosis and Management

The diagnosis of HCN poisoning requires a high index of suspicion. It should be suspected in every individual with any of the above signs or symptoms for which there is no other obvious cause. It should routinely be suspected in smoke inhalation victims, victims of industrial accidents in which cyanide could have been released, and victims of terrorist attacks. Blood and urine cyanide concentrations can be obtained, but the results of these tests are usually confirmatory and because these tests are not routinely performed in most laboratories, results can only be used to confirm the diagnosis. Treatment for this potentially life-threatening poisoning must be initiated based on diagnostic suspicion alone.

There are several important clues that can be helpful in making a clinical diagnosis of HCN intoxication. In smoke inhalation victims, HCN toxicity should be suspected whenever CO intoxication occurs, and in fact, the likelihood increases with increasing carboxyhemoglobin levels [39]. Regardless of the etiology of HCN exposure, metabolic acidosis with an increased anion gap and an elevated serum lactate concentration should typically be present. Arterial and venous blood gases can provide potentially useful information. Arterial oxygen tension is usually above 90 mm Hg, whereas venous oxygen tension may be significantly elevated above the normal range of 35 to 45 mm Hg because of poor cellular extraction and utilization of oxygen. Similarly, arterial oxygen saturation is typically in the normal range of 95% to 100%, whereas the oxygen saturation of mixed venous blood may be in the vicinity of 85% or greater. Thus, the mixed venous oxygen saturation may be significantly higher than the normal range of 60% to 80%. This so called arteriolarization of venous blood can be a useful clue in considering the diagnosis of HCN intoxication [44].

Because HCN poisoning can rapidly progress, treatment must begin as soon as possible in patient presenting with seizures, coma, hypotension, or cardiac arrest in whom HCN toxicity is suspected [45,46]. The United States Food and Drug Administration has approved two forms of therapy for cyanide toxicity. The newest is the Cyanokit antidote consisting of Hydroxocobalamin, a precursor to vitamin B_{12}. It is a relatively benign substance with minimal side effects and rapid onset of action. For these reasons, it may be a superior antidote to the older more commonly available cyanide antidote kit (CAK) consisting of sodium nitrite and sodium thiosulfate [47,48]. Hydroxocobalamin has no adverse effect on the oxygen-carrying capacity of the red blood cells and no negative impact on the patient's blood pressure—significant benefits when treating victims of smoke inhalation. The mechanism of action is surprisingly simple: Hydroxocobalamin binds to cyanide forming vitamin B_{12} (cyanocobalamin), a nontoxic compound excreted in the urine. Patients tolerate the drug without hypotension or allergic reactions. Quickly passing side effects include reddish color to the skin, urine, and mucous membranes, which may interfere with some colorimetric laboratory tests (i.e., blood glucose, iron levels, creatinine, total hemoglobin concentration, carboxyhemoglobin, oxyhemoglobin, methemoglobin) [49,50]. Victims presenting with seizures, hypotension, or a coma in a setting consistent with cyanide toxicity should be considered candidates for empiric administration of Hydroxocobalamin 5 gm IV over 15 minutes through two intravenous or intraosseous lines. Consideration should be given to obtaining a blood sample for subsequent analysis for HCN and for baseline laboratory tests that could be interfered with by the presence of hydroxocobalamin.

Sodium nitrite and sodium thiosulfate can also be used for the treatment of HCN poisoning. These antidotes are found in the CAK, along with ampules of amyl nitrite inhalant. Sodium nitrite generates methemoglobin by changing the normal ferrous state of iron in the heme molecule of hemoglobin (Fe^{+2}) to the ferric state (Fe^{+3}). The ferric heme molecules in methemoglobin have a high affinity for HCN. Thus, HCN molecules preferentially bind to the methemoglobin generated by sodium nitrate, which in turn prevents HCN from entering cells and inhibiting cellular respiration. The adult dose of sodium nitrite is 300 mg in 10 mL of diluent (30 mg per mL) administered intravenously over 2 to 4 minutes and the pediatric dose is 0.33 mL per kg of a 3% solution, intravenously over 2 to 4 minutes, not to exceed 10 mL [42,43]. Following the administration of sodium nitrite, sodium thiosulfate should be administered intravenously. Sodium thiosulfate acts as a substrate for rhodanese, a detoxifying enzyme found in the liver. In the presence of sodium thiosulfate, rhodanese catalyzes the conversion of HCN cyanide to thiocyanate that is then excreted in the urine. The adult dose is 12.5 g of sodium thiosulfate in 50 mL of diluent (25% solution), administered intravenously at a rate of 3 to 5 mL per minute. The pediatric dose of sodium thiosulfate is 412.5 mg per kg (1.65 mL per kg) of a 25% solution, given intravenously at a rate of 3 to 5 mL per minute [42,44].

The inhalation of amyl nitrite from ampules can be used as a temporizing measure until venous access for the administration of sodium nitrite and sodium thiosulfate is obtained. The inhalation of amyl nitrite should never be considered a substitute for the administration of intravenous sodium nitrite and sodium thiosulfate. In fact, amyl nitrite can itself be associated with serious reactions such as hypotension, syncope, methemoglobinemia, and hemolysis in G6PD-deficient patients. These effects are more pronounced in children, the elderly, and in patients with cardiopulmonary diseases. Dose regimen is difficult to control and could even result in exposure of the healthcare provider to amyl nitrite's adverse effects. For these reasons, administration of amyl nitrite may be unwarranted, especially since hydroxocobalamin is now available [51].

One hundred percent oxygen should be administered to all patients with HCN poisoning to maximize the oxygen-carrying capacity of blood. Ventilatory support should be provided as needed. The administration of sodium bicarbonate should be considered for the treatment of severe lactic acidosis in patients who are unconscious or hemodynamically unstable. Arterial blood gas analysis should be used to guide the need for repeat doses of sodium bicarbonate to ensure that metabolic alkalosis does not develop.

Hydrogen Sulfide

Pathophysiology

Hydrogen sulfide (H_2S) is a colorless, highly flammable gas that has the characteristic odor of "rotten eggs." It is produced in a variety of settings, most commonly sewer systems, manure pits on farms, oil fields, and petroleum refining plants [52–54]. Its noxious, "rotten eggs" odor is detectable by smell at low concentrations but may not be detectable at high concentrations or after prolonged exposure because of olfactory fatigue. Inhaled H_2S is both a chemical asphyxiant and a respiratory tract irritant. As such, it can produce a variety of clinical effects, including central nervous system dysfunction [55], cardiac dysrhythmias, and pulmonary edema as a result of acute lung injury. The severity of symptoms and prognosis are dependent on the dose of H_2S inhaled.

As a chemical asphyxiant, H_2S blocks the cellular utilization of oxygen by inhibiting the activity of cytochrome a_3, a mitochondrial enzyme of the cytochrome oxidase system that is involved in aerobic metabolism. In this regard, the pathophysiologic mechanism of H_2S asphyxiation is identical to that of HCN. As with HCN intoxication, disruption of aerobic metabolism by H_2S causes a shift to anaerobic metabolism within affected cells that, in turn, leads to metabolic acidosis and an elevated anion gap due to increased lactate production. H_2S is lipid soluble and readily crosses the alveolar membrane after inhalation. Inhalation is the primary route of H_2S toxicity. After absorption through the lungs, H_2S easily dissolves in the blood and is rapidly distributed to tissues throughout the body. The respiratory system and organs with high oxygen demand, such as the brain and heart, are particularly vulnerable.

The severity of clinical signs and symptoms associated with H_2S toxicity depend on the exposure dose. Signs and symptoms of asphyxiation and mucosal irritation typically exist simultaneously. Local irritant effects dominate at low exposure doses, whereas pulmonary edema and life-threatening chemical asphyxiation dominate at higher exposure doses. Clinically detectable eye, mucous membrane, and respiratory tract irritation begin to occur at low exposure doses in the vicinity of 50 parts per million (ppm). Low-dose exposures in the range of 50 to 200 ppm are typically characterized by burning of the eyes, increased lacrimation, sore throat, nausea, cough, and occasional wheezing. Because olfactory function is lost at around 100 to 200 ppm, if exposed individuals can still smell the "rotten eggs" odor of H_2S, the concentration is usually not high enough to cause severe asphyxiation or irritant injury. At exposure concentrations of 200 to 250 ppm, H_2S produces intense irritation of mucous membranes, corneal ulceration, blepharospasm, and dyspnea. Pulmonary edema may occur at these concentrations as a result of irritant-induced acute lung injury. At concentrations greater than 500 ppm, chemical asphyxiation of the brain may produce headache, seizures, delirium, confusion, and lethargy. The central nervous system effects of H_2S toxicity may be exacerbated by hypoxemia secondary to severe pulmonary edema. In survivors, long-term neurologic sequelae, such as ataxia, intention tremor, sensorineural hearing loss, muscle spasticity, and memory impairment may occur [53].

Concentrations in the range of 750 to 1,000 ppm will cause severe inhibition of aerobic metabolism within the central nervous system and heart. Myocardial ischemia, arrhythmias, and dilated cardiomyopathy have all been reported after significant exposures [56,57]. As doses increase, loss of consciousness, cessation of brainstem function, and cardiopulmonary arrest will occur.

Diagnosis and Management

A high index of suspicion is the key to making the diagnosis of H_2S intoxication. Although blood levels of thiosulfate are helpful in confirming the diagnosis of H_2S poisoning [58], these tests are not readily available in most clinical laboratories. When available, atmospheric measures of H_2S concentration can be used to increase diagnostic suspicion and in classifying the expected severity of exposure and intoxication. In the absence of specific exposure information, signs of ocular irritation, inflammation of mucosal membranes, and the smell of "rotten eggs" on the clothing or breath of a patient should suggest the diagnosis of H_2S intoxication.

The inhibition of cytochrome a_3 by H_2S toxicity causes a decrease in the extraction and utilization of oxygen by affected cells. As a result, blood gas analyses typically show a PaO_2 in the normal range and an elevated mixed venous oxygen tension (PvO_2), typically in the range of 35 to 45 mm Hg. There may also be a "saturation gap" between the arterial saturation of oxygen (SaO_2) calculated from arterial blood gas data and the SaO_2 measured by cooximetry as a result of sulfide ions binding to some oxygen binding sites on hemoglobin molecules, forming molecules of sulfhemoglobin. In addition, both methemoglobin and sulfhemoglobin are produced during the treatment of H_2S poisoning with sodium nitrite and amyl nitrite, as discussed later. Therefore, if H_2S poisoning is known or suspected, SaO_2 should be measured by cooximetry. A rapid decline in either PaO_2 or SaO_2 could indicate the development or progression of pulmonary edema. Serum lactate concentration is typically elevated as a result of the inhibition of aerobic metabolism. The elevated lactate concentration causes a metabolic acidosis and elevation of the anion gap.

The treatment for H_2S intoxication is similar to that for HCN intoxication—100% oxygen, antidote, and possibly HBOT. One hundred percent oxygen should be given to all patients. Assisted ventilation should be provided as necessary. Sodium nitrite can be used as an antidote to generate methemoglobin by changing the normal ferrous state of iron in the heme molecule of hemoglobin (Fe^{+2}) to the ferric state (Fe^{+3}). The ferric heme molecules in methemoglobin have a high affinity for H_2S [59]. The preferential binding of H_2S molecules to methemoglobin results in the formation of sulfhemoglobin that prevents circulating H_2S from entering cells and inhibiting cellular respiration. Sodium nitrite should be administered as soon as possible after exposure. Inhalation of amyl nitrite from ampules contained in cyanide antidote kits can be administered as a temporizing measure until venous access is obtained for the administration of sodium nitrite. The detoxifying enzyme rhodanese is not involved in H_2S metabolism, as it is in HCN metabolism. Therefore, sodium thiosulfate or hydroxocobalamin should not be given for the treatment of H_2S intoxication. Several case reports argue for a beneficial effect of HBOT in H_2S intoxication [60,61]. Basic supportive measures should not be forgotten and include irrigation of the eyes with sterile saline and the treatment of irritant-induced bronchospasm with inhaled β_2-agonists. Consideration should be given to the administration of sodium bicarbonate for the treatment of severe metabolic acidosis in unconscious or hemodynamically unstable patients. A benzodiazepine, such as diazepam, or a barbiturate can be used to control seizures if present. If a

benzodiazepine or barbiturate is given, patients should be carefully monitored for signs of respiratory insufficiency.

IRRITANT GASES

Irritant gases are those that cause chemical injury to the airways and lung tissue upon inhalation. The nature, location, and severity of respiratory tract injuries associated with the inhalation of an irritant gas are dependent on the physical and chemical properties of the gas, exposure dose, and host factors of exposed individuals. The most important physical and chemical properties are the water solubility and density of the gas. Exposure dose is determined by the concentration of the gas in the environment and the duration of exposure. Minute ventilation, age, and the presence of preexisting respiratory disease are the most important host factors (Table 64.5).

The sites of injury following inhalation of an irritant gas are dependent on the water solubility of the gas that determines where most of the gas will be deposited in the respiratory tract (Table 64.6). Highly soluble gases, such as ammonia and sulfur dioxide, generally cause irritant damage to exposed mucous membranes, such as the eyes and upper airway (nose, lips, pharynx, and larynx), while sparing the lower airways. At high concentrations, however, a highly soluble irritant gas can overwhelm the upper respiratory tract, and significant amounts may reach the upper and lower airways, thereby producing both mucous membrane and airway injury. Irritant gases of intermediate solubility, such as chlorine, may produce significant upper airway injury, especially in the pharynx and larynx, but the mucous membrane irritation is usually not as intense as that caused by highly soluble gases. Because of its intermediate solubility, the irritant effects of chlorine will extend more distally at higher concentrations. Thus, high concentrations of inhaled chlorine can produce both upper and lower airway injury, as well as pulmonary edema due to alveolar damage. The inhalation of low-solubility irritant gases, such as phosgene and oxides of nitrogen, typically produces minimal upper airway irritation but can cause intense lower airways and alveolar damage. As a result of lung tissue injury, the development of noncardiogenic pulmonary edema is more likely following inhalation of a low-solubility irritant gas or at high concentrations of gases with intermediate solubility. Irritant gases that are associated with the development of pulmonary edema are listed in Table 64.7. The inhalation of gases that are lipid soluble, but not water soluble, such as chloroform, ether, or other halogenated hydrocarbons, will produce central nervous system effects and little, if any, respiratory injury. Methylene chloride, found in paint remover and other solvents, is an exception to this rule in that high doses may cause pulmonary edema [62].

TABLE 64.5

DETERMINANTS OF SEVERITY OF LUNG INJURY

Duration of exposure
Minute ventilation
Age of victim
Proximity to source
Density of gas and height of victim
Temperature of gas
Toxicity of gas
Water solubility of gas
Particle size of mist, fog, or vapor
Breathing pattern-oronasal vs. mouth breathing
Host factors such as preexisting asthma, coronary disease, chronic obstructive pulmonary disease
Orthopedic problems that affect the ability to evacuate quickly

High solubility gases
Ammonia
Methyl isocyanate
Sulfur dioxide
Intermediate solubility gas
Chlorine
Low solubility gases
Hydrogen sulfide
Oxides of nitrogen
Phosgene

Irritant gases cause damage to airways and lung tissues by direct cellular injury, cellular injury secondary to the production of free radicals, and production of an inflammatory response. Direct cellular injury is commonly produced by irritant gases that possess either a highly acidic or a highly alkaline pH. Chlorine and phosgene, for example, produce hydrochloric acid when they come in contact with water in mucous membranes. Ammonia forms a strong alkali, ammonium hydroxide, when it comes in contact with water in mucous membranes and airways. Ammonium hydroxide causes liquefaction damage to cells and tissues on contact, with the severity of damage directly related to the hydroxyl ion concentration. Damage to respiratory tract cells and tissues can also be caused by irritant gases that generate the production of free radicals. Oxides of nitrogen, for example, cause the production of free radicals that cause cellular damage by lipid peroxidation. Both direct cell damage and cell damage secondary to free radical formation result in the release of a variety of inflammatory mediators that elicit an inflammatory response, thereby causing further oxidant damage to respiratory tract cells. In the airways, the

TABLE 64.7

TOXIC GASES AND FUMES THAT CAN PRODUCE PULMONARY EDEMA

Acetaldehyde	Methylene chloride
Acrolein	Nickel carbonyl
Ammonia	Nitrogen dioxide
Antimony tri- or pentachloride	Osmium tetroxide
Beryllium	Ozone
Bismuth pentachloride	Paraquat
Boranes	Perchloroethylene
Cadmium and cadmium salts	Phosgene
Chloramine	Phosphine
Chlorine	Polytetrafluoroethylene
Cobalt metal	Selenium dioxide
Dichlorosilane	Silanes
Dimethyl sulfate	Silicone tetrachloride
Dioxane dimethyl sulfate	Silicone tetrafluoride
Fire smoke	Sulfur dioxide
Glyphosate herbicides	TDI in high concentrations
Hydrogen chloride	Titanium tetrachloride
Hydrogen fluoride	Trimellitic anhydride
Hydrogen selenide	Vanadium
Hydrogen sulfide	War gases
Lithium hydride	Zinc oxide and chloride
Mercury	Zirconium chloride
Methyl bromide	

damage caused by irritant gases is manifested by mucosal edema, mucus production, increased smooth muscle contraction, and airway obstruction. At the alveolar level, damage of type 1 pneumocytes occurs followed by capillary leakage due to epithelial cell damage, disruption of epithelial cell tight junctions, endothelial damage, and increased vascular permeability.

Specific Irritant Toxic Gases

Ammonia

Ammonia (NH_3) is a colorless, pungent, alkaline gas that is less dense than air and highly soluble. It forms ammonium hydroxide (NH_4OH) upon contact with water. Most inhalational injuries from NH_3 occur as a result of exposures occurring during fertilizer production [63], chemical manufacturing, and oil refining or the use of cleaning solutions [64]. Recently, exposures have occurred during the illicit production of methamphetamine [65]. The strong, pungent smell associated with NH_3 can be readily detected at a concentration as low as 50 ppm. Few individuals can tolerate a concentration greater than 100 ppm without experiencing nasal stuffiness and irritating cough.

As a highly soluble gas, NH_3 primarily causes irritation to the eyes, mucous membranes of the nasal–oral pharynx, and mucosa of the upper respiratory airways. The reaction of NH_3 with water in the conjunctivae, mucous membranes, and upper airway mucosa results in the formation of NH_4OH that causes liquefaction necrosis and intense pain in the eyes, mouth, nose, and throat. The voice is lost shortly after exposure, and patients typically experience sensations of choking and suffocation. The eyes are erythematous, swollen, and may show signs of corneal opacification or ulceration. Edema, ulceration, necrosis, and sloughing of the mucous membranes are typically seen. Airway obstruction due to laryngeal edema, bronchial inflammation, bronchoconstriction, and plugs of sloughed epithelium may cause dyspnea, wheezing, and hypoxemia [66]. Death from laryngospasm can occur within 1 minute after exposure to high concentrations ($\geq$1,500 ppm). With exposure to high concentrations, alveolar damage and pulmonary edema can occur within 24 hours [66]. Secondary bacterial bronchopneumonia may occur within days. Long-term sequelae of NH_3 inhalation include persistent airway obstruction from reactive airways dysfunction syndrome (RADS), asthma, bronchitis, bronchiectasis, and bronchiolitis obliterans [66,67].

Chlorine

Chlorine (Cl_2) is a dense, greenish-yellow gas under ambient conditions. It is highly reactive, has intermediate solubility, and has the characteristic pungent odor of bleach. Industrial uses of Cl_2 include the production of chemicals and bleaches, paper manufacturing, textile processing, and the production of polyvinyl chloride. Most Cl_2 exposures result from accidental releases at industrial sites, from ruptured tanks during its transportation or at swimming pools [68–70]. The relatively high density of Cl_2 causes it to accumulate in low-lying areas, which should be avoided following its accidental release.

Chlorine is detectable by smell at levels of 1 ppm. On contact with mucous membranes, chlorine reacts with water to produce hydrochloric acid (HCl), hypochlorous acid (HClO), and free oxygen radicals. Individuals exposed to low concentrations of Cl_2 typically experience burning of the eyes and mucous membranes, as well as choking and coughing due to inflammation of the nasal–oral pharynx and upper airway. At higher concentrations, laryngeal edema, lower airway inflammation, bronchoconstriction, and pulmonary edema can develop. The development of stridor reflects upper airway obstruction due to laryngeal edema and should be considered as a sign of impending respiratory failure. However, in some cases, slight wheezing and erythema of the conjunctivae and mucous membranes may be the only physical findings that are evident within the first hour after exposure. Unfortunately, the initial paucity of significant signs and symptoms may not reflect the true severity of the inhalational injury, and exposed individuals may be sent home from the emergency department prematurely. For example, an exposure concentration of 50 ppm may produce relatively mild signs and symptoms initially but can cause death from laryngospasm or massive pulmonary edema within 1 to 2 hours after exposure. The onset of pulmonary edema may also be delayed up to 24 hours after exposure. At any time within 2 days after Cl_2 exposure, airway inflammation and mucosal desquamation may cause plugging of medium and small bronchi, leading to airflow obstruction and atelectasis. Individuals with a history of asthma or airway hyperactivity may have particularly severe bronchospasm. Secondary bacterial bronchopneumonia may develop as a consequence of ulceration and desquamation of airway mucosa and/or alveolar damage. Fortunately, most exposed individuals will recover completely if they receive prompt medical treatment and survive the acute effects of Cl_2 exposure. However, chronic pulmonary problems may develop in some individuals, including RADS, asthma, bronchiectasis, and bronchiolitis obliterans [70–72].

Phosgene

Phosgene ($COCl_2$) is a heavy, poorly soluble, colorless gas that has the smell of freshly mown hay. Upon contact with water, it hydrolyzes to form CO_2 and HCl. $COCl_2$ has been used as a chemical warfare agent and was responsible for most gas fatalities during World War I [42]. It is currently use as a chlorinating agent in a variety of industrial processes, including the production of isocyanates, pesticides, dyes, and pharmaceutical agents. Fire fighters, welders, and paint strippers may be exposed to $COCl_2$ as a result of its release from heated chlorinated hydrocarbons, such as polyvinyl chloride [73]. Phosgene is approximately four times as dense as air and tends to accumulate close to the ground and in low-lying areas. Therefore, exposed individuals should avoid low-lying areas following an accidental release.

As a gas with low solubility, $COCl_2$ is less irritating to the eyes and mucous membranes than NH_3 or Cl_2 and causes mostly irritant damage in the lower airways and cellular damage at the alveolar level. Immediate symptoms include burning of the eyes, increased lacrimation, sore throat, rhinorrhea, coughing, choking, dyspnea, and chest tightness, which may be relatively mild and may resolve within several minutes after cessation of $COCl_2$ exposure. Laryngeal edema can occur shortly after high concentration exposures, with stridor and the potential for sudden death. As a result of its low solubility, the mucous membranes and upper airways are typically spared and there may be few, if any, additional symptoms for 2 to 24 hours following the acute inhalation of $COCl_2$. However, inhaled $COCl_2$ will eventually hydrolyze to form HCl in the lower airways and alveoli causing oxidative and inflammatory injury. As a result, bronchospasm and pulmonary edema typically develop between 2 and 6 hours following exposure, but pulmonary edema may be delayed for up to 24 hours. The pulmonary edema can progress to the acute respiratory distress syndrome (ARDS) and respiratory failure. Most victims survive without long-term sequelae if they receive prompt medical care. Those with ARDS have the worst prognosis and will require assisted ventilation and circulatory support as needed. Chronic problems may develop in some individuals with RADS, asthma, bronchiectasis, and bronchiolitis obliterans [74].

Nitrogen Oxides

The four stable oxides of nitrogen are nitrous oxide (N_2O), nitric oxide (NO), nitrogen dioxide (NO_2), and nitrogen tetroxide (N_2O_4). Oxides of nitrogen are used in the production of dyes, lacquer, and fertilizer. They are also generated in a variety of processes, including arc welding [73], chemical engraving, explosives, and the storage of fresh silage [75]. All oxides of nitrogen can produce serious acute respiratory tract injury upon inhalation. However, NO_2 is the most common and clinically important toxicant in this group. NO_2 is an irritating, low solubility, dense orange-brown gas. It forms nitric acid (HNO_3) and nitrous acid (HNO_2) upon contact with water.

NO_2 causes silo filler's disease, one of the best-characterized syndromes of toxic gas exposure. Silo filler's disease develops following exposure to NO_2 gas that accumulates just above the silage in recently filled, top-loading silos. During the first 2 weeks in the silo, carbohydrates in the silage ferment and produce organic acids. The organic acids then oxidize nitrates in the silage into NO_2. Within hours after it starts to be produced, NO_2 rapidly accumulates to toxic levels of 200 to 2,000 ppm. High concentrations of NO_2 typically persist for 1 to 2 weeks, then decrease. Entry into a silo without proper respiratory protection, especially within the first 2 weeks of the silo being filled with fresh silage, can cause a rapid loss of consciousness and sudden death. The incidence of this disorder is estimated to be 5 cases per 100,000 silo-associated farm workers per year [75].

The lower airways and lung are the primary sites of injury following acute inhalation of NO_2. The low water solubility of NO_2 results in a paucity of eye, mucous membrane, and upper airway irritant symptoms. The most significant effects occur in the lower airways and lungs as a result of the conversion of NO_2 to HNO_3 upon contact with water in bronchial mucosa and alveoli. The clinical response to inhaled NO_2 occurs in three phases [75,76]. The first phase is the *acute illness phase* that typically occurs within the first hour after exposure. The severity of symptoms in this first phase is dose related. At doses up to 100 ppm, cough, wheezing, dyspnea, and chest pain develop as a result of lower airway irritation and bronchospasm. Hypotension may occur in severe cases. At doses greater than 100 ppm, pulmonary edema may develop within 1 to 2 hours after exposure. The hypoxemia resulting from pulmonary edema is further exacerbated by NO_2-induced methemoglobinemia.

Without further NO_2 exposure, symptoms of the *acute illness phase* usually resolve over a period of 2 to 8 weeks. During this *latent phase*, the patient may have mild cough and wheezing, or may be totally asymptomatic. The patient may then develop a *delayed illness phase* that is characterized by the sudden onset of fever, chills, cough, dyspnea, and generalized lung crackles [75,76]. The *delayed illness phase* is characterized by bronchiolitis obliterans. Lung biopsies have shown that this is bronchiolitis of the proximal type without organizing pneumonia [75,76]. The bronchioles are typically packed with inflammatory exudate and fibrin that may obliterate the entire lumen. The bronchiolitis obliterans of the *delayed illness phase* may be extensive and cause severe, life-threatening hypoxemia. Symptom severity in the *acute illness phase* does not always correlate with the severity of bronchiolitis obliterans in the *delayed illness phase*. Therefore, patients with relatively mild symptoms in the days following acute NO_2 exposure may experience severe, life-threatening bronchiolitis obliterans in the *delayed illness phase*.

Sulfur Dioxide

Sulfur dioxide (SO_2) is a colorless, dense, irritating gas that is highly soluble in water. It has a readily identifiable, strong, pungent, odor. SO_2 is a common atmospheric pollutant from the combustion of coal and gasoline. It is used in a variety of industrial process, such as bleaching, refrigeration, and paper manufacturing [77]. SO_2 forms sulfuric acid (H_2SO_4) upon contact with water in human tissues. As a highly soluble gas, the predominant effects of SO_2 exposure are irritation of the eyes, nose, mucous membranes, pharynx, and upper respiratory tract. Exposure doses greater than 10 ppm typically cause bronchospasm with symptoms of cough, wheezing, dyspnea, and chest pain. Symptom severity increases with increasing exposure doses. Individuals with preexisting asthma or chronic obstructive lung disease are 10 times more likely to develop severe exacerbations [77]. These include RADS, asthma, bronchiolitis obliterans, and restrictive lung disease [77,78].

SMOKE

Smoke is a toxic, irritant mixture of gases, vapors, fumes, liquid droplets, and carbonaceous particles generated by the incomplete combustion or pyrolysis of multiple substances at very high temperatures. Approximately 80% of all fire-associated deaths are attributed to inhalation injury [79]. Smoke inhalation is the most common cause of death in fire victims without surface burns. Inhalation injury exerts a greater influence than burn size or age in determining burn mortality [80]. Patients being treated in burn centers have a mortality rate of 29% in the presence of inhalation injury, in comparison with a mortality rate of 2% in its absence [81].

Combustion occurs when oxygen reacts with fuel molecules under intense heat and the fuel molecules are oxidized to smaller compounds. Pyrolysis occurs as a result of heat alone, does not require oxygen, and consists of the melting or boiling of heated material. The toxic products of incomplete combustion or pyrolysis generated in a given setting are determined by multiple factors, including the type of fuel consumed, temperature, rate of heating, and distance from the source [79]. Black smoke results from particles of carbon or soot generated during the combustion or pyrolysis of carbon-containing materials. Common combustible materials in a fire include wood, paper, plastics, polyurethane, paints, and other polymers present in carpeting and upholstery.

Toxic gases are released during combustion and pyrolysis. These gases include both asphyxiants and irritants. CO and HCN are common asphyxiants found in smoke. Aldehydes, acrolein, NO_2, SO_2, and HCl are common irritants found in smoke. These irritant gases are more likely to be released during pyrolysis than combustion [82]. Particulates present in smoke adsorb these irritant chemicals to their surface, which can concentrate the chemicals and increase irritant damage to the respiratory tract upon inhalation [83].

Victims of smoke inhalation are exposed to multiple irritant gases [79,84], but several deserve special mention. Acrolein is an aldehyde released in fires involving polyethylene, polypropylene, vinyl materials, wood, and other organic fuels. At low concentrations, acrolein is intensely irritating to the upper respiratory tract and can cause significant upper airway edema. At high concentrations (>10 ppm), acrolein inhalation can cause severe, life-threatening pulmonary edema [85]. Isocyanate, a known cause of asthma, is also among the toxic products produced in fires. The inhalation of isocyanate contained in smoke can precipitate severe bronchospasm in individuals with or without a history of airway disease.

Smoke particles cause airway damage due to direct injury from heat and steam, irritation of the airway mucosa by the particles themselves, and from inflammation as a result of the irritant effects of toxic chemicals absorbed to their surface. Heat injury from hot gases and steam is usually limited to the upper respiratory tract as heat rapidly dissipates across the upper airways [85]. Smoke particles greater than 10 μm in diameter also contribute to upper airway injury (rhinosinusitis, pharyngitis, laryngitis, and upper airway edematous obstruction), as

they do not penetrate into the lower airways unless present at high concentrations. Subglottic or supraglottic edema following smoke inhalation can lead to significant upper airway obstruction. Upper airway obstruction occurs in up to 30% of burn patients and may occur as early as 4 hours or as late as 24 hours after exposure [86]. The production of upper airway edema is due to a variety of factors, including direct mucosal damage and ulceration from heat and superheated steam, the release of inflammatory mediators from the damaged mucosa, and the production of oxygen free radicals from toxic chemicals on the surface of smoke particles. Acute upper airway edema following smoke inhalation usually resolves within 3 to 4 days. Rarely, thermal injury can produce circumferential, constricting eschars or scarring of the upper airway after the acute edema resolves. Such eschars can produce chronic upper airway obstruction.

In the large to medium size airways of the chest, tracheobronchitis can develop as a result of smoke inhalation. Severe cough and chest tightness without bronchoconstriction are common presenting symptoms. Tracheobronchitis is due to irritant chemical and/or particulate injury. Heat injury is rare and occurs only after the inhalation of superheated steam [85].

Particles less than 3 μm in diameter travel to the distal portions of the respiratory tract and can cause small airways and alveolar injury. Lower airway penetration by small smoke particulates can cause irritation, inflammation, and bronchoconstriction. Individuals with preexisting asthma or chronic obstructive pulmonary disease may experience exacerbations, but bronchoconstriction can also occur in individuals with no prior history of airway disease. Small smoke particles can also cause alveolar-capillary injury in the lung parenchyma by direct oxidative damage from adsorbed irritants and by oxygen free radicals and inflammatory mediators released by neutrophils that migrate to areas of irritant damage. Pulmonary edema can occur as a consequence of alveolar-capillary injury and may occur hours to days after smoke inhalation. Although pulmonary edema occurs in far less than 10% of smoke inhalation victims, it has a high mortality rate [87].

Airway injury, whether it is tracheobronchitis or small airway bronchoconstriction, can cause sloughing of necrotic tissue into the lower airways that can lead to mucous plugging, bronchial obstruction, atelectasis, hyperinflation, and altered mucociliary clearance. Secondary bacterial pneumonia can develop in obstructed lung segments or as the result of alveolar damage adversely affecting local immunodefenses.

Most smoke inhalation deaths are caused by asphyxiation as a result of CO or HCN in the inhaled smoke [14,39–41]. CO intoxication is responsible for 80% of smoke inhalation fatalities, and approximately one fourth of these occur in victims with underlying cardiac or pulmonary disease [10]. NO_2 may also be a component of inhaled smoke. In addition to being a potent irritant, NO_2 can cause the development of methemoglobinemia, which can further decrease the already impaired oxygen-carrying capacity of hemoglobin caused by carboxyhemoglobinemia. Coexisting HCN intoxication needs to be considered in all smoke inhalation victims with CO intoxication, especially those with clinical evidence of altered neurologic or cardiac status. In a study from Paris, a clear association was found between blood HCN levels and percent carboxyhemoglobin levels [39]. This association was strongest in patients with metabolic acidosis and elevated lactate levels [39]. In a study from the Dallas County Fire Department, an HCN blood level above 1.0 mg per L was a strong predictor of death, but the association between CO and HCN levels was not strong [88]. In this study [88], of the 144 patients that reached the emergency room alive, 12 had blood cyanide concentrations exceeding 1.0 mg per L and 8 of the 12 subsequently died. In these 12 patients, the relationship between percent carboxyhemoglobin levels and HCN blood levels was poor. For example, the highest percent carboxyhemoglobin level found was 40.0%, in a patient with a blood HCN level of 1.20 mg per L. The highest HCN level found was 11.50 mg per L in a patient with a percent carboxyhemoglobin level of 22.4%.

Diagnosis and Management of Irritant Toxic Gases, Including Smoke Inhalation

The most important factors in the diagnosis of toxic inhalational injury are a history of circumstances that caused the exposure, identification of the specific toxic gas to which an individual has been exposed, and an estimate of the exposure concentration. Exposure duration is based not only on exposure time but also on the patient's minute ventilation during that time. Chemical analyses of material at the site of exposure, if available, can be particularly helpful in identifying the offending toxicant and estimating its exposure concentration. The relative solubility of a toxic gas can be helpful in determining the areas of the respiratory tract where irritant injuries are most likely to occur, and obviously patients with preexisting pulmonary disease are most at risk. When the irritant toxic gases are in the setting of smoke inhalation, the exposure will be to multiple gases and particulates. Facial burns, singed eyebrows, soot in the upper airway, and carbonaceous sputum make smoke inhalation highly likely.

The management of acute inhalational injury from toxic irritants is at first supportive. All contaminated clothing should be removed to prevent further inhalation and percutaneous absorption of the toxic substance. Superficial burns should be treated conservatively with a topical antibiotic such as silver sulfadiazine. The eyes should be thoroughly flushed with sterile normal saline as soon as possible. Careful attention to the eyes is important because cataracts can occur following heavy exposures. Humidified oxygen should be given by face mask. Not everyone exposed to fire smoke warrants hospital admission. Victims with mild inhalation exposures may be treated and released if they are (i) asymptomatic with normal mental status and absent of confusion; (ii) no burns, carbon material, or edema in the upper airway; (iii) normal pulmonary examination without signs of respiratory distress, stridor, or wheeze; and (iv) if available a pulse oximeter and noninvasive carboxyhemoglobin reading that are normal or at baseline. Upon release, patients should be advised to seek medical attention if symptoms occur or reoccur, as the clinical manifestations of inhalation injury may take 4 to 24 hours to develop [87]. It is for this reason that borderline patients or patients with significant comorbidity should be observed rather than released whenever possible.

The medical evaluation after any exposure to potentially toxic irritant gases should focus on assessing the nature and extent of upper and lower respiratory tract injury, the adequacy of oxygenation, cardiac function, and the hemodynamic stability of the patient. Inhalation victims may be unconscious or have altered mental status at the time of presentation. Typical patient complaints include eye irritation, headaches, confusion, sore throat, chest tightness, and difficulty breathing. Common physical findings include irritation of the eyes, skin and other exposed mucosal surfaces, tachypnea, cough, stridor, wheezing, and rhonchi. Rales on presentation are unusual, as pulmonary edema is a later complication [87].

Arterial blood gases, oxygen saturation, should be obtained on all patients. The methemoglobin level should be measured in patients with suspected NO_2 exposure or after treatment with amyl or sodium nitrites for suspected HCN toxicity. Serum lactate concentration should be measured, and the magnitude of metabolic acidosis should be assessed. Although chest radiographs may be normal shortly after acute exposure, serial

radiographs are useful for detecting the development of pulmonary edema and secondary bacterial pneumonia in hypoxemic individuals. An electrocardiogram should be obtained to detect the presence of myocardial ischemia and cardiac dysrhythmias. Hemodynamic monitoring may be necessary in complex, critically ill patients with pulmonary edema.

The carboxyhemoglobin level, a measure of CO intoxication, should be obtained in all patients with suspected exposure to smoke, fires, or other sources of combustion. If high levels of carboxyhemoglobin, methemoglobin, or HCN exist, the arterial oxygen tension (PaO_2) is not useful in assessing the adequacy of oxygen transport or tissue oxygenation. Arterial oxygen saturation should be measured by cooximetry because pulse oximetry and the calculation of SaO_2 from the PaO_2 will overestimate the actual oxygen saturation of hemoglobin.

All individuals with known or suspected inhalation injury should be given 100% humidified oxygen as soon as possible. This will help to improve the oxygen-carrying capacity of hemoglobin when high levels of carboxyhemoglobin or methemoglobin are present. High levels of methemoglobin are unusual but, if present, can be treated with intravenous methylene blue. The fraction of inspired oxygen can be titrated down to maintain a PaO_2 greater than 60 mm Hg once carboxyhemoglobin and methemoglobin levels have returned to normal. When available, HBOT should be considered for the treatment of CO intoxication according to the criteria for previously delineated in the section in this chapter. HBOT has been used to treat patients with extreme levels of CO poisoning ($\geq$25% carboxyhemoglobin) or end-organ sensitivity to CO at elevated but lower levels. Examples of this might include neurologic abnormalities or hemodynamic instability that was felt to be caused by CO poisoning.

Severely ill smoke inhalation patients presenting with seizures, coma, hemodynamic instability, and/or severe lactic acidosis should be suspected of having both CO and HCN intoxication [39–41,88]. Blood HCN levels can be measured, but results cannot be obtained in time to make therapeutic decisions and therefore the decision to treat for HCN toxicity should be based on the exposure characteristics and clinical presentation. NYC Fire Department protocol is to intubate such patients; provide hemodynamic support as needed; empirically treat for HCN poisoning with hydroxocobalamin; and, if noninvasive carboxyhemoglobin levels are elevated, to transport to a HBOT center. In addition, all smoke inhalation victims found in cardiac arrest receive hydroxocobalamin during cardiac resuscitation.

In smoke inhalation patients, with suspected HCN poisoning, hydroxocobalamin is preferable to sodium thiosulfate because of its rapid onset of action. Inhaled amyl nitrite and intravenous sodium nitrite should be avoided because they generate methemoglobin that can further impair the oxygen-carrying capacity of blood hemoglobin if high levels of carboxyhemoglobin or methemoglobin are already present. The Paris Fire Brigade routinely administers hydroxocobalamin to smoke inhalation patients and published their experience in 2006 [46]. Of the 29 patients in cardiac arrest, 18 (62%) recovered with cardiac resuscitation and hydroxocobalamin treatment. The average time between hydroxocobalamin administration and recovery of spontaneous cardiac activity was 19 minutes. In 15 hemodynamically unstable patients not in cardiac arrest, 12 (80%) showed hemodynamic improvement (blood pressure >90 mm Hg) after hydroxocobalamin. The average time for hemodynamic improvement was 49 minutes from the start of and 29 minutes from the end of hydroxocobalamin infusion. In a second study, 28 of 42 patients (67%) admitted to the ICU with smoke inhalation and confirmed a posteriori HCN poisoning survived after hydroxocobalamin administration [47].

Respiratory symptoms and distress are not only related to oxygen delivery/utilization problems. Irritant, toxic gases can also cause tachypnea, stridor, and hoarseness due to upper and lower airway disease. Patients are at high risk of developing progressive laryngeal edema with complete obstruction of the upper airway. Smoke inhalation further adds to this risk due to heat and particulate matter exposure. Patients with laryngeal edema can be extremely difficult to intubate and if intubation is delayed may require an emergency tracheostomy. However, not all patients require intubation [89]. Prompt inspection of the larynx with a laryngoscope is imperative [86]. Immediate intubation should be considered if there is evidence of significant upper airway edema or blisters. All patients with upper airway edema should be treated with nebulized racemic epinephrine and systemic corticosteroids. If edema is minimal and early intubation is not required, airflow can usually be maintained with positive pressure breathing administered by the use of continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP). An inhaled mixture of helium and oxygen can also improve upper airway airflow by reducing turbulence as a result of its low density. If the clinical decision is not for immediate or early intubation [89], then patients with upper airway edema should be admitted to the hospital and closely monitored for signs of edema progression and the need for emergent intubation at a later time.

Lower airway involvement from irritant gas or smoke inhalation is typically diagnosed by history and physical examination. However, additional diagnostic evidence can be provided by laryngoscopic or bronchoscopic demonstration of edema, hemorrhage, or carbonaceous material distal to the vocal cords. Inhalation injury to the smaller airways and lung parenchyma can be confirmed by Xenon 133 ventilation scanning [90] or noncontrast chest CT scans [91,92]. Inhalation injury on chest CT should be suspected with findings of ground glass infiltrates (more central than peripheral). Sensitivity for both types of scans is high, but there are false positives, especially in patients with obstructive airway disease and their value in determining the need for intubation, treatment, and prognosis has not been determined [90–92].

Lower airway involvement should be suspected on physical examination when wheezing is present or when spirometry or challenge testing demonstrates acute reductions in lung function, bronchodilator responsiveness, or airway hyperreactivity [93–96]. Acute bronchospasm should be treated with β_2-agonists. Ipratropium can be added if significant improvement is not obtained with a β_2-agonist alone. In the presence of significant burn injuries, treatment with systemic corticosteroids is usually contraindicated, as their use is associated with increased mortality from sepsis [87,97]. Systemic corticosteroids should be reserved for severe upper airway obstruction, severe bronchospasm resistant to bronchodilator therapy, and failed extubation due to stridor or bronchospasm [87,97]. Low-dose inhaled corticosteroids have not been studied in large case series, but it is unlikely that they would negatively impact on mortality in burn patients. Animal studies have shown that inhaled corticosteroids improve oxygenation and attenuate the development of acute lung injury following chlorine exposure [98,99]. Although inhaled corticosteroids are often given following chlorine and phosgene inhalation, there are no controlled clinical trials regarding their efficacy. Chest physiotherapy and frequent suctioning may be helpful in those patients with mucus plugs and thick secretions. Intubation may be necessary if bronchial secretions are excessive and frequent bronchoscopic suctioning may be needed.

Noncardiogenic pulmonary edema from acute lung injury (ARDS) is far less common than airway injury but should be suspected in patients with worsening oxygenation and increasing dyspnea. A chest radiograph should be obtained if signs of respiratory distress, abnormal breath sounds, or worsening hypoxemia are noted. Pulmonary edema or ARDS from inhalation injury typically presents as scattered, nodular

alveolar infiltrates on chest radiographs, although large, diffuse, confluent infiltrates may occur as the illness progresses. Careful attention to fluid and electrolyte balance is essential, especially if surface burns are present. If gas exchange abnormalities are severe, positive pressure ventilation with CPAP or BiPAP may help to support adequate oxygenation. If there is no response or secretions are burdensome, then intubation and assisted ventilation are required. Nasotracheal intubation should be avoided because of the severe nasal inflammation that typically occurs following the inhalation of chemical irritants and because the smaller endotracheal tube diameters needed for nasotracheal intubation do not allow for the repeated bronchoscopic suctioning that may be needed if secretions become a problem. Positive end-expiratory pressure in the range of 5 to 10 cm H_2O may help to improve oxygenation in mechanically ventilated patients [100–102]. The use of systemic corticosteroids for the treatment of pulmonary edema or ARDS following toxic irritant inhalation remains controversial [103]. Again, there are no controlled clinical trials evaluating the efficacy of corticosteroid treatment. Most experts believe that corticosteroids are not useful as pulmonary edema, or ARDS typically resolves 48 to 72 hours after inhalation exposure, with most patients surviving if appropriate supportive treatment is given. However, whether corticosteroids might be useful in preventing the few that develop pulmonary bronchiolitis obliterans or pulmonary fibrosis remain to be determined. Experimental studies suggest that treatment to block inflammatory mediators and free radicals may be effective in smoke inhalation victims [104–106]. Recent examples include retrospective analyses of mechanically ventilated smoke inhalation patients, adult [107] and pediatric [108] demonstrating successful treatment with nebulized unfractionated heparin and *N*-acetylcysteine. However, controlled clinical trials have not been conducted for any of the above experimental agents.

Secondary bacterial pneumonia can occur as a complication of irritant-induced airway or lung injury [109]. There is no evidence that the administration of prophylactic antibiotics reduces the incidence of secondary bacterial pneumonia. Antibiotics should be given only if pneumonia occurs, and the specific antibiotics chosen should be based on standard practice according to known community organisms and sensitivities until culture results return.

LONG-TERM COMPLICATIONS OF ACUTE INHALATION INJURY

Although most patients exposed to irritant gases or smoke will recover completely, others may develop chronic, long-term sequelae. The most common long-term complications are listed in Table 64.8. Some of these disorders may become evident in the days or weeks following acute exposure, whereas others may take months, or even years, before clinical symptoms and signs become evident. Therefore, all patients with acute inhalational injury require medical follow-up for the potential development of these disorders, even if they are initially asymptomatic after resolution of acute signs and symptoms.

TABLE 64.8

LONG-TERM EFFECTS OF ACUTE INHALATION INJURY

Complete resolution of symptoms
Sinusitis/rhinitis
Gastroesophageal reflux
Asthma
Reactive airways dysfunction syndrome
Chronic bronchitis or chronic obstructive pulmonary disease
Bronchiectasis
Bronchiolitis obliterans
Bronchostenosis
Restrictive interstitial fibrosis

Some individuals may develop a chronic cough syndrome, dyspnea, and/or wheezing following recovery from acute inhalation injury. Pulmonary function tests, chest radiographs, and high resolution CT scans of the chest can be helpful in determining the etiology of chronic cough in such patients. When chest radiographs and chest CT scans are normal, the chronic cough is usually due to asthma, RADS, bronchitis, rhinosinusitis, and/or gastroesophageal reflux [110,111]. Pulmonary function tests may be normal. Such patients could have rhinosinusitis and/or gastroesophageal reflux disease and could also have RADS or irritant asthma. The diagnostic evaluation of such patients should be guided by a careful history and physical examination. RADS is characterized by immediate and persistent, nonspecific airway hyperreactivity following inhalation of a toxic substance in individuals with no prior history of cigarette smoking, allergen, or airway disease [112]. Irritant asthma is the more proper terminology if symptoms were not immediate or if there is a history of prior allergies, pulmonary disease, or smoking. When pulmonary function tests are normal, bronchial challenge testing (methacholine, histamine, mannitol, cold air, exercise) may be performed to evaluate airway hyperreactivity in patients suspected of having RADS or irritant asthma. Transient, self-limited bronchial hyperreactivity may occur in the weeks following irritant gas or smoke exposures, so the detection of early bronchial hyperreactivity may not always be predictive of RADS [93–96]. The evaluation of fire fighters with heavy exposure to dust and irritant gases during the first days after the World Trade Center collapse showed that bronchial hyperreactivity demonstrated by methacholine challenge testing after 1 month or 3 months postexposure was predictive of persistent airway hyperreactivity and RADS [96]. It can take months or years for the symptoms of RADS to resolve, and some patients may never have complete resolution. Treatment with an inhaled bronchodilator should be considered if a significant bronchodilator response is found. Even in the absence of a documented bronchodilator response, a trial should be considered if there is a history of symptoms with exercise, irritants, or change in temperature/humidity. Inhaled corticosteroids should be considered not only for symptom control but also for the possibility, albeit unproven concept, that early treatment may prevent progression or lead to resolution [113].

If symptoms persist, serial measurements of spirometry, lung volumes, and diffusion capacity should be assessed to determine if there is accelerated decline in lung function, hyperinflation, bronchiolitis obliterans, emphysema, or pulmonary fibrosis. A study of more than 12,000 firefighters and EMS workers exposed to dust and gases from the September 11, 2010, attack on the World Trade Center found that the decline in lung function in the first 6 to 12 months after the attack was 12 times the expected annual decline and even more important for the majority of those exposed to this decline persisted for the next 6 years [114]. Another study of firefighters exposed to World Trade Center dust and gases demonstrated that interstitial pulmonary fibrosis was exceedingly rare and that airway obstruction was probable cause of the persistent lung injury [115].

Bronchiolitis obliterans is a rare but particularly ominous complication following the inhalation of certain toxic gases, particularly NO_2, other oxides of nitrogen, SO_2, mustard gas, and/or smoke [116–119]. Inhaled toxicants that can produce bronchiolitis obliterans are listed in Table 64.9. Bronchiolitis obliterans can take two forms following acute inhalation injury. The first form is manifested by the acute onset of fever,

TABLE 64.9

AGENTS THAT CAN PRODUCE BRONCHIOLITIS OBLITERANS

Ammonia	Methyl isocyanate
Chlorine	Mustard gas
Cocaine free-base	Oxides of nitrogen
Fire smoke	Phosgene
Hydrogen selenide	Sulfur dioxide

chills, cough, dyspnea, and generalized lung crackles that develop 2 to 8 weeks after acute exposure to an offending gas, as discussed in "Nitrogen Oxides" section. Chest radiographs or high resolution CT scans typically show a diffuse "miliary" pattern of small nodules. Although lung biopsies are usually not necessary to make the diagnosis with a history of acute inhalation injury, they show a proximal bronchiolitis with occlusion of the bronchioles by inflammatory exudates and fibrin, but without organizing pneumonia [116]. This form of bronchiolitis obliterans can be life threatening if untreated, but typically resolves with systemic corticosteroid therapy [116]. It is recommended that patients with this form of bronchiolitis obliterans be treated with 40 to 60 mg of prednisone daily for at least 2 months, with the dose tapered after all symptoms and radiographic findings resolve. The second form of bronchiolitis obliterans occurs in patients who have persistent cough and dyspnea with an obstructive ventilatory impairment on pulmonary function tests that does not respond to inhaled corticosteroids or bronchodilators [116]. Chest radiographs may appear normal, but high-resolution CT scans of the chest often show areas of hyperinflation and air trapping. Lung biopsy may be necessary to make a definitive diagnosis and typically shows a pure constrictive bronchiolitis. This form of bronchiolitis obliterans is usually not responsive to corticosteroid therapy, and the prognosis for improvement is poor. Patients affected with this form of bronchiolitis obliterans may get progressively worse and suffer life-long disability. The administration of prophylactic corticosteroids to prevent bronchiolitis obliterans following inhalation injury is controversial with treatment effects in either direction [120,121].

CHAPTER 65 ■ DISORDERS OF TEMPERATURE CONTROL PART I: HYPOTHERMIA

M. KATHRYN STEINER, FREDERICK J. CURLEY AND RICHARD S. IRWIN

This chapter reviews the normal physiology of temperature regulation and the major hypothermic syndromes. Iatrogenic and intentional hypothermia are also reviewed. Three hyperthermic syndromes—heat stroke, malignant hyperthermia, and neuroleptic malignant syndrome—are reviewed in Chapter 66.

NORMAL PHYSIOLOGY OF TEMPERATURE REGULATION

The equilibrium between heat production and heat loss determines body temperature. In healthy, resting individuals, this equilibrium is tightly regulated, producing an average oral temperature of 36.60°C ± 0.38°C [1]. Table 65.1 is a conversion chart of temperatures in Celsius to Fahrenheit. Small shifts of this temperature set point occur, with a normal diurnal variation producing a peak temperature usually near 6:00 PM. Minute-to-minute changes in body temperature are quickly sensed, and appropriate changes are made in body heat production and loss to restore a normal balance.

Heat Production

In a neutral environment (28°C for humans), humans generate all net body heat from the energy released in the dissociation of high-energy bonds during the metabolism of dietary fats, proteins, and carbohydrates. At rest, the trunk and viscera supply 56% of the body heat, but during exercise up to 90% may be generated by the muscles. Although shivering or an increase in muscle tone may produce a fourfold rise in net heat production [2], vigorous exercise may cause a sixfold increase.

Heat Loss

Under usual environmental conditions, heat exchange with the environment takes the form of heat loss. Heat may be exchanged by radiation, conduction, convection, or evaporation [3–6]. Radiation exchange—the transfer of thermal energy between objects with no direct contact—accounts for 50% to 70% of heat lost by humans at rest in a neutral environment. Conduction involves the direct exchange of heat with objects in direct contact with the body. Large quantities of heat may be rapidly exchanged when the body is submerged in water; this is due to the much greater thermal conductivity of water as compared with air. Convection involves the exchange of heat with the warmer or cooler molecules of air that pass by the skin. Heat exchange by this mechanism increases rapidly with greater temperature differences between the skin and the air and with rapid airflow. Evaporative heat loss in humans occurs primarily through perspiration. Evaporation of sweat from the skin requires that energy be supplied by the skin, resulting in a net loss of heat from the body of 0.6 kcal per g of sweat absorbed. Unlike the other methods of heat exchange, evaporation can exchange heat loss even when a warmer environment surrounds the skin. Therefore, evaporation is the major means by which the body prevents hyperthermia in a warm environment.

Temperature Control Systems

The anatomy and regulation of the system that controls body temperature have been reviewed in depth by several

investigators [2–6], as outlined in the previous edition and are only briefly described here. Neurons that are directly responsive to temperature ascend from the skin, the deep viscera, and the spinal cord through the lateral spinothalamic tract to the preoptic anterior hypothalamus. When the hypothalamus perceives a temperature increase, it modulates autonomic tone to produce (a) an increase in evaporative heat loss through increased sweat output by the body's 2.5 million sweat glands, (b) cutaneous vasodilation that allows direct flow of heat to the skin to increase convective and conductive heat losses, and (c) decreased muscle tone and activity to prevent any unnecessary heat production. When the hypothalamus perceives a temperature decrease, it modulates autonomic tone to cause (a) sweat production to cease or decrease, (b) cutaneous vasculature to constrict, and (c) muscle tone to increase involuntarily and shivering to begin.

The monoamines, baroreceptor data, hypothalamic calcium and sodium concentrations, and inflammatory cytokines (interleukin-1, interleukin-6, tumor necrosis factor-α [TNF-α]) are believed to be modulators of the anterior hypothalamic thermostat. They produce effects slowly and they have little to do with the regulation of acute temperature changes.

Voluntary responses play an important role in thermoregulation. Humans may respond to thermal stress by (a) adding or removing clothes (affecting evaporative, conductive, and radiant heat exchange), (b) moving to a warmer or cooler climate, (c) changing the level of activity, and (d) changing posture. Impairment of voluntary control places an unnecessary stress on autonomic control mechanisms and thereby predisposes to an imbalance in heat exchange and a change in body temperature.

The ability to regulate temperature effectively declines with age [7,8], probably as a result of deterioration in sensory afferents. Although younger individuals usually notice temperature changes as low as 0.8°C, older persons may not notice changes of up to 2.3°C. Moreover, because the sweat threshold increases and sweat volume decreases with age, an older individual may be more susceptible to hyperthermia than a younger person [9]. Old age may also be a liability for hypothermia because of (a) a lower basal metabolic rate, (b) a higher heat conductance due to a decline in body mass, (c) a decrease in the heat generated by shivering due to a smaller muscle mass, and (d) an inability to vasoconstrict cutaneous vessels in response to cold. In the elderly, restricted mobility or deterioration in cortical function can lead to a greater impact on the voluntary responses to temperature changes compared with the young.

UNINTENTIONAL HYPOTHERMIA

Hypothermia, defined as a core temperature less than 35°C, may occur at all ambient temperatures and in patients of all ages but more commonly in the elderly. Hypothermia often occurs within 24 hours of admission in more than 3% of intensive care unit admissions [10]. Hypothermia is a diagnosis that is frequently missed and underreported. When all data are reviewed, the overall mortality from hypothermia in the United States has been conservatively estimated at 30 deaths per 1 million population per year [11]. The mortality for treated hypothermia ranges from 12% [12] to 73% [13].

Causes and Pathogenesis

The most frequent causes of hypothermia appear to be exposure, use of depressant drugs, and hypoglycemia. Understanding the causes of hypothermia (Table 65.2) and their pathogenesis enables one to develop a rational approach to treatment.

Exposure to Cold

Wet, wind, and exhaustion contribute to increased loss of body heat. Wet clothing loses 90% of its insulating value [14], rendering soaked individuals effectively nude. Exposure to rain or snow contributed greatly to the development of hypothermia in 15 of 23 incidents in hikers discussed in one review [14]. Convective heat loss because of wind may increase to more than five times baseline values, increasing with wind velocity [15]. Hikers with poor selection of clothing, campers who fail to seek appropriate shelter, or skiing in unfavorable weather can result in fatal hypothermia [15]. Victims of hypothermia display inappropriate behavior that worsens hypothermia. Up to 25% may remove their clothing and burrow, hiding under a bed or on a shelf [16]. Many quickly experience loss of coordination and then stupor or collapse. Death may occur within an hour of the onset of symptoms [15]. Immersion in water at a temperature colder than 24°C leads to extremely rapid heat loss. Core temperature drops at a rate proportional to the temperature of the water [17]. Although survival times of 1 to 2 hours have been reported for individuals immersed in water at 0°C to 10°C, death may occur within minutes.

Drugs

Alcohol, phenothiazines, barbiturates, and paralytic agents frequently produce hypothermia by depressing sensory afferents, the hypothalamus, and effector responses. Alcohol impairs the perception of cold, clouds the sensorium, and acts as a direct vasodilator [18,19]. Alcoholics are also thought to be more susceptible to exposure because of a state of relative starvation, increased conductive losses from decreased subcutaneous

Trauma

fat, and high levels of blood alcohol that potentially impair the metabolic response to hypothermia by decreasing blood sugar and increasing acidosis. Most sedative–hypnotic drugs, such as barbiturates and phenothiazines, cause hypothermia by inhibiting shivering and impairing voluntary control. Phenothiazines increase the threshold necessary to produce shivering and lead to hypothalamic depression [10,20]; barbiturates decrease effective shivering [21]. Paralytic agents used to suppress ventilation prevent shivering and eliminate all voluntary control mechanisms [22,23]. Unexplained hypothermia has resulted from the administration of common antibiotics, such as penicillin [24] and erythromycin [25]. Bromocriptine may cause hypothermia by altering central dopaminergic tone [26].

Endocrine Dysfunction

Diabetic ketoacidosis, hyperosmolar coma, and hypoglycemia are frequently reported causes of hypothermia [18]. In one survey, 20% of patients with blood glucose levels less than 60 mg per dL had temperatures of less than 35°C. Hypoglycemia lowers cerebral intracellular glucose concentrations and impairs hypothalamic function [27]. In acute hypoglycemia (e.g., insulin administration), hypothermia occurs due to peripheral vasodilation and sweating. At glucose concentrations less than 2.5 mmol per L, subjects fail to perceive cold environments and fail to shiver [28]. This impairment appears transient because normal regulatory mechanisms and euthermia may be restored when normal serum glucose levels are restored.

The prevalence of hypothyroidism in patients ranges from 0% to 10%. Several patients with mild hypothyroidism have been safely rewarmed to euthermia without administration of exogenous thyroid hormone. In contrast, myxedema coma, a rare presentation of hypothyroidism, is associated with subnormal temperatures in 82% of cases [29]. It has a high mortality if not treated with exogenous thyroxine. Myxedema coma occurs most frequently in middle-aged to older women, and more than 90% of cases occur in winter [29]. Severe hypothermia with temperatures less than 30°C occurs in 15% of patients [29]. Coma arises because of a cerebral thyroxine deficiency. Hypothermia then results from a combination of loss of voluntary control mechanisms, from stupor or coma, decreased calorigenesis from thyroid deficiency, and decreased shivering, presumably from impaired hypothalamic regulation [29,30].

Panhypopituitarism and adrenal insufficiency are also rare causes of hypothermia. Unless profound insufficiency exists, these conditions rarely produce significant hypothermia in the absence of some other insult to the thermoregulatory system.

Central Nervous System Disorders

Diseases such as stroke, primary and metastatic brain tumors, luetic gliosis, and sarcoidosis may produce hypothermia by direct anatomic impingement on the hypothalamus [31,32]. Metabolic derangements from carbon monoxide poisoning or thiamine deficiency (Wernicke–Korsakoff syndrome) can also produce hypothermia, by affecting the hypothalamus [33–38]. Patients with anorexia nervosa have been shown to have multiple hypothalamic abnormalities resulting in the lack of shivering and vasoconstriction and a rapid drop in core temperature when they are exposed to cold [39]. Agenesis or lipoma of the corpus callosum has been reported to cause spontaneous periodic hypothermia by an unclear mechanism [21,40]. Several patients with multiple sclerosis have experienced transient hypothermia with flares of their neuropathy, suggesting the presence of hypothalamic plaques [41]. Drugs that are active on the central nervous system, such as neuroleptics or guanabenz, have resulted in hypothermia [42].

Spinal Cord Transection

Loss of skin and core temperature afferents, reduced body muscle mass, inability to shiver effectively, and, if mobility is compromised, inability to alter the environment make patients with spinal cord injury susceptible to thermal stress and hypothermia exposed to low ambient temperatures [43–45].

Skin Disorders

Skin disorders characterized by vasodilatation or increased transepithelial water loss may lead to hypothermia. Inappropriate conductive and convective heat losses in psoriasis, ichthyosis, and erythroderma have been shown to be associated with increased evaporative losses of up to 3 L per day; this computes to a potential loss of more than 1,700 kcal of heat per day [46,47]. Patients with extensive third-degree burns have been reported to have an even larger evaporative heat loss, losing up to 6 L fluid, or more than 3,400 kcal per day. When an additional cause of hypothermia is present, these patients may be in danger of severe drops in temperature. Heat loss and caloric requirements can be decreased dramatically by covering the skin with impermeable membranes to decrease evaporative losses [48–50].

Debility

Case reports suggest that hypothermia may occur in patients with debilitating illnesses such as Hodgkin's disease [51]; systemic lupus erythematosus [52,53]; and severe cardiac, renal, hepatic, or septic failure. In Israel, 29% of hypothermic elderly individuals had preexistent renal failure [54]. The exact causes are unclear, but many mechanisms are likely acting in concert to produce a drop in temperature. A decrease in cardiac index from 2.8 to 1.4 L per minute results in a drop in temperature from 37°C to 35°C [55]. Temperature promptly rises when cardiac index increases. Hypothermia in hepatic failure might result from intermittent hypoglycemia. Most debilitated patients are also compromised by some degree of immobility or decreased voluntary control.

Trauma

Trauma patients often are hypothermic [56,57], due to multiple insults to the thermoregulatory system, for example, loss of voluntary control in adverse environments, the presence of alcohol in up to 62% of cases in some series, and the rapid transfusion of unwarmed blood [57]. In patients with moderately elevated injury severity scores, during the first day of hospitalization, 42% experience hypothermia, with 13% having temperatures less than 32°C [56]. The presence of shock [56] and massive transfusion [57] significantly contributed to the development of hypothermia in these patients.

Pathophysiology

Profound metabolic alterations occur in every organ system in response to a core temperature less than 35°C. Beyond the immediate cardiovascular changes induced by vasoconstriction, metabolic changes that appear to be temperature dependent occur in two phases: shivering and nonshivering. The shivering phase, usually occurring in the range of 35°C to 30°C, is characterized by intense energy production from the breakdown of stored body fuels. In the nonshivering phase, which occurs approximately less than 30°C, the metabolism slows down dramatically, resulting at times in multiple organ failure.

Shivering involves an increase in muscle tone and rhythmic contraction of small and large muscle groups. The metabolic changes during the shivering phase parallel those seen during muscular exercise. In different patient populations with

different measurement techniques, heat production has been shown to increase by four times the normal amount [58], oxygen consumption by two to five times [20], and metabolic rate by six times [59]. Central pooling of blood resulting from peripheral vasoconstriction may raise central venous pressure and slightly elevate cardiac output. Because cardiac output remains relatively close to normal and oxygen demand increases dramatically, mixed venous oxygen saturation decreases [60]. Although hepatic and muscular glycogenolysis may cause blood sugar levels to rise, this rise may not be seen in starved or exhausted patients or those with prolonged hypothermia [61,62]. The catabolism of fat increases the serum levels of glycerol, nonesterified fatty acids, and ketones. Anaerobic metabolism causes a rise in lactate levels; levels as high as 25.2 mmol per L have been reported [63]. The metabolic acidosis induced by this intense catabolism is compensated for the most part by the increased metabolism of lactate in the liver and increased minute ventilation [62]. Cortisol levels rise [13]. Most of these metabolic changes peak near 34°C or 35°C and become much less pronounced near a temperature of 30°C.

As core temperature falls toward 30°C, shivering nearly ceases and metabolism slows down dramatically. Near 30°C, metabolic rate approaches basal levels [64], and it may be half basal value by 28°C [59]. As shivering and metabolism slow down, oxygen consumption declines. At 30°C, oxygen consumption decreases to approximately 75% of basal value [64]; at 26°C to 35% to 53% [20]; and at 20°C to only 25% of basal value. This profound decrease in metabolism is reflected by changes in every organ system (Table 65.3).

Cardiovascular Function

Increasing degrees of hypothermia result in malignant arrhythmias, depressed cardiac function, and hypotension. A decrease in cardiac conductivity and automaticity [65–67] and an increase in refractory period [68,69] begin during the shivering phase and progress as core temperature decreases. The electrocardiogram (ECG) in mild hypothermia may show bradycardia with prolongation of the PR, QRS, and QT intervals. Below 30°C, first-degree block is usual, and at 20°C, third-degree block may be seen [61,70]. Below 33°C, the ECG commonly shows the characteristic J-point elevation (Fig. 65.1). As temperature drops below 25°C, the J wave increases [71,72], most prominent in the mid-precordial and lateral precordial leads [73]. J waves may persist 12 to 24 hours after restoration of normal temperature [74,75].

Atrial fibrillation is common at temperatures of 34°C to 25°C, and ventricular fibrillation frequently occurs at temperatures less than 28°C. The incidence of ventricular fibrillation increases with physical stimulation of the heart and is associated with intracardiac temperature gradients of greater than 2°C [76]. Purkinje cells show marked decreases in excitability in the range of 14°C to 15°C [67], and asystole is common when core temperatures drop below 20°C. Recovery of spontaneous electrical activity after hypothermic asystole may be related to protection from the calcium paradox afforded by hypothermia [77].

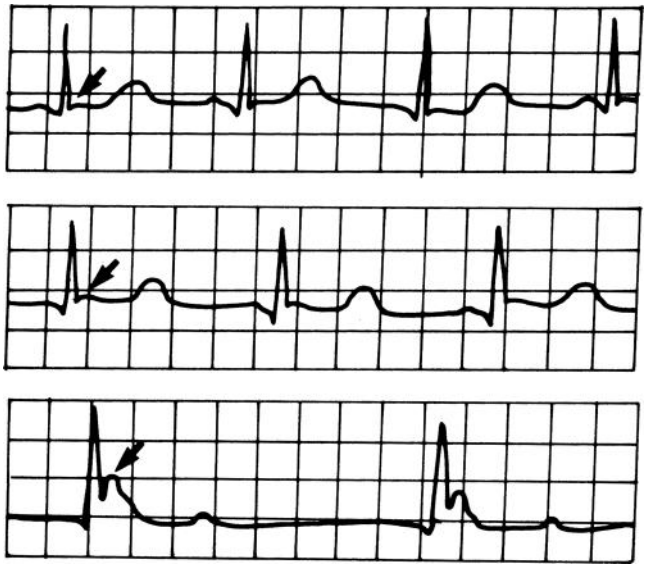

FIGURE 65.1. The electrocardiographic changes of hypothermia. As temperature decreases (*top to bottom*), the rate slows down and the PR and QT intervals become prolonged. J waves (*arrows*) appear at a temperature less than 35°C and become prominent by a temperature near 25°C. The J wave initially is seen (*top*) as a widened QRS interval with a slight ST elevation at the J point.

Consequently, there is a gradual decrease in cardiac output. Systole may become extremely prolonged [78], greatly decreasing ejection fraction and aortic pressures. Ventricular compliance is severely reduced [79]. Output decreases to approximately 90% of normal at 30°C and may decrease rapidly at lower temperatures, with increasing bradycardia or arrhythmia. Regional blood flow is altered to preserve myocardial and cerebral perfusion [80]. Although blood pressure appears to be initially maintained by an increase in systemic vascular resistance (SVR) [81], systemic resistance decreases and hypotension is common [61] at temperatures less than 25°C. Oxygen demand usually decreases more rapidly than does cardiac output, causing mixed venous oxygen content to increase as the nonshivering phase begins.

Pulmonary Function

Pulmonary mechanics and gas exchange appear to change little with hypothermia [61,82–84]. Although the ventilatory response to an elevation in carbon dioxide tension (PCO_2) may be blunted [82], there is no clear decrease in hypoxic drive [61]. As the increased oxygen demand and acidosis of the shivering phase decline, minute ventilation decreases. Tidal volume and respiratory rate decline at lower temperatures [20]. At 25°C, respirations may be only 3 or 4 per minute [19]; at temperatures less than 24°C, respiration may cease [59]. Apnea is presumed to be secondary to failure of respiratory drive at a brainstem level.

Renal Function

As blood pressure decreases during the nonshivering phase, glomerular filtration rate (GFR) may decrease by 85% [61] and renal blood flow by 75% [20], without a significant change in urine production. Maintenance of a good urine output, despite decreases in blood pressure and GFR in hypothermia, has been termed *cold diuresis*. This results from a defect in tubular

TABLE 65.3

COMMON EFFECTS OF HYPOTHERMIA

Metabolic depletion	Anemia, hemoconcentration
Cardiac arrhythmia	Thrombocytopenia
Hypotension	Ileus
Hypopnea	Pancreatitis
Dehydration	Hyperglycemia
Coma	Pneumonia
Granulocytopenia	Sepsis
Altered drug clearance	

reabsorption. The urine may be extremely dilute, with an osmolarity of as low as 60 mOsm per L and a specific gravity of 1.002 [85]. The stimulus for this dilute diuresis may be the triggering of volume receptors as central volume increases with peripheral vasoconstriction [78], a relative insensitivity to antidiuretic hormone [75], or a direct suppression of antidiuretic hormone release [19]. Although kaliuresis and glycosuria may accompany the dilute diuresis, the net result for the patient is dehydration and a relatively hyperosmolar serum.

Neurologic Function

Hypothermic patients present with coma. Complete neurologic recovery has been described in hypothermic adults after 20 minutes of complete cardiac arrest [18] and after up to 3.5 hours of cardiopulmonary resuscitation (CPR) [85]. The mechanism by which hypothermia produces a seemingly protective effect is not well understood; it probably relates to a significant decrease in cerebral metabolism and a smaller injury by the no-reflow phenomenon [86], a mechanism whereby the brain is protected from injury until reperfusion.

Cerebral oxygen consumption decreases by approximately 55% for each 10°C decrease in temperature [87]. Cerebral blood flow decreases from 75% of normal at 30°C to only 20% of normal at 20°C [61]. The supply of nutrients and removal of wastes are adequate at these extremes given patient recovery and experimental evidence that the intracellular pH of brain tissue cooled to 20°C is unchanged even after 20 minutes of anoxia [88].

Visual [89,90] and auditory [91,92] evoked potentials demonstrate delayed latencies; latency increases as temperature decreases. The spectrum of electroencephalographic frequencies also changes with hypothermia. In healthy men cooled to 33°C by immersion, theta and beta activity increased by 17% and alpha activity decreased by 34% compared with control values [90]. Electromyography during hypothermia has been reported to be normal [93].

Hematologic Function

Hypothermia affects white blood cells (WBCs), red blood cells, platelets, and perhaps coagulation mechanisms. The WBC count in mild hypothermia remains normal to slightly elevated and drops severely at temperatures lower than 28°C [94,95]. The hematocrit usually rises in hypothermic patients at a temperature of 30°C in part due to hemoconcentration from dehydration caused by cold diuresis and in part due to splenic contraction [96]. The increase in blood viscosity in hypothermic patients appears to be due to decreased deformability of the red cell membrane [97]. After intravascular volume and euthermia have been restored, a mild anemia may last up to 6 weeks. Bone marrow aspirates obtained from these patients show erythroid hypoplasia and increased ringed sideroblasts, suggesting a maturation arrest [98]. Platelet counts drop as temperature decreases, and prolongation of the bleeding time has been noted at 20°C [94]; normal levels and function return on rewarming [99]. The decrease in platelet count is thought to be secondary to hepatic sequestration.

No clear evidence indicates that a coagulopathy is associated with hypothermia. Deep venous thrombosis (DVT) and disseminated intravascular coagulopathy (DIC) have been reported in hypothermic patients [34,100].

Gastrointestinal Tract Function

Ileus, pancreatitis, and hepatic dysfunction accompany hypothermia. Ileus is present at temperatures 30°C and lower. Subclinical pancreatitis appears to be common. Although patients usually lack symptoms of acute pancreatitis, more than half have amylase elevations greater than 550 Somogyi units and up to 80% of patients who die of hypothermia have evidence of pancreatitis at autopsy [101]. The relationship between alcohol use and pancreatitis in these patients is unclear. Hepatic dysfunction occurs commonly and involves synthetic and detoxification abilities [20]. Profoundly hypothermic patients in whom an acidosis develops are less able to clear lactate. Postmortem studies of patients who died from exposure-induced hypothermia have emphasized that gastric submucosal hemorrhage is common [102]. Duodenal ulceration and perforation may also be seen [103].

Endocrine Function

Hypothermia directly suppresses the release of insulin from the pancreas and increases resistance to insulin's action in the periphery [104,105]. The blood glucose level rises in early hypothermia, due to glycogenolysis and increased corticosteroid levels, and remains elevated because of a decreased concentration and the action of insulin. Elevations in blood glucose, however, are usually mild; only 9% of patients in one series had blood glucose levels higher than 200 mg per dL. Changes in thyroid and adrenal function occur, but they are less well defined. The responses to thyroid stimulating hormone (TSH) and adrenocorticotrophic hormone appear blunted [61]. In hypothyroid patients, TSH increases in response to cold [106]. Although corticosteroid levels vary a great deal among patients, they rarely appear to be severely depressed [62,107,108]. Urinary catecholamine levels are increased threefold to sevenfold on average in hypothermic deaths compared with death due to other causes [102].

Immune Function

Infection is a major cause of death in hypothermic patients. Hypoperfusion increases the risk of bacterial invasion in ischemic regions of the skin and intestine. Central nervous system depression reduces the cough reflex, leaving the patient more susceptible to aspiration pneumonia. A decrease in tidal volume and minute ventilation increases the risk of atelectasis, making subsequent infection possible. Survival in hypothermia varies directly with the severity of cold-induced granulocytopenia [95,109]. Evidence from hypothermic animals with induced sepsis indicates an impaired release of PMNs from the marrow [95], as well as delayed clearance of staphylococcal [110] and Gram-negative organisms from the blood. Ineffective clearance of organisms may permit a continued low-grade bacteremia [110]. Ineffective clearance probably relates to impaired phagocytosis, migration [111], and a decrease in the half-life of circulating PMNs in hypothermia [109]. Impaired killing of bacteria by pulmonary alveolar macrophages exposed to cold in vitro has been reported and presumably increases susceptibility to pneumonia. The role of changes in antigen–antibody interactions, known to be impaired by cold in vitro, has not been clearly defined in hypothermic patients. Wound healing is delayed in patients with mild perioperative hypothermia [112]. Cytokine production may be delayed and prolonged [113]. Few human data are available regarding the activation of inflammatory mediators in hypothermia. Interleukin-6 and TNF-α are assumed to play a role in modulating an inflammatory cascade that must occur with hypothermia. Interleukin-6 concentrations fall with rewarming [114]. Thus, the hypothermic host is more susceptible to invasion by pathogens and less equipped to defend itself if invasion occurs.

Drug Clearance

Little is known about the clearance of drugs in hypothermic adults. Complex interactions of reduced cardiac output, dehydration, slowed hepatic metabolism, decreased GFR, abnormal

renal tubular filtration and reabsorption, and altered protein–drug dissociation constant alter the volume of distribution and total body clearance of many drugs [115]. The half-life of thiopental has been shown to increase 4 to 11 times at 24°C [20]. Because bile flow may be reduced by up to 75% at similar temperatures, excretion of toxins in the bile is also decreased [20].

Diagnosis

The diagnosis of hypothermia may be suggested by a history of exposure or immersion, clinical examination, and laboratory abnormalities. Elderly, alcoholic, diabetic, quadriparetic, or severely debilitated patients are at high risk of hypothermia. Signs of hypothermia vary with the patient's temperature. Cool skin, muscle rigidity, shivering, and acrocyanosis are present in most noncomatose patients. In obtunded patients, myxedema-type facies have been reported [101,116]. Although mental status changes vary widely among patients, they follow a typical pattern: between 35°C and 32°C, the patient may be stuporous or confused; between 32°C and 27°C, the patient may be verbally responsive but incoherent; and at temperatures less than 27°C, 83% of patients are comatose but able to respond purposefully to noxious stimuli [117]. Muscle tone remains increased after shivering stops. Reflexes remain normal until body temperature is lower than 27°C, when they become depressed and or absent. Plantar reflexes may be upgoing. The pupillary reflex may be sluggish below 30°C and may become fixed at temperatures less than 27°C. ECG changes are almost always present.

In the absence of an accurate temperature reading, the ECG can be used to gauge the degree of hypothermia [71,73]. J waves become prominent as temperature decreases and in the absence of a cerebrovascular accident appear to be pathognomonic for hypothermia. Prolonged PR or QT intervals in the presence of muscle tremor artifact and bradycardia strongly suggest the diagnosis. Because of the increased solubility of carbon dioxide and oxygen, blood gases reported at 37°C may show a value of partial pressure of oxygen (PO_2) + PCO_2 greater than 150 mm Hg on room air, a biochemical impossibility at euthermia. An elevated hematocrit, a good output of dilute urine with hypotension, ileus, and an elevated amylase are helpful but nonspecific indicators of hypothermia.

Because the symptoms of hypothermia frequently mimic those of other disorders, the diagnosis may be missed unless there is a clear history of exposure or an accurate temperature reading is taken. Thermometers calibrated to record temperatures less than 35°C must be used. Electronic temperature probes are accurate at low temperatures, can be used in several body sites, have a rapid response time, and can be left indwelling to provide online temperature readings during treatment. The lower temperature limit on individual probes must always be checked.

The site for recording the temperature is important (see Chapter 26). Oral or nasopharyngeal temperatures may not reflect core temperature because of the influence of surrounding airflow. Bladder, rectal, tympanic, esophageal, or great vessel temperatures are preferable. Bladder temperatures are accurate and convenient for initial measurements [118,119]. Great vessel temperature can be measured using the thermistor on a Swan-Ganz catheter. Esophageal temperature is mostly influenced by the inhalation of warmed air, great vessel temperature is highly affected by the infusion of heated fluids, and rectal temperature is greatly influenced by warmed peritoneal dialysis. During extracorporeal rewarming, bladder and pulmonary artery temperatures may increase faster than esophageal and rectal temperatures [119]. It may be helpful to monitor at least two core sites.

Differential Diagnosis

Clinical changes produced by hypothermia can mask and mimic other diseases. Rigidity of the cervical musculature may indicate meningitis. The abdomen is frequently boardlike, and absent bowel sounds simulate a state of intra-abdominal catastrophe. Because shock and coma have broad differential diagnoses, clinical judgment must guide the workup of these disorders.

Despite wide interpatient variation, deviation from the temperature–symptom relationship should suggest that the cause of a symptom may be other than hypothermia. For example, ventricular fibrillation or coma with a temperature higher than 30°C or shock with a low hematocrit or heme-positive stools should alert the physician to suspect another diagnosis and pursue further diagnostic evaluations. In a patient with hypothermia, especially after vigorous resuscitation attempts, establishing a diagnosis of myocardial infarction can be difficult. Creatine kinase, lactate dehydrogenase, and serum glutamic oxaloacetic acid transaminase values may be elevated because of hepatic hypoperfusion and presumed skeletal muscle damage. Elevations in MB and BB fractions of the creatine kinase have been reported in hypothermic patients with no evidence of myocardial or cerebral infarct [64]. The ECG changes in hypothermia do not mimic those seen in myocardial infarction. Therefore, an ECG is a more reliable indicator of myocardial damage than are enzyme elevations in hypothermic patients.

Treatment

With immediate appropriate treatment, mortality should be low. Accumulated statistics suggest that mortality varies with the severity of the underlying disease and the temperature at initial examination. The overall mortality in a series of city-dwelling hypothermic patients was 12%, but this increased to nearly 50% if a serious underlying disease was present [13]. In the same series of patients, mortality increased to 1.8% for each 1°C decrease in temperature on admission. Mortality is higher if hypothermia occurred indoors [120]. In healthy young mountain climbers, mortality was also found to vary with body core temperature on admission: Mortality was 25% for temperatures higher than 32°C versus 66% for temperatures lower than 27°C [59]. In patients in Ireland with hypothermia due to exposure, the overall mortality was 33%, and each 5°C drop in ambient temperature was estimated to double the mortality. In multivariate analysis, the strongest predictors of mortality were prehospital cardiac arrest, low or absent blood pressure, elevated blood urea nitrogen, and the need for tracheal intubation or nasogastric tube placement in the emergency department [121]. The Mount Hood tragedy suggests that serum potassium levels greater than 10 mEq per L, fibrinogen less than 50 mg per dL, and ammonia greater than 250 mmol per L at the time of diagnosis make survival unlikely [118]. Asphyxia due to submersion resulting in severe hypothermia may be associated with up to a 95% mortality rate [122]. The higher survival rates in city-dwelling patients are believed to represent the benefits of immediately accessible care. Many experts believe that without treatment, mortality in profound hypothermia may approach 100%.

Treatment should be aggressive. Functional survival in adults has been reported even after 6.5 hours of CPR [123]. Treatment includes initial field care and transport, stabilizing

cardiopulmonary status, treating the cause of hypothermia, preventing the common complications of hypothermia, and rewarming.

Initial Field Care and Transport

The field management of hypothermia from exposure or immersion is important. Wet clothes should be removed and replaced with dry ones, if available. The victim should be insulated from cold and wind as much as possible with blankets or a sleeping bag. Sharing the body heat of another person in the same sleeping bag appears to offer no significant advantage [124]. Drinking hot drinks is no longer encouraged because it may increase hypothermia by producing peripheral vasodilation through a pharyngeal reflex [125]. Glucose drinks have been advocated, but recent work has shown that glycogen depletion does not impair shivering or rewarming [126].

A number of precautions should be taken to transport the victim. Patients should not be transported in the upright position because seizures may result, presumably from orthostatic hypotension [16]. Rough handling must be avoided because even minor manipulations can induce ventricular fibrillation [79,125,126]. Clothing should be cut off, and a team of many rescuers should carry the victim as gently as possible. A patient without a blood pressure or palpable pulse may already be in fibrillation and thus should be resuscitated in the usual fashion until adequate ECG and pressure monitoring are available (see Chapter 22) [127].

Stabilizing Cardiopulmonary Status

Because early death from hypothermia is due to hypotension and arrhythmia, the goal of initial in-hospital management of hypothermic patients should be to achieve a safe, stable cardiopulmonary status. Shock in mild hypothermia is usually due to the dehydration that results from cold diuresis; in more profound hypothermia, it may be cardiogenic. Fluid resuscitation should be attempted in all patients in hypothermic shock. Delivery of fluids through a central rather than a peripheral catheter is preferable for several reasons: vasoconstriction makes insertion of peripheral intravenous (IV) catheters difficult, vasoconstriction may impair delivery of peripherally injected medications, peripheral IV catheters may cause unnecessary damage to frostbitten extremities, and central catheter placement permits monitoring of central venous pressure and helps guide fluid management. Because most patients are hemoconcentrated and hyperosmolar, slightly hypotonic crystalloid fluids should be given. Whenever possible, all IV fluids should be warmed to at least room temperature before infusion. If fluid resuscitation fails, pressor agents should be administered. Although pressor agents increase the risk of ventricular fibrillation, they have been used safely in patients with hypothermia [127,128]. The use of arterial and central venous pressure monitors may help guide treatment. Swan-Ganz catheter monitoring can be performed safely and may aid in evaluation and treatment [129]. A low SVR in mild-to-moderate hypothermia strongly suggests infection or sepsis [81]. The increased risk of hemorrhage from hypothermia-induced thrombocytopenia and prolongation of bleeding times must, however, be considered when undertaking invasive procedures such as central venous catheter placement or intubation.

The management of arrhythmias must be approached in a nontraditional manner because many pharmacologic agents, pacing efforts, and defibrillation attempts do not work in the hypothermic patient [130–132]. Because supraventricular arrhythmias and heart block generally resolve spontaneously on rewarming [72,84], therapy is usually unnecessary. Digitalis should be avoided because the efficacy of the drug is unclear in hypothermia, and toxicity increases as the patient is warmed [68]. Little is known regarding the efficacy of calcium channel blockers in treating supraventricular tachyarrhythmias in hypothermic patients.

In hypothermic patients experiencing ventricular fibrillation, procainamide has been of little help [20] and lidocaine has been of only modest benefit [126]. Bretylium appears to be the drug of choice [125,133–135]. Electrical defibrillation should probably be attempted at least once, but it is unlikely to succeed until core temperature surpasses 30°C [18,76,136]. The role of pacing in patients with fibrillation and asystole is unclear [68,137]. If other avenues of support are unavailable, however, pacing should be tried [138].

Acid–base status and oxygenation should be assessed immediately. Accurate assessment of acid–base status in hypothermic patients is complicated by several issues. First, blood gases measured at 37°C produce different values of pH and PCO_2 than exist in a patient at a lower temperature. Second, normal values for pH and PCO_2 also change with temperature. Third, body buffer systems respond differently at colder temperatures. When blood is drawn from a hypothermic patient and then rewarmed to and measured at 37°C, the solubility of carbon dioxide decreases, resulting in higher PCO_2 and lower pH values than actually exist [139].

Normal values for pH and PCO_2 also change with temperature. At a temperature of 20°C, a pH of approximately 7.65 permits continued cellular function, and this value, not a pH of 7.40, should be regarded as normal. Normal values for $PaCO_2$ are altered because of the higher content of carbon dioxide in cooled blood, decreased rate of production of carbon dioxide, and slower rate of carbon dioxide elimination from relative alveolar hypoventilation. Respiratory exchange ratio values as low as 0.32 have been reported. On balance, these changes result in lower $PaCO_2$ values at colder temperatures.

Temperature changes the protein–drug dissociation constant of chemical reactions and reduces the ionization level of buffer proteins [139]. This produces a smaller effective protein buffer pool and places a greater reliance for buffering on the less efficient carbonic acid system. Because of this less effective buffering, acid–base disturbances that would be well tolerated at 37°C might be poorly tolerated at lower temperatures.

Despite these complex considerations, $PaCO_2$ and pH values that are uncorrected for temperature can be accurately used to assess the hypothermic patient's acid–base status, enhance the ease of interpretation, and morbidity or mortality does not change [140–145].

Because of a decrease in the solubility of oxygen on warming the blood to 37°C, arterial oxygen tension values reported at 37°C may be substantially higher than the actual value in colder patients. Therefore, PO_2 values must be corrected for temperature, or the presence of significant hypoxemia may be overlooked. Several nomograms to permit correction exist [140,146–148]. For clinical purposes, the following formula can be used to correct PO_2 for temperature: decrease the PO_2 measured at 37°C by 7.2% for each degree that the patient's temperature is less than 37°C.

Because acute respiratory distress syndrome may, and pneumonia [103] frequently does, accompany hypothermia, a chest radiograph should be obtained. Ninety percent to 100% oxygen should be administered until adequate oxygenation has been demonstrated. Oxygen saturation, after correction for temperature, should be maintained at greater than 90% to help prevent hypoxic damage. Stuporous or comatose patients should have prophylactic intubation to decrease the risk of aspiration pneumonia. Blind nasotracheal intubation may be required; orotracheal intubation may be difficult because the mandible may be unmovable as a result of muscle rigidity [130]. If respiratory failure is evident on blood gas analysis, the trachea should be intubated and the lungs mechanically ventilated.

Experiences during hypothermic surgery and in the treatment of unintentional hypothermia indicate that the initial ventilator settings should be similar to those normally used at temperatures of 37°C [140,141] (see Chapter 58).

Treating the Cause of Hypothermia

Diseases that are known to predispose to hypothermia should be diagnosed and treated early. Hypoglycemia is easily and rapidly detected by a glucose test strip and confirmed by blood glucose value. As a result of the ineffective action of insulin at low temperatures and the relatively high serum osmolarity from water diuresis, serious and difficult-to-treat hyperosmolarity may result from boluses of high concentrations of glucose [62,84]. Therefore, treatment with highly concentrated glucose solutions should be delayed until some measure of the blood glucose has been obtained. Once hypoglycemia has been documented, the patient should be given 25 to 50 g glucose as a 50% dextrose solution. Some patients have been reported to shiver on correction of hypoglycemia and to correct their hypothermia rapidly.

The possibility of alcohol or sedative drug use or overdose is usually indicated by history and confirmed by toxicologic screening. No reports indicate adverse effects of naloxone in hypothermia; it should routinely be given if coma is present.

A thorough neurologic examination may suggest central nervous system or peripheral nervous system disease. If the patient has a history of trauma, the neck should be stabilized until a cervical spine radiograph has been obtained. Flaccid extremities suggest a cord or peripheral nerve injury. Cerebral edema secondary to tumor may be seen on funduscopic examination. Treatment with thiamine is benign and should be given routinely in stuporous hypothermic patients until Wernicke–Korsakoff syndrome can be ruled out. Thiamine should be given with glucose if hyperglycemia is absent to decrease the chance of cerebral dysfunction. If the patient has Wernicke–Korsakoff encephalopathy, response to thiamine treatment may be seen within hours; if thiamine is not given, efforts to increase temperature may be futile [36,40]. Cyclic hypothermia is rarely fatal and responds to cyproheptadine, ephedrine, and naloxone [149,150].

Thyroid hormone should not be given routinely to every patient with hypothermia because such treatment is potentially harmful and hypothyroid coma is rare. In all cases of suspected myxedema, however, treatment with thyroid hormone is mandatory because it may be life saving. Conventional treatment of myxedema hypothermic coma begins with immediate IV administration of 0.2 to 0.5 mg thyroxine. If the patient has not clearly responded in 24 hours, this dose is repeated and the patient is maintained on 0.05 to 0.10 mg thyroxine IV daily until clinically stable (see Chapter 104).

Debilitating diseases such as congestive heart failure, sepsis, hepatic, or renal failure should be treated in a conventional manner. In diabetic patients, insulin resistance increases rapidly below 30°C; insulin administration should be delayed when possible until the patient's temperature is more than 30°C. If insulin is given during hypothermia, it must be administered intravenously because subcutaneous absorption is impaired by hypoperfusion. Also, insulin should be given in small doses, because its degradation may be delayed at low temperature and cumulative doses may produce hypoglycemia and rebound hypothermia as the patient is warmed.

Preventing Common Complications

Early attention to the prevention, diagnosis, and treatment of diseases that are commonly associated with hypothermia may significantly reduce morbidity and mortality [151]. Diabetic patients who have hypothermia and infection have a particularly grave prognosis. In patients with diabetic ketoacidosis, the prevalence of hypothermia was four times higher in those with underlying infection and mortality was three times higher [152]. The possibility of infection should be carefully evaluated in diabetic patients with hypothermia, and early intervention with antibiotics should be considered.

Pneumonia is a common complication in hypothermic patients who survive the rewarming period. The incidence of pneumonia can probably be reduced by early intubation in stuporous or comatose patients to protect the airway and thereby minimize aspiration. In addition, periodic hyperinflation [83], elevation of the head of the bed, and attention to pulmonary toilet may decrease the incidence of pneumonia in hypothermic patients. Antibiotics should only be given when infection is already likely to be present [151,153]. A study demonstrated that a low SVR in patients with mild-to-moderate hypothermia strongly indicates the presence of infection [81]. When SVR is low or diabetic ketoacidosis is present, we believe it is reasonable to give broad-spectrum antibiotic coverage for 24 to 48 hours pending results of the culture.

Because pancreatitis and ileus are both commonly associated with hypothermia, a nasogastric tube should be passed, a baseline amylase level should be obtained, and the patient should not be allowed to eat or drink until fully stable.

Prophylaxis of DVT in patients with hypothermia is a difficult issue. Subcutaneous heparin should not be used because it may be poorly absorbed for several days until skin function returns to normal. Pneumatic boots should not be placed on frostbitten extremities. Because of these concerns and because it is not clear that the risk of DVT from hypothermia outweighs that of systemic anticoagulation, we do not routinely recommend immediate prophylaxis for DVT. Because DIC has been reported, baseline clotting studies may be of value. DIC has occurred even in heparinized patients [154].

Acute tubular necrosis has been reported in hypothermia [70], but it is infrequent and probably results from shock and hypoxia, not as a direct action of hypothermia itself. Renal damage may be minimized by careful cardiovascular support. Hypermagnesemia reduces temperatures in hypothermic patients with renal failure and should be avoided [155]. Hypophosphatemia must be looked for because it may result from treatment [156]. Electrolyte levels must be carefully followed because serum potassium levels vary greatly during treatment.

In cases of exposure, frostbite frequently occurs on the ears, nose, face, penis, scrotum, and extremities. It may be painless and go unrecognized by the victim until he or she is rewarmed. Frostbite is detectable on physical examination because recently frozen tissue usually appears gray, white, or waxy. Soon after warming, the skin may become edematous, blister, or turn red or black because of hemorrhage or necrosis. The extent of damage and eschar formation is usually demarcated within 10 days. Limbs should be handled gently. Thawing frostbitten areas is best postponed until core temperatures have risen to normal and the patient's condition is otherwise stable. It is best accomplished by immersion for 30 to 60 minutes in water heated to 38°C to 43°C. After thawing, whirlpool débridement, intra-arterial reserpine, and anticoagulation with heparin or dextran may be helpful. Amputation may be necessary but should always be delayed as long as possible to allow a clear demarcation of viable tissue [125].

Because of the risk of relapse, hypothermic patients require prolonged monitoring. Elderly patients who have had one episode of hypothermia may experience relapse and, in addition, may be at greater risk for future hypothermic episodes [157]. Any patient who has sustained severe hypothermia under conditions other than extreme exposure should be monitored closely for recurrent episodes.

Rewarming

Rewarming methods can be divided into three categories: passive external rewarming, active external rewarming, and active central rewarming. These methods vary in level of invasiveness and the usual speed with which they provide rewarming.

Passive External Rewarming. Passive external rewarming is the least invasive and slowest rewarming technique. It requires that the patient be dry, sheltered from wind, and covered with blankets to decrease heat loss, thereby allowing thermogenesis to restore normal temperature. Temperature increase varies inversely with patient age; the average rate of temperature increase with this method is only 0.38°C per hour [64]. Passive rewarming is, therefore, appropriate only when hypothermia is not profound (i.e., when the patient's core temperature is >30°C).

Active External Rewarming. Active external rewarming is by far the most controversial method. It involves raising the core temperature by heating the skin with hot blankets, electric heating pads, and hot water bottles; circulating warmed air immediately adjacent to the skin [158,159]; or immersion in a tub of warm water. This method works [18,59,125,157,160] and has been successful in patients with temperatures as low as 17°C [161]. Initial reports [158,159] suggest that rewarming by covering the patient with a plastic blanket that contains tubes of circulating heated air is helpful for the mild hypothermia seen in the perioperative setting. Several studies have now documented that rewarming by the heated air method is safe and effective in moderate hypothermia of numerous etiologies [162]. Mortality with active external rewarming, however, appears to be higher than with passive or central rewarming methods [13]. This possible increase in mortality may be due to a (a) less accurate control over the rate of temperature increase, (b) increased risk of peripheral vasodilation and shock from warming the skin before the core, and (c) increased incidence of acidosis resulting from abrupt return of blood to the core from relatively hypoperfused areas. Treatment by immersion is extremely inconvenient and sometimes impossible in patients who require continuous ECG and temperature monitoring, central venous access, and artificial ventilation and who are in imminent danger of shock or arrest. Experience with patients undergoing external rewarming suggests that aggressive hydration and Swan-Ganz catheter monitoring are helpful [132]. Several studies have shown that the further drop in temperature experienced during the initial phase of active external rewarming is mostly independent of circulatory factors and merely reflects the natural physical laws of heat loss [162–164].

Active Central Rewarming. The fastest and most invasive warming methods are those designed to permit active central rewarming. Although commercial Food and Drug Administration–approved warmers limit fluid warming to 40°C, heated IV crystalloid to temperatures as high as 65°C have been shown to be safe in animal trials [165]. Oxygen that has been humidified and heated to 40°C to 46°C is a safe [13,166] and effective [161] rewarming technique; it can be delivered by face mask or an endotracheal tube. In the hospital, heated oxygen can be provided with a cascade humidifier, available in many ventilator systems. In other settings, portable systems that involve heat production by carbon dioxide and soda lime have been useful [167]. Temperature must be monitored orally to ensure that inspired air does not exceed 46°C, or mucosal damage or burns might occur. Temperature increase with heated oxygen is usually less than 1°C per hour.

Lavage by gastric or esophageal balloons also produces a slow temperature increase and has been shown to be effective [168]; however, this method involves risk of aspiration and ventricular fibrillation during balloon insertion. Peritoneal lavage can be performed conveniently at most hospitals, and it safely raises temperatures at a rate of up to 4°C per hour [85,100,169–171]. Average warming rates, however, are closer to 2°C per hour. Saline or dialysate fluid is heated to 38°C to 43°C and exchanged every 15 to 20 minutes. Alternatively, two peritoneal trocars can be placed and a continuous infusion and drainage circuit established. Pleural lavage with two chest tubes has also been reported and appears to be effective [172,173].

Insertion of femoral artery and vein catheters allows blood to be removed, heated, and returned to the body. This is usually performed with a hemodialysis machine [152] or pump oxygenator such as that used during cardiopulmonary bypass. Rewarming at a rate of 1°C to 2°C per hour has been reported by passing the blood from a surgically created arteriovenous fistula through a countercurrent fluid warmer with [174] or without [175,176] a roller pump. In patients with severe cardiopulmonary collapse, a pump oxygenator offers the advantage of hemodynamic support, rapid elevation of temperature, and nearly complete regulation of acid–base and oxygen disorders [70,79,118,126,134,177,178]. In one review of 68 patients presenting with a mean core temperature of 21°C and being treated with cardiopulmonary bypass primarily by the femoral route, there was a 60% survival, and 80% of survivors returned to their previous level of function [178]. No survival is reported in patients presenting with temperatures of less than 15°C. In cases of profound hypothermia, a median sternotomy approach may be preferable because of the possibilities of direct cardiac massage, improved blood flow, and easy access [118].

The desired rate of rewarming varies according to the patient's cardiopulmonary status and underlying disease. Results of experiments performed on hypothermic dogs suggest that if intramyocardial temperature gradients can be maintained at less than 2°C, the risk of fibrillation decreases [76]. This research argues that safe warming should be either slow enough to allow uniformity in tissue temperatures or fast enough to minimize the period of risk. Slower warming techniques allow a prolonged period of hypothermia and presumably should produce a higher risk of infection because of prolonged immune suppression and a higher incidence of acid–base and intravascular volume problems. A diagnosis of diabetes or myxedema may also influence the desired rate of rewarming. In diabetic ketoacidosis, for example, insulin resistance and the severity of the acidosis could be substantially improved by rapid rewarming, and a more active rewarming technique might therefore be preferred [101].

The rewarming method selected must be appropriate for the individual patient being rewarmed. In one study of 55 patients with accidental hypothermia, extracorporeal membrane oxygenation was used for those in cardiopulmonary arrest; peritoneal dialysis for those with unstable hemodynamics; and airway rewarming, insulation, and warmed fluids for those with stable hemodynamics. Survival was 100% [179].

IATROGENIC HYPOTHERMIA

Iatrogenic hypothermia occurs frequently in surgical recovery rooms and intensive care units [180–183], is associated with increased morbidity, and can be minimized with a systematic team approach. Although subnormal temperatures occur frequently during the postoperative period, frank hypothermia (temperature <35°C) is uncommon. In a series of 195 patients who underwent noncardiothoracic surgery, 60% had temperatures less than 36°C, 29% had less than 35.5°C, and 13% had less than 35°C [184]. Iatrogenic hypothermia results from the infusion of blood products or fluids at lower than body core temperatures [180,184], from continuous ultrafiltration

at high flow rates in the intensive care unit [185], and from anesthesia and surgery performed in cool (<23°C) operating rooms [22,23,181,186,187]. In another series of 101 patients undergoing elective surgery under general anesthesia, 78% had temperatures less than 36°C. The average temperature decrease was 0.77°C, and maximal decrease was 2.5°C [187].

A detailed review of the evolution of anesthetic practices for hypothermic surgery or the management of specific classes of postoperative patients is beyond the scope of this chapter. Discussion is limited to those problems that are most pertinent to the intensive care physician.

Causes and Pathogenesis

Perioperative hypothermia results from increased heat loss, decreased heat production, and compromised thermoregulation [188]. Heat loss may be increased by loss of behavioral control mechanisms, decreased insulation because of exposure of larger skin surfaces, cutaneous vasodilation resulting from anesthetics, increased evaporative losses from serosal surfaces and volatile antiseptics applied to skin, and exposure to air-conditioned environments. Decreased heat production results from muscular paralysis. Impaired thermoregulation results from slowed or compromised afferent and efferent nerve impulses and hypothermic reflexes due to sedative anesthetics. Redistribution of heat from the core to the periphery is felt to be a primary factor in the cause of perioperative hypothermia. Temperature change may be abrupt with a 1°C core heat loss within 30 minutes of induction due to redistribution of heat from the core to the periphery [189].

The frequency and severity of heat loss increase with patient age [180,182,183], open chest or abdominal surgery [180,182,190], low operating room temperature [22,23], length of surgery [181], infusion of cool IV solutions, and certain types of anesthetics. Elderly patients experience a decrease in temperature, shiver less frequently, and take longer to rewarm than do younger patients [180,183]. Temperature decrease during surgery involving open body cavities may result in almost twice the decrease in temperature seen in extremity surgery [182]. Lightly anesthetized, paralyzed, draped patients who are not provided with active warming experience a temperature decrease of 0.3°C per hour at ambient temperatures less than 21°C [23]. Surgery involving muscle paralysis with curare-type agents produces twice the temperature decrease of nonparalyzing procedures [182]. Although halothane and epidural anesthesia may increase heat loss because of vasodilation, no major differences have been detected in the heat loss from most inhalational agents [182,183]. Laparoscopic procedures produce hypothermia that may be more severe than open laparotomy. Massive infusion of chilled solutions can induce hypothermia, as heat loss from infusion of room temperature solutions approximates 16 kcal per L [183]. Blood infused at its stored temperature of 4°C produces a heat loss of 32 kcal per L [184]. In an average human, infusion of 1 L of 4°C blood produces a 0.5°C decrease in temperature [180]. The mean temperature of patients given more than 20 units of blood in 24 hours has been reported to be 32.9°C ± 1.7°C [57]. Although most of these patients had multiple reasons for development of hypothermia, the rapid transfusion of blood not warmed to body temperature must be considered a risk factor for the development of mild hypothermia. The mean temperature of survivors and nonsurvivors after massive transfusion was no different.

Pathophysiology

Perioperative complications from mild hypothermia arise directly from the hypothermia and from the hypermetabolism triggered by the patient's efforts to restore body temperature. From the preceding in-depth discussion of patients with noniatrogenic, unintentional hypothermia, it is reasonable to suspect that an otherwise healthy individual with a temperature ranging from 34°C to 36°C should do well and should have (a) a slightly increased cardiac output, (b) an oxygen consumption up to five times basal levels, (c) an elevated SVR because of peripheral vasoconstriction, (d) a decrease in mixed venous oxygen saturation because of increased oxygen extraction, (e) shivering or muscle rigidity, and (f) a slightly depressed mental status. The alveolar-arterial oxygen gradient and even the arteriovenous oxygen difference [81] may be in the normal range [132]. Therefore, deviations from this pattern in the perioperative period and subsequent morbidity must reflect the additive effects of surgery and anesthesia on metabolism.

Alternatively, in critically ill postoperative patients with cardiac depression, one must be most concerned about the potential effects of mild hypothermia, because an increase in oxygen consumption could easily lead to acidosis and hypoxemia. Although acidosis results from an increase in anaerobic metabolism as metabolic demand outstrips oxygen delivery, minute ventilation is usually maintained to the degree necessary to preserve acid–base balance [191]. Hypoxemia may result from the combination of increased pulmonary parenchymal shunt (venous admixture) after surgery and lower mixed venous PO_2. In one study, shivering appeared to be accompanied by a drop in PO_2; arterial oxygen saturation fell below 90% in 53% of shivering patients and remained above 90% in all nonshivering patients [191]. However, the authors provided little information about inspired oxygen concentrations, raising the possibility that PO_2 may have been significantly improved by merely increasing the concentration of inspired oxygen. Although decreased temperature and shivering can elevate oxygen consumption and in some patients lower PO_2 [183,192], the clinical consequences of these physiologic changes remain obscure. Several studies have now demonstrated an increased morbidity due to hypothermia. Increased perioperative cardiac ischemia, ventricular tachycardia [193], delayed wound healing [112], perioperative bleeding requiring transfusion [113,194,195], increased length of stay in recovery, and increased length of stay in hospital [112] may occur with perioperative hypothermia. Patients with prolonged postoperative hypothermia have a higher mortality than those who return to normal temperatures in the first postoperative hour [196].

Prevention and Treatment

Numerous interventions have been attempted to minimize perioperative temperature decrease and shivering. The use of postoperative warming blankets alone does not prevent significant temperature loss because the body surface area exposed to heat is small [18,186,197]. The use of warming blankets plus heating of all infused liquids can maintain average temperature on arrival in the recovery room above 36°C [197]. Heating and humidifying the carbon dioxide used for laparoscopic insufflation to 30.0°C to 30.5°C decrease the heat loss associated with laparoscopic procedures [198]. Crystalloids can be easily warmed in a microwave oven to 39°C in 2 minutes [199]. The inhalation of heated, humidified air can be safely applied to most intubated patients and is effective in preventing temperature loss [192,200,201] and shivering [192]. Most publications clearly favor the use of preoperative, intraoperative, and postoperative forced air warmers [202–204]. Preliminary studies indicate that different manufacturers' products are not equally effective [205,206]. One hour of prewarming with an air warmer set to 43°C may minimize redistribution loss and decrease hypothermia for brief procedures. Vasodilators such

as nitroprusside or nifedipine may be started hours preoperatively resulting in peripheral vasodilation and minimizing redistribution loss by prewarming the peripheral tissues. Cutaneous rewarming minimizes shivering. Meperidine may lower the shivering threshold and control pain in postoperative patients. Prewarming is felt to be the most effective strategy for high-risk patients [189].

All patients undergoing surgery should be observed closely for the development of hypothermia. Simple measures, such as minimizing preoperative and postoperative time in chilled rooms, covering the patient with drapes or blankets whenever possible, and infusing all solutions at least at room temperature, should be taken in all patients. Special measures should be taken in high-risk individuals. Groups of patients at high risk of hypothermia include those undergoing major abdominal or cardiothoracic surgery, surgery involving intentional hypothermia, or surgery with anesthesia times in excess of 4 hours; patients older than 60 years undergoing surgery; and patients with known or expected cardiac depression who are undergoing surgery. In these high-risk patients, preventive measures, including the use of preoperative [207–209] and intraoperative [203,210] forced warm air, heating of infused solutions to 37.5°C, and inhalation of heated humidified oxygen, should be beneficial. In any patient undergoing any type of extracorporeal bypass, the addition of a heat exchanger to the bypass circuit is simple and effective [211]. Blood and colloid solutions can be safely heated to 37.5°C [212]. These measures have been shown to be safe and effective in numerous clinical series and can provide the patient potential benefit at little cost or change in perioperative routine.

INTENTIONAL HYPOTHERMIA

Intentional hypothermia has been induced by partial immersion or surface or central cooling techniques to treat cancer, limit the toxicity of sepsis, help prevent the alopecia of chemotherapy, reduce carbon dioxide production in refractory status asthmaticus, assist in the amputation of limbs, and minimize the hypoperfusion injury associated with cardiothoracic surgery. Currently, mild-to-moderate hypothermia (32°C to 35°C) is the first treatment with proven efficacy for postischemic neurological injury, and employing intentional hypothermia to retard postcardiac arrest brain injury is now recommended by the American Heart Association.

Therapeutic Hypothermia after Cardiac Arrest

Therapeutic hypothermia improves survival and neurological outcomes after sudden cardiac arrest in several randomized controlled trials [213–215]. Adoption of this treatment has been slow, particularly in the United States, despite consensus recommendations by the liaison committee on resuscitation for the use of therapeutic hypothermia after sudden cardiac arrest [216]. Possible barriers to applying this therapeutic strategy include the complexity of implementing it, relative little published research in its use, and the need for improved cooling devices. A recent compilation of recent experiences, where implementation of therapeutic hypothermia within hospital systems outside clinical trials were compared, noted an increased survival with an odds ratio of 2.5 (95% confidence interval, 1.8 to 3.3) and favorable outcome with an odds ratio of 2.5 (95% confidence interval, 1.9 to 3.4) [216].

Cardiac arrest results in immediate termination of blood flow and loss of oxygen leading to neurological ischemic injury after only several minutes and permanent loss after 5 to 10 minutes. If resuscitation results in restoration of circulation, an additional reperfusion injury occurs. Several animal models including dogs showed that cooling after prolonged cardiac arrest (10 minutes no flow following 5 minutes low flow) provided considerable neurological benefit [217]. Subsequently, two pivotal, randomized, controlled trials were conducted and confirmed efficacy [214,215]. The first of these was a large, multicentered, randomized, controlled trial that enrolled 275 patients in nine European hospitals who had sustained a cardiac arrest with an initial rhythm of ventricular fibrillation. The second randomized, controlled trial enrolled 77 patients from four hospitals in Victoria, Australia, with similar inclusion criteria, however, did not exclude older patients or those who were hypoxic. The American Heart Association recommended, in review of these two studies, therapeutic hypothermia for 12 to 24 hours following resuscitation from out-of-hospital cardiac arrest for the treatment of neurological injury when the initial rhythm is ventricular fibrillation [218].

However, the role of therapeutic hypothermia is uncertain when the initial rhythm is asystole or pulseless electrical activity or when the cardiac arrest is in hospital or pediatric or due to a noncardiac cause such as asphyxia or drug overdose [219]. Also hemodynamically unstable patients were excluded from the European trial. In addition, the trials used therapeutic hypothermia several hours after resuscitation and therefore the role for earlier cooling or prolonged cooling was not evaluated. Given that survival rate in these other conditions is very low, it is unlikely that clinical trials will be undertaken to test the efficacy, as a very large sample size would be necessary to show a difference in outcomes. Given that the induction of hypothermia has become more feasible, the side effects are generally easily managed in the critical care setting, and there is a benefit for anoxic brain injury; consideration may be given to treat comatose post–cardiac arrest non–ventricular fibrillation patients with therapeutic hypothermia [219].

For Acute Myocardial Infarction

Timely myocardial reperfusion using thrombolytic therapy or angioplasty is the most effective therapy for patients with ST elevation myocardial infarction. Although mild hypothermia appears feasible and safe, its ability to limit infarct size or reduce rates of adverse cardiac events has not been proven [220].

For Spinal Cord Injury

Hypothermia strategies date back to the 1960s for the treatment of acute spinal cord injury, but no randomized phase III trials have been conducted to confirm efficacy and safety, let alone the appropriate therapeutic window. Hypothermia remains an experimental treatment with unknown clinical relevance for patients with acute spinal cord injury [221].

For Ischemic and Hemorrhagic Stroke

Hypothermia reduces brain edema and intracranial pressure (ICP) in patients with traumatic brain injury; however, only very few small pilot studies have investigated the role hypothermia may have in the treatment of acute ischemic stroke. There are no controlled trials performed for hypothermia in hemorrhagic stroke. Currently, barriers to its clinical use include critical care to start immediately in the emergency room, inability to induce hypothermia within 3 to 6 hours due to slow cooling rates, the necessity for proactive antishivering therapy for cooling, slow rewarming to prevent rebound brain edema, and increased risk for infectious and cardiovascular complications

TABLE 65.4

ADVANCES IN MANAGEMENT OF HYPOTHERMIA BASED ON RANDOMIZED CONTROLLED TRIALS

Induced hypothermia benefits survivors of cardiac arrest: Unconscious adult patients with recovery of spontaneous circulation after out-of-hospital cardiac arrest should be cooled to 32°C to 34°C (89.6°F to 93.2°F) for 12 to 24 hours when the initial rhythm was VF Similar therapy may be beneficial for patients with non-VF arrest out of hospital or for in-hospital arrest
VF, ventricular fibrillation.

[222]. On the contrary, the use of normothermia protocols is being actively studied.

For Acute Liver Toxicity

Patients with rapidly progressive acute liver failure, such as with acetaminophen overdose, are at high risk for developing cerebral edema, intracranial hypertension, brainstem herniation, and brain death or anoxic brain injury and permanent brain impairment. Techniques such as manipulating the body position, increasing sedation, and increasing osmolarity through medications can temporarily control this phenomenon. However, these steps often postpone but do not stop the development of brain herniation unless liver transplantation or spontaneous liver regeneration follows immediately. Using therapeutic hypothermia has been shown to effectively bridge patients to transplant by reducing cerebral edema and intracranial hypertension by decreasing splanchnic ammonia production, lowering oxidative metabolism within the brain, and restoring normal regulation of cerebral hemodynamics [223]. However, hypothermia has not been adequately studied for its safety, and concerns of increasing the risk of infection, cardiac arrhythmias, and bleeding may be accentuated. Multicenter, randomized, control trials are needed to determine if hypothermia protects the brain and improves survival without causing harm.

In Multisystem Trauma

Hypothermia may be helpful in attenuating the damage to tissues before adequate blood volume resuscitation can be restored in traumatic blood loss. Clinical trials to determine its efficacy are needed [224].

Advances in hypothermia, based on randomized, controlled trials or meta-analyses of such trials, are summarized in Table 65.4.

Methods of Cooling

Induction and maintenance of hypothermia requires blocking the body's normal thermoregulation mechanism as well as active heat exchange. Therapeutic hypothermia can be achieved through four mechanisms individually or in combination and include conduction, convection, radiation, and evaporation as previously described in this chapter. There are four phases of temperature modulation during therapeutic hypothermia: induction, maintenance, decooling, and normothermia [225]. Induction is typically initiated prehospital, especially in out-of-hospital cardiac arrests, but can occur in hospital for patients awaiting a liver transplant, with cerebral edema from acute liver failure and for control of refractory elevated ICP. Among cardiac arrest survivors, contraindications to perform therapeutic hypothermia would include if the patient can follow verbal commands, more than 8 hours have elapsed since return of spontaneous circulation, life-threatening bleeding or infection, cardiopulmonary collapse is imminent despite vasopressor or mechanical hemodynamic support, or an underlying terminal condition exists. It is commonly achieved by rapid bolus administration of 30 to 40 mL per kg cold (4°C) isotonic resuscitation fluid [225] targeting a goal temperature of 32°C to 34°C. Serum potassium will drop, and empirically repleting potassium for a goal of more than 3.8 mEq per dL is needed. Close monitoring and treatment for seizures is necessary. Simultaneous sedation, paralysis (for shivering), and use of commercial surface or intravascular cooling devices are concomitant therapeutic strategies [225].

Maintenance phase occurs in the intensive care unit and is a phase where both metabolic and hemodynamic homeostasis are maintained. The core temperature is kept at 33°C for 18 to 24 hours. Maintenance of brain perfusion by keeping mean arterial perfusion pressure at 65 mm Hg or more (cerebral perfusion pressure [CPP] may need to be monitored given cerebral autoregulatory failure [226]), normocarbia with volume-cycled mechanical ventilation to maintain a normal pH as hypercarbia is to be avoided; maintain a perfusing rhythm, antibiotic prophylaxis if pulmonary infiltrates present [225,227], maintenance of a blood glucose of 120 to 160 mg per dL [226], maintenance of normal electrolyte levels [225] and appropriate medication dosing given the reduction in drug metabolism and duration of action [225], skin care, and aggressive treatment of shivering with neuromuscular blockade [225].

After 24 hours of therapeutic hypothermia, the decooling phase starts and is associated with hemodynamic instability often referred to as the postresuscitation syndrome. It is characterized by an increase in inflammatory cytokine levels, vasodilatation, and hypotension [225]. The patient is also at increased risk for an elevation in the ICP and a decrease in the CPP [225]. Slow decooling at a goal rate of 0.2°C to 0.33°C per hour until the patient is at 36.5°C or 37°C is preferred to avoid large hemodynamic fluctuations. Supportive fluid boluses, inotropes, and vasopressors may be necessary to maintain CPP, especially if there are signs of elevated ICP. Use of neuromuscular blockade until the temperature reaches 35°C to avoid shivering and sedation is weaned once the body temperature reaches 36°C is recommended [225].

In patients who have undergone therapeutic hypothermia post–cardiac arrest, a rebound fever can occur and is harmful [228]. Brain injury may be attenuated by fever control [229]. Maintaining normothermia for at least 72 hours from return of circulation is thus common practice [225]. This is easily achieved by employing commercial cooling devices and resetting target temperature to 36.5°C to 37.5°C. Nursing attention to onset of fever spikes and frequent adjustments to the cooling device set points need to be closely observed.

A number of issues occur with induction, maintenance, and withdrawal of therapeutic hypothermia and require close attention. (i) Serum potassium needs to be aggressively replaced if levels are less than 3.8 mEq per dL as soon as therapeutic hypothermia is employed and the levels should be followed every 3 to 4 hours during the induction phase. (ii) One needs to be able to accurately measure the core temperature continuously and this is preferably achieved by bladder, rectal, central venous, or esophageal measurements. Bladder measurement may be inaccurate in oliguric patients and other monitoring sites are preferred. (iii) When using neuromuscular blockade to control shivering and or help in the induction phase of hypothermia, thorough neurology exam and adequate sedation a priori is important. (iv) None of the cooling devices currently

used for therapeutic hypothermia post–cardiac arrest have been approved despite the fact that they have been routinely employed and thus the application of any of the cooling devices constitutes "off-label" use. (v) The incidence of pneumonia in post–cardiac arrest patients treated with hypothermia is 30% to 50% [215]. The etiology may be related to aspiration at the time of cardiac arrest or from the immunosuppressive effects from hypothermia. Preliminary data supports prophylactic antibiotics for presumed pneumonia [227]. (vi) Seizures can occur 19% to 34% of the time and go undetected with neuromuscular blockade [230]. Thus, continuous EEG monitoring in the paralyzed patient may be necessary. If continuous monitoring is not available, then empirically using antiepileptic sedatives to sedate the patient may be warranted [225]. (vii) Hemodynamic instability is common during the decooling phase due to cutaneous vasodilatation and the inflammatory state [225]. Close attention to monitoring adequate cardiac output, global tissue perfusion, and brain perfusion using intravenous isotonic fluids, inotropes, and/or vasopressor agents may be necessary. Hemodynamic monitoring may be achieved by using invasive or noninvasive cardiac output devices, urinary output if kidney function is normal, and central venous oxyhemoglobin saturation for tissue perfusion or direct invasive monitoring of brain metabolism [225]. To reduce shivering, focal counter rewarming [225] can be employed in which the face, neck, and extremities are actively warmed while the torso and central venous system are cooled. This paradoxically increases the cooling process by enhancing the cutaneous vasodilatation.

COOLING TECHNIQUES

The conventional method involves the use of cold saline or ringer's lactate solution at 4°C administered at 30 to 40 mL per kg and has been shown to decrease core temperature by 2°C to 4°C without left ventricular systolic dysfunction and a reduction in cardiac output [231]. This method is supported by multiple safety and efficacy trials [225] and should be the preferred method for induction in conventional cooling. Thereafter cooling can be maintained with ice packs applied to the neck, groin, and axilla and rubber cooling mats or blankets as used in the operating room. Ongoing infusion of cold fluid has not been shown to be an effective method to maintain hypothermia [232]. A number of issues associated with this method include the lack of an internal feedback loop making an accurate temperature maintenance difficult, a high incidence of overcooling, and the need for high level of nursing care. Nonetheless, it is widely available and cost-effective.

There are a number of commercial surface cooling devices of which the most widely available is the Arctic Sun device (Medivance, Louisville, CO) which uses proprietary heat exchange pads that adhere to the skin using a hydrophilic gel that conducts heat. The pads cover 40% of the body surface area and circulating water temperature is continually modulated by a servo mechanism to maintain a core body temperature at goal. This device was studied in the Hypothermia After Cardiac Arrest trial [233] and was noted to be relatively safe with infrequent overcooling and lack of vascular complications, sparing of the femoral and subclavian sites for catheterization, and allowing for defibrillator pads and compatibility with cardiac catheterization. However, it is not inexpensive with a potential for rare skin conditions [225].

Other devices such as CoolBlue (Innercool Therapies, San Diego, CA), Blanketroll III (Cincinnati SubZero Products, Cincinnati, OH), and Thermo wrap (MTRE Advanced Technologies, Rehovot, Israel) are less expensive and recently introduced but not as quick at reducing the temperature. They are without the gel-adhesion system, employ servo mechanisms and thus are safe and reduce nursing work, and cool by conduction as water circulates through pads that encircle the patient without adhering directly to the patient's skin. Experience with these devices is limited and efficacy has yet to be demonstrated in clinical trials [225]. The fastest cooling device is the Thermosuit System (Life Recovery Systems, Kinnelon, NJ), a cold immersion system that can cool human-sized swine to 33°C in 30 to 45 minutes [234]; however, safety data are awaited.

Methods using commercial intravascular cooling devices are dependent on central vascular catheters and its associated inherent risks [235]. Two devices include the Alsius temperature management system and the Celsius Control System (Inner cool Therapies) [225]. The Alsius system has a number of proprietary intravascular devices that serves as both a cooling device and central venous catheter, both of which are servo-controlled temperature modulation systems. In the Celsius system, water circulates through a metallic catheter with a textured surface in the inferior vena cava [236]. It is effective in providing precise temperature control, it may increase the patient's risk for thromboembolism, and it requires a separate catheter for the administration of supportive medications. Other less commonly used methods to cool include medications such as neurotensin, extracorporeal circuits, body cavity lavage, whole body ice water immersion, continuous venovenous hemoinfiltration, cooling helmets, and air conduction hypothermia devices.

Therapeutic hypothermia can be achieved by conventional modalities that are readily available in most hospitals or with one of the newer devices now commercially available. Temperature management can be complex and the circumstances highly variable, such as persistent neurogenic fever and uncontrollable shivering in patients with a traumatic brain injury despite normothermia with ice packs and cold fluid while other patients are uneventfully cooled and rewarmed. This variability requires close attention by a highly trained intensive care team.

CHAPTER 66 ■ DISORDERS OF TEMPERATURE CONTROL PART II: HYPERTHERMIA

M. KATHRYN STEINER, FREDERICK J. CURLEY AND RICHARD S. IRWIN

This chapter reviews the pathobiology, pathophysiology, diagnosis, differential diagnosis, and treatment of four major hyperthermic syndromes—heat stroke, malignant hyperthermia, neuroleptic malignant syndrome, and drug-induced hyperthermia. Establishing the correct diagnosis and promptly instituting specific therapy are essential to management as mortality rises with any delay in treatment.

HEAT STROKE

Heat stroke is a syndrome of acute thermoregulatory failure in warm environments characterized by central nervous system (CNS) depression, core temperatures usually above 40°C, and typical biochemical and physiologic abnormalities. Most cases of heat stroke occur in youths exercising in the sun, especially military recruits and athletes, or in elderly or ill patients during severe heat waves. Mortality in some series is as high as 70% [1]. During a warm summer in the United States, approximately 4,000 deaths may occur as a direct result of heat stroke [2–4].

Causes and Pathogenesis

Heat stroke may be subclassified by its two distinct clinical presentations: exertional and nonexertional (classic, heat stroke). Exertional heat stroke is typically seen in younger individuals exercising at higher than normal ambient temperatures. The thermoregulatory mechanisms are intact, but overwhelmed by the thermal challenge of the environment and the great increase in endogenous heat production. Nonexertional heat stroke occurs in the elderly or sick individuals during a heat wave. Patients frequently have some impairment of thermoregulatory control, and temperatures rise easily with increased thermal challenge.

The causes of heat stroke fall into two categories (Table 66.1): increased heat production and impaired heat loss.

Increased Heat Production

Endogenous heat production during exertion ranges from 300 to 900 kcal per hour. Even in conditions favoring the maximal evaporation of sweat, only 500 to 600 kcal per hour of heat may be lost. Endogenous heat production may also be increased by fever, thyrotoxicosis, or the hyperactivity associated with amphetamine and hallucinogen use. In these conditions of increased thermogenesis, especially during maximal exercise, a healthy individual with intact regulatory mechanisms may develop hyperthermia.

Impaired Heat Loss

Schizophrenic, comatose, senile, or mentally deficient patients are at increased risk of heat stroke when ambient temperatures are high, owing to impaired voluntary control [5,6]. These patients may fail to perceive a temperature rise and take appropriate action. Impermeable clothing in hot environments has a great reduction in evaporative heat loss and individuals may suffer heat stroke [7,8].

Acclimatization increases heat tolerance by increasing cardiac output; decreasing peak heart rate; and increasing stroke volume. This lowers the threshold necessary to induce sweating; increases the volume of sweating; and, via an increase in aldosterone, expands extracellular volume and minimizes sweat sodium loss [9,10]. However, unacclimatized individuals who do not mount an adaptive response are at increased risk of suffering exertional heat stroke [11].

Dehydration and impaired cardiovascular performance increases the risk of heat stroke due to a decrease in skin or muscle blood flow, thus decreasing the movement of heat from the core to the environment [10,12]. Hypokalemia increases the risk of heat stroke by decreasing muscle blood flow, impairing cardiovascular performance, and possibly decreasing sweat gland function [9,10]. Adequate fluid intake and maintenance of a normal vascular volume prevents heat stroke. Heat load places a stress on the cardiovascular system and produces hyperthermia in patients with cardiovascular dysfunction. In one report, 75% of patients with compensated cardiac failure developed overt heart failure and temperatures up to 38.0°C after as little as 4 hours' exposure to temperatures of 32.2°C. Respiratory rate, blood pressure, and central venous pressure (CVP) also tended to rise [13].

Many drugs are known to predispose to heat stroke. Anticholinergic drugs such as phenothiazines, butyrophenones, thiothixenes, and anti-Parkinson's medications reduce sweat activity [14]). Barbiturate overdose may produce sweat gland necrosis [10]. Diuretics promote dehydration and hypokalemia. Beta-blockers may increase the risk of heat stroke because of cardiodepression. Alcohol consumption may increase the risk of heat stroke 15-fold because of dehydration secondary to antidiuretic hormone inhibition and inappropriate vasodilation [6].

Skin disorders that impair sweat gland function, such as cystic fibrosis and chronic idiopathic anhydrosis, predispose to heat stroke [15]. Hypothalamic lesions impair thermoregulation. During the early stages of heat stroke, the hypothalamus regulates autonomic responses to limit hyperthermia to occur. In the later stages, after thermal toxicity has occurred, hypothalamic regulation is impaired [16]. Anhydrosis has been reported in up to 100% of heat stroke victims in some series [17]. The hypothalamic set point may be elevated. The exact cause of hypohidrosis remains unclear and may reflect hypothalamic dysfunction or only the secondary effects of dehydration and cardiovascular collapse. Electron microscopic studies of eccrine sweat glands in a patient with fatal exertional heat stroke show changes suggestive of sweat gland fatigue [18]. Heat stroke can, however, occur in individuals who perspire profusely, indicating that sweat gland malfunction is not the only factor contributing to the pathogenesis of the syndrome.

TABLE 66.1

CAUSES OF HEAT STROKE

Increased heat production
Exercise
Fever
Thyrotoxicosis
Amphetamines
Hallucinogens
Impaired heat loss
High ambient temperature or humidity
Ineffective voluntary control
Lack of acclimatization
Dehydration
Cardiovascular disease
Hypokalemia
Drugs
Anticholinergics
Phenothiazines
Butyrophenones
Thiothixenes
Barbiturates
Anti-Parkinson's agents
Diuretics
Beta-blockers
Alcohol
Debilitating conditions
Skin diseases
Cystic fibrosis
Central nervous system lesions
Older age

The increased risk of heat stroke in the elderly is predominantly due to a decreased ability to sweat and a compromised cardiovascular response to heat exposure when compared with younger individuals [8,19]. In one report, 84% of elderly patients showed no evidence of sweating at the time heat stroke was diagnosed [20]. Elderly patients are more likely to have deficient voluntary control, poor acclimatization, and they take drugs that adversely affect thermoregulation.

Pathophysiology

The primary injury in heat stroke is due to the direct cellular toxicity of temperatures above 42°C, the *critical thermal maximum* [21]. Cell function deteriorates owing to cessation of mitochondrial activity, alterations in chemical bonds involved in enzymatic reactions, and cell membrane instability. This toxic effect may account for the widespread organ damage seen in all three of the major hyperthermic syndromes [22].

Heat stress activates numerous cytokines that modulate the body's response to increased temperature [23]. In most cases, the inflammatory response in heat stroke parallels that seen in heat stress from exertion. Tumor necrosis factor α, interleukin-(IL)1β, IL-2, IL-6, IL-8, IL-10, IL-12, and interferon gamma are typically increased in heat stroke. IL-6 is activated in the muscles and modulates inflammatory response by controlling cytokine levels and hepatic production of acute phase proteins. Endotoxemia from bacterial translocation of an ischemic gut further exacerbates the inflammatory response. Endothelial injury activates the coagulation cascade, promoting a prothrombotic state. Heat shock proteins are transcribed in response to heat stress and act in the brain to induce tolerance to heat stress [24].

Dehydration, metabolic acidosis, and local hypoxia alter the pathophysiologic consequences and clinical presentation of each of the hyperthermic syndromes. For example, classic heat stroke may occur with relatively little metabolic acidosis because no exertion was involved in its onset; however, it may be associated with more pronounced dehydration due to the gradual rise in temperature and prolonged sweating. Exertional heat stroke, alternatively, may be accompanied by a severe metabolic acidosis and hypoxia due to muscular exercise. It is typically associated with a more normal volume status because the onset of temperature elevation is abrupt.

Muscle Effects

Muscle degeneration and necrosis occur as a direct result of high temperatures. Muscle damage is more severe in exertional heat stroke owing to the local increases in heat, hypoxia, and metabolic acidosis associated with exertion. Significant muscle enzyme elevation and severe rhabdomyolysis are extremely common in exertional heat stroke [12,25,26] but rare in classic heat stroke [27].

Cardiac Effects

Cardiac output is increased [28] due to increased demands and low peripheral vascular resistance secondary to vasodilation and dehydration. Dehydration frequently results from sweat rates that may easily reach 1.5 to 2.0 L per hour during episodes of heat stroke [29]. CVP is initially elevated [30].

Hypotension occurs commonly as a result of high-output failure or temperature-induced myocardial hemorrhage and necrosis with subsequent cardiac depression and failure [9,12,31]. Tachyarrhythmias are frequent. Postmortem specimens show focal myocytolysis, myocyte necrosis, and hemorrhage in subepicardial, intramuscular, subendocardial, or intravalvular tissues [32].

Central Nervous System Effects

Direct thermal toxicity to brain and spinal cord rapidly produces cell death, cerebral edema, and local hemorrhage. These may lead to profound stupor or coma, almost universal features of all the hyperthermic syndromes. Seizures secondary to edema and hemorrhage are not uncommon. Because Purkinje cells of the cerebellum are particularly sensitive to the toxic effects of high temperatures, ataxia, dysmetria, and dysarthria may be seen acutely and in survivors of hyperthermia [10,33]. Progressive cerebellar atrophy has been documented by computed tomography and magnetic resonance imaging [34]. Lumbar punctures in classic and exertional heat stroke may reveal increased protein levels, xanthochromia, and a slight lymphocytic pleocytosis [12,20]. Survivors of severe heat stroke may show premature cataract formation, considered to be secondary to dehydration [35]. Up to 33% of survivors of heat stroke have at least moderate neurologic impairment after discharge from the hospital [36].

Renal Effects

Renal damage occurs in nearly all hyperthermic patients; it is potentiated by dehydration, cardiovascular collapse, and rhabdomyolysis. In classic heat stroke, acute renal failure occurs on average in 5% of patients as a result of dehydration [9]. In exertional heat stroke, acute renal failure occurs in up to 35% of cases [9,31]. Dehydration, pigment load, hypoperfusion, and urate nephropathy are thought to contribute to a clinical picture of acute tubular necrosis [31]. Other features include low serum osmolarity, moderate proteinuria, active sediment, and

characteristic machine-oil appearance of the urine. In one series, the incidence of acute tubular necrosis increased with survival time [32]. Hypocalcemia and creatine phosphokinase values above 10,000 U per L increase the risk of acute renal failure [37]. Respiratory alkalosis is common in mild hyperthermia with metabolic acidosis predominating at temperatures greater than 41°C [24].

Gastrointestinal Tract Effects

The combination of direct thermotoxicity and relative hypoperfusion of the intestines during hyperthermia leads to ischemic intestinal ulcerations that may result in frank bleeding [9]. Hepatic necrosis and cholestasis occurs 2 to 3 days after hyperthermic insult, and 5% to 10% of cases result in death [10].

Hematologic Effects

White blood cell counts are elevated owing to catecholamine release and hemoconcentration. Anemia and a bleeding diathesis [29] are present due to (a) direct inactivation of platelets and bleeding factors by the heat, (b) a decrease in coagulation factor synthesis owing to liver failure, (c) a decrease in platelet and megakaryocyte counts, (d) platelet aggregation [38], and (e) disseminated intravascular coagulation (DIC). Megakaryocyte counts are reduced in up to 50% of specimens, and surviving megakaryocytes are morphologically abnormal [32]. DIC is present in most cases of fatal hyperthermia [32,39], most frequently appearing on the 2nd or 3rd day after hyperthermic insult. It is thought to be due to activation of the clotting cascade by vascular endothelial damage and generalized cell necrosis [40]. In cases of DIC, cardiac, CNS, pulmonary, gastrointestinal (GI) tract, and renal complications are exacerbated. An increase in blood viscosity of up to 24% has been postulated to facilitate thromboses [41].

Endocrine Effects

Hypoglycemia may occur in severe exertional heat stroke due to metabolic exhaustion [26]. In milder heat stroke, hyperglycemia and elevations of serum cortisol have been reported [42]. Although in autopsies the adrenal glands frequently show pericortical hemorrhages, survivors show little evidence of adrenal dysfunction [22,31]. Growth hormone and aldosterone levels actually increase abruptly during severe, acute heat exposure and are thought to act to preserve volume.

Electrolyte Effects

Hyperthermia produces frequent imbalances in potassium, sodium, phosphate, and calcium levels [29,43]. In heat stroke, sweating involves the active excretion of potassium from the body, producing normal to low serum potassium levels and slightly decreased total body potassium concentrations. In cases of exertional heat stroke with severe cell injury, potassium levels may be extremely elevated owing to cell lysis. Although mild hypophosphatemia occurs frequently as a result of intracellular trapping and possible parathyroid hormone resistance, phosphate levels may decrease to less than 1 mg per 100 mL in cases of hyperthermia with severe rhabdomyolysis [43]. Calcium values may fall 2 to 3 days after cellular injury owing to intracellular precipitation. In patients with severe tissue injury rebound, hypercalcemia may occur 2 to 3 weeks after hyperthermia as a result of parathyroid hormone activation [43].

Pulmonary Effects

Direct thermal injury to the pulmonary vascular endothelium may lead to cor pulmonale or acute respiratory distress syndrome. This and the tendency toward myocardial dysfunction make pulmonary edema common. Increased oxygen demands and acidosis frequently produce a respiratory alkalosis. Metabolic acidosis is, however, the most common acid–base disorder [44].

Diagnosis

Heat stroke is usually readily suggested by history and physical examination, and the diagnosis confirmed by recording a rectal temperature above 40°C. The temperature of any individual found comatose during a heat wave should be taken. Any laborer or athlete displaying incoordination followed by stupor and collapse while exercising in the heat should be assumed to have heat stroke until proven otherwise. Because more than 6 million workers in the United States experience occupational heat stress [8], a history of the exact events precipitating collapse may be helpful.

Heat stroke should be expected in any patient exercising in hot weather or in susceptible individuals during heat waves (see Table 66.1). Coma or profound stupor is nearly always present, but the other traditional criteria of anhidrosis and core temperature above 41°C may be absent. Although anhidrosis occurs in 84% of elderly patients with classic heat stroke [20], profuse sweating is typically present in exertional heat stroke [10]. Thus, the presence of anhidrosis is helpful, but its absence is not. Likewise, by the time the patient receives medical care, the temperature may have fallen significantly owing to cessation of exertion, removal from a hot environment, or cooling measures undertaken during transport. Most patients do have a temperature above 40°C, however. Because the level of serum creatine kinase is almost always elevated, the authors believe diagnostic criteria for heat stroke should include (a) a core temperature above 40°C, (b) severely depressed mental status or coma, (c) elevated serum creatine kinase level, and (d) compatible historical setting.

Classic heat stroke occurs more frequently when ambient peak temperatures exceed 32°C and minimum temperatures do not fall below 27°C. The risk is greater in urban areas, where minimum temperatures may exceed that in surrounding communities by more than 5°C [3]. Death rates during these heat waves may exceed twice the normal rates, and heat stroke deaths usually lag behind peak temperatures by approximately 24 hours. More than 80% of heat stroke victims are older than 65 years [20,40]. Other major high-risk groups are schizophrenics, patients with parkinsonism, alcoholics, and paraplegics or quadriplegics [45,47].

Exertional heat stroke may be seen when ambient temperatures are in the 25°C range, but more frequently it occurs at higher temperatures. Exertional heat stroke is frequently seen in military recruits during basic training [11,26], amateur football players [10,48], and marathon runners [49–52]. Miners and others who labor in hot local environments are also at high risk [31]. Heat stroke remains the second leading cause of death in athletes, second only to injuries of the head and spinal cord [9].

Differential Diagnosis

Several publications outline an approach to fever in the critically ill patient [53,54]. Table 66.2 lists the common causes of hyperthermia. Hyperthermia and coma may occur with hypothalamic injury, severe infection, or endocrinopathy [55]. Hypothalamic tumors or hemorrhage may produce hyperthermia by elevating the regulated temperature set point and may be distinguished from heat stroke by the constancy of the temperature and associated defects, such as diabetes insipidus and

TABLE 66.2

DIFFERENTIAL DIAGNOSIS OF HYPERTHERMIA

Hyperthermic syndromes

Central nervous system
Hypothalamic bleed
Acute hydrocephalus

anhidrosis, which may be unilateral [56]. Meningitis and encephalitis usually lack the characteristic enzyme elevations and may be distinguished by lumbar puncture.

Treatment

Primary Therapy of Hyperthermia

Primary therapy includes cooling and decreasing thermogenesis. Some cooling may be achieved in the field by moving the victim to a shaded, cooler area; removing the clothes; constantly wetting the skin; and fanning or transport in an open vehicle to create a breeze. Once the victim reaches hospital, cooling and subsequent supportive care are best provided in an intensive care setting.

Cooling by evaporative or direct external methods has proved effective. Evaporative cooling methods involve placing a nude patient in a cool room, wetting the skin with water, and encouraging evaporation by using fans. In one specially designed evaporative cooling unit, patients were sprayed with 15°C water and their skin fanned at 30 times per minute with air heated to 45°C to 48°C. Temperature reduction was rapid and mortality was 11% [57]. There was no mortality in 25 patients with nonexertional heat stroke treated with cooling by covering with a cool, wet, 20°C sheet and fanning with two 35-cm electric fans. Fanning was adjusted to maintain skin temperature at 30°C to 32°C; skin temperature fell 1°C every 11 minutes [58]. In 14 patients with nonexertional heat stroke, there was one death when evaporative/convective cooling was employed. The median time to return to temperature less than 39.4°C was 60 minutes.

Direct external cooling involves immersing the patient in ice water or packing the patient in ice. Ice water immersion with massage has been effective with little complication [59]. Colder water cools more rapidly (up to 0.35°C per minute), with one study demonstrating that 2°C water cooled volunteers twice as rapidly than 8°C water [60]. Because cold skin temperatures produce vasoconstriction, however, constant massage may be necessary to allow circulation to carry heat from the core. Direct external cooling is highly effective but makes patient monitoring and management extremely inconvenient. Therefore, some authors advocate evaporative cooling as a safer cooling method in patients at high risk of cardiovascular collapse [52]. As comparative studies of cooling techniques use different water temperatures for immersion and different evaporative cooling protocols, there is no consensus on which technique is superior. In most cases, treatment will be determined by what resources are immediately available. The Israeli Defense Forces protocol involves moving the collapsed patient to the shade, removing clothing, splashing the skin with water while fanning, and transport to hospital in an open vehicle. These measures yielded a cooling rate of 0.11°C per minute [61]. The US Marine Corps protocol calls for covering the patient with sheets covered with ice and then fanning the patient. This has had no mortalities in 200 cases and has reduced temperatures to below 39°C in 10 to 40 minutes [62].

In rare instances in which evaporative and direct external cooling methods fail to reduce the temperature, peritoneal lavage with iced saline cooled to 20°C or 9°C, gastric lavage, or hemodialysis or cardiopulmonary bypass with external cooling of the blood may be necessary to reduce the temperature. Temperature should be continuously monitored and cooling stopped as it approaches 39°C. Although chlorpromazine in an intravenous (IV) dose of 10 to 25 mg has been advocated to prevent shivering during cooling, it is usually unnecessary. Cooling blankets, although commonly used, are extremely ineffective and are not recommended [63]. Dantrolene has been shown to be ineffective in reducing hospitalization rate in heat stroke [64], and although it may improve cooling rate, it did not alter mortality [65].

Therapy for Complications of Hyperthermia

Arrhythmias, metabolic acidosis, and cardiogenic failure complicate the early management of hyperthermic crises. Supraventricular tachyarrhythmias usually require no treatment because they respond to restoration of normal temperature and metabolism. Digitalis should be avoided owing to the likelihood of hyperkalemia.

Hypotension should be treated initially with normal saline and, if necessary, isoproterenol. Dopaminergic and α-agonists should be avoided because they tend to produce peripheral vasoconstriction. Volume expansion with dextran is contraindicated owing to its anticoagulating effect. Pulmonary artery and arterial catheter monitoring may be helpful in the management of hypotension because patients frequently have low peripheral resistance, dehydration, and impaired cardiac function and are at a high risk for congestive heart and renal failure. As 64% of patients may have a normal central venous pressure before resuscitation, volume expansion in most cases should be guided by intravascular pressure monitoring where available [66]. Seizures, quite common in heat stroke, usually respond to diazepam.

Blood gas status should be determined early in treatment. Blood gases drawn at temperatures above 39°C should be corrected for temperature, although to our knowledge no studies have demonstrated that this is clinically necessary. The solubility of oxygen and carbon dioxide increases as blood drawn from the patient is cooled to 37°C for analysis. This lowers the carbon dioxide and oxygen tensions and elevates the pH when compared with values present in the patient. Therefore, the patient is more acidotic and less hypoxic than the uncorrected values indicate. Normal values of intracellular pH and changes on the body's buffering system in hyperthermia have been poorly described. Because normal values for blood gases in hyperthermic patients are unavailable, by convention the blood gas values are corrected for temperature, using any reliable nomogram, and clinical decisions are made as if the patient were euthermic [67–69]. The following approximate corrections have been used: for each 1°C that the patient's temperature is above 37°C, the oxygen tension is increased by 7.2%, carbon dioxide (CO_2) tension increased by 4.4%, and pH is lowered by 0.015 units. More research is needed before definite

conclusions can be made. Nevertheless, 100% oxygen should be delivered until adequate oxygenation is ensured. Bicarbonate should be administered, guided by frequently obtained arterial blood gas values. The base deficit is frequently large, and up to 30 g of bicarbonate has been required for correction. Comatose patients should have prophylactic intubation to protect their airways from aspiration.

Urine output should be closely monitored with an indwelling bladder catheter. Patients should be routinely given 1 to 2 mg per kg of mannitol over 15 to 20 minutes to promote continued urine flow and possibly decrease cerebral edema. Continuous urine output should then be maintained with intermittent doses of furosemide. In all cases of hyperthermia, serum potassium levels should be closely followed. In cases of oliguria or potential renal failure, polystyrene sulfonate should be given early because hyperkalemia frequently increases.

Moderate-to-severe liver failure is common, may prolong illness, and, in combination with renal failure, may make administration of several drugs difficult or impossible. Although no clinical data are yet available, histamine receptor type 2 (H_2)–blocking drugs or proton pump inhibitors given prophylactically may decrease the incidence of GI tract bleeding.

The occurrence of DIC greatly affects mortality: Most patients who die of heat stroke have evidence of DIC [70]. Coagulation parameters such as prothrombin time, partial thromboplastin time, platelet count, and fibrinogen should be carefully followed. Should DIC occur, traditional recommendations for treatment should be followed (see Chapter 108).

The use of steroids and prophylactic antibiotics are not recommended [20,26]. Steroids are of no known benefit in heat stroke. Infection has not been reported as a major cause of morbidity and mortality in hyperthermia, and antibiotics are associated with superinfections.

Prognosis

Morbidity and mortality are directly related to the peak temperature reached and time spent at elevated temperatures. A delay in treatment of only 2 hours may result in the likelihood of death up to 70% [11,52]. When heat stroke is swiftly recognized and aggressively treated, mortality should be minimal. For example, in one series of 15 patients with exertional heat stroke, all were successfully treated with no mortality and little morbidity [11]. Another study predicts mortality of only 5% when heat stroke patients are managed properly [10]. A recent review of 34 elderly patients with classic heat stroke revealed 18% mortality. Seventy-three percent recovered without sequelae, and 9% had some residual neurologic deficit.

Although patients with temperatures as high as 46.5°C have survived without sequelae [71], mortality is increased with premorbid debility and higher maximal temperatures [44]. When ventricular fibrillation, DIC, coma lasting more than 6 to 8 hours, or high lactate levels complicate hyperthermia, mortality is predictably increased. A continued rise in growth hormone levels despite therapy has been reported to be associated with a worse prognosis [72].

With respect to morbidity, neurologic function usually rapidly returns to normal after restoration of euthermia; however, some patients may be left with a mild cerebellar disorder [73]. Hepatic and renal failure in mild and moderate cases is usually completely resolved. Moderate muscle weakness may persist for several months in patients with severe muscle damage.

Although it has not been proven, patients who have experienced hyperthermic crises should be considered at high risk to develop a recurrence on exposure to similar heat stresses and should be advised accordingly.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia is a drug- or stress-induced hypermetabolic syndrome characterized by vigorous muscle contractions, an abrupt increase in temperature, and subsequent cardiovascular collapse. Malignant hyperthermia occurs, on average, in 1 of every 50,000 to 150,000 adult patients given anesthesia [71,74]. With treatment, mortality is between 10% and 30% [75].

Cause and Pathogenesis

The cause of the temperature increase in malignant hyperthermia is similar to that of exertional heat stroke: Increased thermogenesis overwhelms the patient's ability to dissipate heat. When exposed to various drugs, muscles may develop sustained or repeated contractions (Table 66.3). Current evidence indicates that patients with malignant hyperthermia have a defect in calcium metabolism in skeletal muscle cell membranes [76–79]. In most cases, a defect in the ryanodine receptor (RYR1) results in release of calcium from the sarcoplasmic reticulum, resulting in muscle contraction and heat generation [80]. Heat production occurs due to sustained or repetitive muscular contractions with hydrolysis of adenosine triphosphate and the activation of catabolic pathways, hepatic and muscular glycogenolysis, and catecholamine-induced accelerated turnover of substrates and metabolism of lactate.

Although halothane and succinylcholine are involved in more than 80% of cases, malignant hyperthermia has developed after the use of many other agents as well (see Table 66.3). Stress, excitement, anoxia, viral infections, and lymphoma have also been reported to trigger malignant hyperthermia [81,82]. Some data suggest that conditions of ischemia or hypoxia are the common triggers to hyperthermia in susceptible individuals. It is generally assumed that the causes of heat stroke would also increase the likelihood of malignant hyperthermia in susceptible individuals (see Table 66.1).

TABLE 66.3

DRUGS AND MALIGNANT HYPERTHERMIA

Drugs known to trigger malignant hyperthermia
Halothane
Methoxyflurane
Enflurane
Succinylcholine
Decamethonium
Gallamine
Diethyl ether

Ethyl chloride
Trichloroethylene
Ketamine
Phencyclidine
Cyclopropane
Drugs generally considered safe for patients with malignant hyperthermia
Nitrous oxide
Barbiturates
Diazepam
Tubocurarine
Pancuronium, vecuronium
Opiates

The hyperthermic reaction to anesthetics is not allergic in nature; patients may have received the same anesthetic previously or may be exposed later without developing a reaction. There is little evidence that impaired heat dissipation or altered hypothalamic regulation is instrumental in producing acute hyperthermia in these patients. However, sympathetic activity and heat dissipation may be abnormal during exercise [83].

Pathophysiology

Direct thermal injury is the predominant cause of toxicity in malignant hyperthermia. Damage results from the metabolic consequences of a sudden increase in temperature to levels frequently above 42°C. Physiologic and pathologic changes parallel those described for patients with exertional heat stroke [84]. DIC, hepatic failure, seizures, ventricular dysrhythmias, and electrolyte abnormalities are more common and severe than in heat stroke.

Vigorous muscle contracture at the onset of malignant hyperthermia almost immediately precipitates a severe metabolic acidosis, with increased CO_2 production and compensatory hyperventilation. High elevations of creatine kinase, lactate dehydrogenase, and aldolase are present [65] and reflect ongoing rhabdomyolysis. Hyperkalemia follows within minutes to hours [76]. Renal failure frequently occurs in malignant hyperthermia, most likely secondary to pigment load. Dehydration and low cardiac output do not contribute until later. The degree of hypocalcemia, hypophosphatemia, and hyperkalemia varies with the duration and peak of hyperthermia and degree of secondary myonecrosis. All three are more severe in malignant hyperthermia than in heat stroke. Direct thermal injury producing cerebral edema and cerebral hemorrhage results in coma. Seizures occur in most uncontrolled cases. DIC is a nearly universal finding [85]. Initially, volume status is normal because little volume has been lost in sweat. Cardiac output increases to meet metabolic demands and in response to the vasodilation of muscle beds. Sinus tachycardia, supraventricular tachyarrhythmias, and ventricular fibrillation occur soon after temperature exceeds 40°C. Tissue hypoxia, acidosis, and hyperkalemia make ventricular arrhythmias common. Because higher maximal temperatures are usually seen in malignant hyperthermia, hepatic failure and GI tract bleeding are more prominent than in heat stroke [85]. In survivors, hepatic necrosis and cholestasis peak in 2 to 3 days and may be severe.

Diagnosis

The metabolic predisposition to malignant hyperthermia appears, in general, to be inherited in an autosomal dominant fashion, with variable penetrance and expressivity. Although multiple screening strategies have been attempted [76,86–89], tests using caffeine or halothane stimulation of excised muscle are the standard screening tests recommended by the Malignant Hyperthermia Association of the United States [90]. Their false-positive rate is near 10% and false-negative rate near zero [91]. Because there is no one noninvasive test suitable for screening the general population, screening of family members of proven cases remains the best method of identifying susceptible individuals before hyperthermic crisis occurs. RYR1 gene mutation analysis of cells from buccal samples may help identify high-risk individuals. Only 25% of those susceptible have an identified mutation. Although an identified mutation would suggest susceptibility, the absence of a mutation would not rule out susceptibility [92,93].

Although malignant hyperthermia may occur under any severe stress, it most commonly follows administration of an anesthetic agent. Malignant hyperthermia occurs at any age but is most frequent in young patients; the mean age is 22 years, 65% of patients are male, 21% have had previous uneventful anesthesia, and 76% have no family history of malignant hyperthermia [94,95]. Early signs of hyperthermic crisis vary with the anesthetic agent administered but include masseter muscle contracture after the administration of succinylcholine, muscle rigidity, sinus tachycardia, supraventricular tachyarrhythmias, mottling or cyanosis of the skin, increased CO_2 production, and hypertension. Hyperthermia is typically a late sign in an acute crisis, but it may be rapidly followed by hypotension, acidosis, peaked T-waves on the electrocardiogram owing to hyperkalemia, and malignant ventricular arrhythmias [85]. In one case report, desaturation measured by oximetry preceded temperature elevation by 40 minutes [96].

Two signs may be helpful in making a prehyperthermic diagnosis: increased end-tidal CO_2 and masseter spasm [97–103]. Monitoring of end-tidal CO_2 is recommended for all anesthetic procedures and is mandatory for patients at risk of malignant hyperthermia [91,94,95]. Severe masseter spasm after succinylcholine has been recognized as an early warning sign of malignant hyperthermia; however, the decision to discontinue anesthesia in patients with succinylcholine-induced spasm remains controversial [100–104]. If surgery must be continued, dangerous triggering anesthetics should be avoided, dantrolene should be given or at least be immediately accessible, and temperature and end-tidal CO_2 should be monitored online.

Differential Diagnosis

Because malignant hyperthermia occurs almost exclusively in the perioperative setting, the differential diagnosis is more limited than that for heat stroke (see Table 66.2) [104]. Endocrinopathies and drug reactions, not infection, are the most frequent diseases in the differential diagnosis. Thyroid storm and pheochromocytoma may be very difficult to distinguish from malignant hyperthermia in the anesthetized patient [105]. Thyroid storm is now infrequent, owing to ease and extent of preoperative thyroid function test screening and prophylaxis of patients at risk. Dantrolene in doses used for malignant hyperthermia has been shown to decrease temperature in perioperative thyroid storm [106]. The temperature rise in pheochromocytoma is typically much slower than that in malignant hyperthermia [107]. Hyperthermia, owing to narcotic administration in patients taking monoamine oxidase inhibitors, also must be considered.

Treatment

Dantrolene, a hydantoin derivative, acts by uncoupling the excitation–contraction mechanism in skeletal muscle and lowering myoplasmic calcium. This action is now known to take place directly at the RYR1 receptor [108]. Dantrolene used for less than 3 weeks rarely causes toxicity [109]. In an acute crisis, 1.0 to 2.5 mg per kg of fresh dantrolene should be administered intravenously every 5 to 10 minutes. Effects may be seen 2 to 3 minutes after injection. Although cases that required 42 mg per kg have been reported [110], most authorities advise not to exceed 10 mg per kg [75,76,110,111]. The half-life of action is approximately 5 hours [76], and because relapse may occur, oral or IV dosages of 1 mg per kg IV or 2 mg per kg by mouth every 6 hours should continue for at least 24 to 48 hours [76]. Oral dantrolene provides excellent blood levels and may be substituted once the patient is alert [112]. With dantrolene, temperatures often rapidly decrease; without it, they may increase 1°C to 2°C every 15 minutes [95,97,110]. The cost of dantrolene is currently approximately $35 per 20-mg IV dose vial. As the diluent for dantrolene contains mannitol,

urine output should be carefully monitored. Because even minute quantities of the triggering agent may continue to produce the syndrome, anesthesia should be immediately stopped, and the anesthesia apparatus, tubing, and ventilation equipment should be immediately changed.

Direct external cooling by submersion in ice water is helpful, but management of associated problems such as arrhythmia, arrest, and renal failure then becomes almost impossible. As with heat stroke, iced saline, gastric or peritoneal lavage, evaporative cooling, and infusion of chilled electrolyte solutions may be helpful. Aggressive management with cardiopulmonary bypass with external cooling of the blood may be necessary when dantrolene fails to slow down thermogenesis promptly [113]. When patients respond to therapy quickly, before severe temperature elevation occurs, only minimal supportive measures may be necessary. Once temperature exceeds 41°C, complications are widespread and patients frequently require long-term intensive care unit (ICU) support.

Ventricular fibrillation with subsequent cardiac collapse is the most common cause of death in the early stages of the syndrome. Procainamide should be given to all patients prophylactically as soon as malignant hyperthermia is diagnosed [76]. Procainamide acts to increase the uptake of calcium from the myoplasm directly and in early stages may help reduce hyperthermia. Administration of digitalis should be avoided because of the increased likelihood of hyperkalemia. Hypotension should be treated with saline infusion and isoproterenol. Avoid dopaminergic and α-agonists, as they reduce heat dissipation due to peripheral vasoconstriction. Seizures often occur in malignant hyperthermia. Prophylactic treatment with phenobarbital is strongly recommended because seizures may increase heat production, metabolic acidosis, and hypoxia. Arterial blood gas values should be adjusted for temperature, as noted for heat stroke. Mannitol and furosemide may be needed to promote continued urine output and may reduce the likelihood of cerebral edema and acute tubular necrosis. The serum potassium level increases over several hours and is treated with polystyrene sulfonates. Hepatic failure and DIC require supportive treatment. With prolonged supportive care, hepatic, renal, and neurologic functions typically normalize. Muscle weakness, however, may last for months.

Prognosis

With current management techniques, mortality resulting from malignant hyperthermia should be less than 30%. In one review, prompt dantrolene therapy in cases of confirmed malignant hyperthermia resulted in a 100% survival rate [25].

NEUROLEPTIC MALIGNANT SYNDROME

Neuroleptic malignant syndrome results primarily from an imbalance of central neurotransmitters, usually owing to neuroleptic drug use, and is characterized by hyperthermia, muscular rigidity, and altered consciousness. Most current knowledge is derived from case reports rather than systematic study. Since the syndrome was first described in 1968 [114], fewer than 3,000 cases have appeared in the world's literature, and most are from the 1980s and 1990s.

Retrospective studies estimated the incidence of neuroleptic malignant syndrome to be as high as 1% of all patients taking neuroleptic agents [115]. Prospective studies conducted in inpatient psychiatric hospitals have found incidences as low as 0% [116], 0.07% [117], 0.2% [118], and 0.9% [119]. The highest recent estimate of incidence was 2.2% [120]. Early estimates of mortality were as high as 30% [121]. Incidence also appears to be declining [122]. Mortality rate since 1986 has fallen to less than 12% [123]. Two prospective series reported 24 and 68 cases with mortality rates of 0% [124] and 5% [125], respectively.

The syndrome may be diagnosed in any patient with (a) an unexplained elevation in temperature, (b) muscular rigidity and characteristic extrapyramidal signs, and (c) a history of recent neuroleptic drug use. This liberal definition is more appropriate in the intensive care setting so that cases may not be underdiagnosed. A strict definition would require mental status changes and autonomic instability. Mental status changes, coma, and catatonia are common.

Cause and Pathogenesis

In all reports of neuroleptic malignant syndrome, patients received agents that decrease dopaminergic hypothalamic tone, or the syndrome appeared after withdrawal of dopaminergic agents (Table 66.4). Butyrophenones [126–140], phenothiazines [126,128,131,134,141,142], thioxanthenes [143–145], and dibenzoxazepines [146] are believed to act as dopamine receptor–blocking agents. Atypical antipsychotics, such as risperidone [147], molindone [148], clozapine [149], and fluoxetine [150], and dopamine blockers used to treat GI tract disease, such as metoclopramide and domperidone [151], have also caused the syndrome. The incidence of the syndrome with the newer atypical antipsychotics has not changed [152]. Drugs acting at the D_2 dopamine–binding sites appear to have the greatest potential for causing the syndrome. Most cases occur in patients taking butyrophenones or piperazines, agents with a high incidence of extrapyramidal reactions. The rate of increase in dose appears more important than the maximal

Metoclopramide

dose achieved [123]. Dopamine-depleting agents such as tetrabenazine and α-methyltyrosine produced neuroleptic malignant syndrome in a patient with Huntington's disease [121]. Abrupt withdrawal of levodopa (L-dopa), dopa-carbidopa, or amantadine produced the syndrome in patients suspected of having Parkinson's disease [153–155]. Initiation of metoclopramide therapy has produced the syndrome, presumably owing to alteration in central dopaminergic tone [156–158].

The increase in muscular rigidity, akinesia, mutism, and tremor are considered to be due to hypothalamic dopaminergic imbalance. Motor abnormalities vary, but in general, they are typical of the parkinsonian type extrapyramidal reactions. Unlike typical neuroleptic-induced side effects, however, the muscular effects are frequently seen at low therapeutic doses soon after treatment begins. The central origin of the muscle spasm is further suggested by its resolution with the use of centrally acting dopaminergic agents such as bromocriptine, amantadine, and L-dopa. A role for peripheral muscle abnormality, however, has been suggested, in that sarcoplasmic calcium concentration is higher in patients who have had the syndrome [125], hypocalcemia accompanies 54% of cases [124], the syndrome may resolve with nifedipine use [159], and the syndrome has been reported to be triggered by hypoparathyroidism [160].

Hyperthermia results from an increase in endogenous heat production, impaired heat dissipation, loss of voluntary temperature regulation, and possibly an elevation of the hypothalamic set point. The fact that the degree of temperature increase varies directly with the severity of rigidity evident on examination strongly suggests that muscle contracture is responsible for increased thermogenesis [126]. A decrease in muscle rigidity by uncoupling contraction with dantrolene or by paralysis with succinylcholine results in a decrease in temperature [161]. Impaired heat dissipation from the anticholinergic-induced hypohidrosis of neuroleptics may also occur. The high prevalence of diaphoresis and presumed dehydration in patients with neuroleptic malignant syndrome suggests, however, that this effect may be minimal. The most likely hypothesis is that regulatory reflexes remain intact, but muscle rigidity from hypothalamic influences and subsequent increased thermogenesis exceed dissipative capacity. In this sense, the syndrome is similar to malignant hyperthermia, in which regulatory mechanisms appear intact, but muscle contracture initiated at the level of the muscle, not the hypothalamus, overwhelms dissipative capacity.

Although the development of neuroleptic malignant syndrome is usually described as idiosyncratic, age, sex, and systemic factors appear to be important predisposing factors. The mean and median age at the onset of the syndrome is 40 years [162]. This is surprising because impairment in temperature regulation and the prevalence of parkinsonian side effects of neuroleptics both increase with age. Onset at an early age suggests that neuroleptic drugs are more frequently used in this age group or young persons are unusually sensitive to dopaminergic agents. Neuroleptic malignant syndrome develops 1.8 times more frequently in men than in women [162,163]. The larger muscle mass in men may predispose to the development of hyperthermia. There is, however, no difference in mean maximal temperature between men and women. A case control study has shown that environmental temperature does not affect the incidence of the neuroleptic malignant syndrome but several factors do: total neuroleptic dose, mental retardation, intramuscular administration of a neuroleptic, psychomotor agitation, or increasing dose or recent introduction of a neuroleptic drug [164].

Complications

Because of the relatively low maximal temperatures—39.9°C, on average [163]—in patients with neuroleptic malignant syndrome compared with those of patients with heat stroke and malignant hyperthermia, it is not surprising that direct thermal injury occurs less often. Only 40% of patients have temperatures above 40°C [165]. The complications of neuroleptic malignant syndrome are summarized in Table 66.5. Cardiovascular collapse, renal failure, and electrolyte abnormalities are less common and less severe than in classic heat stroke.

TABLE 66.5

COMPLICATIONS OF NEUROLEPTIC MALIGNANT SYNDROME

Rhabdomyolysis
Renal failure
Seizure
Cardiovascular collapse
Disseminated intravascular coagulation
Hepatic failure
Aspiration pneumonia
Respiratory failure
Death

Rhabdomyolysis, most probably secondary to hyperthermia and muscle rigidity, is frequently seen, with typical creatine kinase elevations in the range of 1,000 to 5,000 IU. Although rhabdomyolysis is usually mild, creatine kinase elevations to greater than 10,000 IU have been reported [145,166,167] and may occur in up to one third of patients [124]. Prolonged muscle weakness or dysfunction in survivors is not described.

Renal failure occurs in 9% to 30% of patients [124,162]. Proteinuria occurs in up to 91% of patients [124]. Renal failure is owing to myoglobin-induced acute tubular necrosis and the dehydration that results from diaphoresis. Renal dysfunction in most patients is transient and mild and, even in cases of acute tubular necrosis, may return to premorbid values after brief periods of dialysis support [129]. Mortality in renal failure patients, however, may be as high as 56% [123].

Neuroleptic malignant syndrome has been associated with worsening of underlying psychiatric conditions, amnesia, cognitive impairments, and peripheral neuropathy [168,169]. Coma is not uncommon in severe cases. Grand mal seizure has rarely been reported [129,144]. The electroencephalogram typically is normal or shows nonspecific diffuse slowing [124]. Computed tomography scans are normal in 95% of patients. Cerebrospinal fluid analysis after lumbar puncture is normal in 97% of patients, showing an elevated protein level in the other 3% [162,170]. In one case, a magnetic resonance imaging scan revealed hyperintensity of the occipitoparietal white matter [171]. Pathologic examinations of patients at autopsy revealed no specific lesions [154].

Although death from cardiovascular collapse has been reported [126], specific cardiac abnormalities have been poorly described. There is no evidence that severe atrophy, heart block, or congestive heart failure occurs frequently in the syndrome.

Hematologic alterations are mild. The white blood cell count is elevated in 78% of cases [124,162], usually less than 20,000 cells per mm^3, and rarely exceeding 25,000 cells per mm^3. Elevation may be due to hemoconcentration and catecholamine release. Platelet count is elevated in 56% of patients [124]. A hemolytic coagulopathy, possibly DIC, has been reported rarely [132]. Deep venous thrombosis or antemortem embolic phenomena are not reported in the English literature. Thrombotic events, when they do occur, may be a result of the patient's immobility due to coma and muscle rigidity rather than to any temperature-mediated change.

Lactate dehydrogenase, serum glutamic oxaloacetic acid transaminase, serum glutamic pyruvic transaminase, and

alkaline phosphatase frequently show mild elevations compatible with rhabdomyolysis and mild hepatic dysfunction. Other significant GI tract abnormalities have not been reported.

Pulmonary complications occur frequently but appear to be related not to hyperthermia but to the extrapyramidal actions of the neuroleptics. Muscle dysfunction produces frequent dysphagia [126]. Sialorrhea can be copious and necessitate intubation [140]. It is reported that several patients have clearly aspirated, presumably owing to muscle dysfunction, and subsequent pneumonias were most likely due to this aspiration. Pneumonia and respiratory distress [131,132,134,140,145, 153,161,163,166] requiring intubation occur in 13% to 21% of patients [124,162] and are probably the most serious frequent sequelae of the neuroleptic malignant syndrome.

Diagnosis

The neuroleptic malignant syndrome may occur after any one of the commonly prescribed neuroleptic agents is used and in any age group. Onset of symptoms may occur within hours after the initial neuroleptic treatment or up to 4 weeks later [162]. In the majority of cases, onset occurs within 1 week from initial neuroleptic drug use, and 88% occur within 2 weeks of a dosage increase of an already prescribed neuroleptic agent [162]. Most reported cases have occurred in patients with underlying neuropsychiatric disorders. Most cases have a slow progression of symptoms over at least 24 to 48 hours and last 2 weeks after stopping the inciting drug [171].

Early symptoms usually include dysphagia or dysarthria owing to diffuse muscular rigidity, pseudoparkinsonism, dystonia, or catatonic behavior. In one series, 96% of patients demonstrated rigidity, 92% of patients demonstrated tremor, and 96% of patients demonstrated muteness or hypophonia in the 48 hours before diagnosis [124]. Rigidity precedes hyperthermia in 59% of patients, is concurrent in 23%, and is subsequent in only 8%. Changes in mental status or rigidity are the presenting symptoms in 82% of patients [172]. Autonomic signs of hypermetabolism usually suggest the onset of hyperthermia. Diaphoresis, tachycardia, changes in blood pressure, and tachypnea reflect efforts to dissipate the thermogenesis of muscle contracture and to expel CO_2 effectively. Peak temperatures are reached within 48 hours after the onset of symptoms in 88% of patients [124]. Temperatures may reach as high as 42.2°C [132] but are typically lower: 53% are more than 40°C and 13% are higher than 41°C [124]. Because many patients may be tachypneic, rectal or core, rather than oral, temperatures may need to be followed to ensure accuracy (see Chapter 26). Elevations in creatine kinase and transaminase levels and leukocytosis parallel the body temperature. Creatine kinase level is elevated in 97% to 100% of patients, typically all MM isoenzyme, exceeds 10,000 IU in 33% of patients, and peaks 2 to 3 days after diagnosis in 64% of patients and by 1 week in 93% of patients [124,163].

Differential Diagnosis

A thorough examination and diagnostic evaluation for other causes of hyperthermia should be conducted (see Table 66.2). In one series, all patients referred to an ICU with a suspicion of neuroleptic malignant syndrome had another diagnosis that would explain fever [119]. Because many patients taking neuroleptic agents develop extrapyramidal side effects and relatively few cases of hyperthermia are a result of neuroleptic malignant syndrome, other more common causes of hyperthermia (e.g., meningitis or streptococcal pharyngitis) could easily be missed if a hasty diagnosis of neuroleptic malignant syndrome is made. Appropriate cultures, chest radiograph, lumbar puncture, and thorough physical examination are mandatory. Patients without classic symptoms are more likely to have another cause of hyperthermia [173].

Catatonia, heat stroke, malignant hyperthermia, and hyperthermic reactions to other drugs may occasionally be confused with the neuroleptic malignant syndrome. Acute lethal catatonia presents with psychotic excitement and automatisms for a few weeks before motor deficit. Thus, in lethal catatonia, hyperactivity and hyperthermia present before the administration of neuroleptics [174]. However, lethal catatonia with rigidity and fatal hyperthermia rarely occurs in patients not taking neuroleptic agents. The treatment and prognosis of these patients remain unclear [163,175,176]. If rigidity and hyperthermia subsequently develop in a catatonic patient, however, the development of neuroleptic malignant syndrome should be presumed and all neuroleptic agents should be stopped. If catatonia has been induced or exacerbated by neurolepsis, withdrawal of the neuroleptic drug should aid in clarifying the diagnosis.

Heat stroke must be considered when temperature elevation develops in a patient taking neuroleptics during periods of high ambient temperature or after vigorous exercise. Unlike neuroleptic malignant syndrome, however, heat stroke is usually accompanied by flaccid obtundation, and muscle rigidity is rare.

Malignant hyperthermia resembles neuroleptic malignant syndrome in that both conditions have increased thermogenesis secondary to muscular rigidity as well as similar laboratory findings, and both respond to dantrolene. In most cases, an adequate history should clearly separate the two syndromes; hyperthermia results from the use of entirely different agents (compare Tables 66.3 and 66.4). Moreover, the symptoms of malignant hyperthermia are much more rapid in onset and more severe. Extrapyramidal symptoms are also very unusual in malignant hyperthermia. In the rare circumstance in which the two syndromes cannot be distinguished, attempts at paralysis with curare or pancuronium may aid diagnosis. These agents produce a flaccid paralysis in neuroleptic malignant syndrome but should have no effect on the postsynaptically medicated muscle contracture of malignant hyperthermia.

Idiosyncratic drug reactions and anaphylaxis accompanying severe hyperthermia may usually be diagnosed by their distinct clinical presentations. Monoamine oxidase inhibitors may produce hyperthermia, especially when administered with meperidine, linezolid, or dextromethorphan [177–180]. In patients with neuropsychiatric disorders who are receiving neuroleptic agents and monoamine oxidase inhibitors, malignant hyperpyrexia may result from either agent. In these cases, both agents should be stopped. Therapies for neuroleptic malignant syndrome, such as bromocriptine or L-dopa, are, however, contraindicated in these patients because of their recent use of monoamine oxidase inhibitors.

Treatment

The goal of treatment for neuroleptic malignant syndrome is to reduce the temperature, reverse extrapyramidal side effects, and prevent sequelae such as renal failure and pneumonia.

Specific agents used to decrease thermogenesis by reducing muscle contracture include dantrolene, curare, pancuronium, amantadine, bromocriptine, and L-dopa (Table 66.6). One study, however, showed no difference between patients receiving active treatment and those receiving only supportive care [181]. The only other controlled study demonstrated a shortened duration of symptoms and more rapid reduction in temperature when methylprednisolone (1 g in 2 days) was administered to Parkinson's patients who developed the

Electroconvulsive therapy

syndrome after withdrawal of medications [182]. Dantrolene reduces thermogenesis by uncoupling muscle contracture at the membrane level and in doses as small as 1 mg per kg may result in a temperature decrease of 1°C to 2°C within hours [135,136,140,183]. Dantrolene may also favorably alter CNS dopaminergic metabolism [184]. Although doses of up to 10 mg per kg have been used, current practice would recommend doses of 1.0 to 2.5 mg per kg IV every 6 hours until a dose of 100 to 300 mg per day by mouth can be given [185,186]. Paralysis with curare or pancuronium should produce a similar prompt decrease in temperature, but this treatment necessitates mechanical ventilation and extensive support [161]. Bromocriptine, amantadine, and dopamine increase central dopaminergic tone; this decreases the central drive, reducing muscular rigidity and thermogenesis. These agents also are beneficial in that they act directly to reduce extrapyramidal side effects. Prompt decreases in temperature have been reported after the use of 2.5 mg of bromocriptine three times per day [134,138,167,187], 100 or 200 mg of amantadine twice per day [139,188], or 10 to 100 mg of carbidopa/L-dopa three times per day [127,155].

Failures of these therapies, however, have also been published [141,143,153,187]. The appropriate dosing remains an important question. Some authorities have advocated bromocriptine doses as high as 60 mg per day [185]. Use of a centrally acting dopamine agonist is clearly warranted when the neuroleptic malignant syndrome is believed to occur because of the withdrawal of anti-Parkinson's agents. The use of dantrolene, bromocriptine, and amantadine has yet to be shown to reduce mortality significantly [123]. Electroconvulsive therapy has been successful in several patients [131,132,189,190] and is the only therapeutic modality that may be used successfully to treat simultaneously hyperthermia, the extrapyramidal side effects, and the underlying neuropsychiatric disorder for which the neuroleptic drug was prescribed. Because of several reports of cardiovascular collapse in patients undergoing electroconvulsive therapy, this therapy should be given only to patients at low risk of cardiovascular disease who have failed other therapy.

Less-specific agents, such as diphenhydramine, benztropine, diazepam, and trihexyphenidyl, have been used successfully [127,130,134,137,139,146] but more typically have not been substantially helpful [121,134,140,141,161,187,188]. Little has been published on the use or efficacy of nonspecific measures, such as acetaminophen [191], cooling blankets, iced saline gastric lavage, and cooled peritoneal dialysis. The usefulness of these methods, however, would be restricted simply to lowering body temperature; they would not be expected to inhibit the underlying ongoing drive to thermogenesis or extrapyramidal reactions.

Reduction in core temperature and muscle rigidity should decrease the risk of renal failure and pneumonia. Decreases in temperature are accompanied by a decrease in creatine kinase levels [126]. By minimizing rhabdomyolysis and aggressive hydration and diuresis, acute tubular necrosis and renal failure might be avoided. Early reversal of coma, dysphagia, and sialorrhea when present should minimize the risk of aspiration and subsequent pneumonia. Prophylactic intubation should be strongly considered for patients with excessive sialorrhea, swallowing dysfunction, or coma. All obtunded patients or those with swallowing difficulty should take nothing by mouth.

The best treatment regimen for neuroleptic malignant syndrome remains to be determined [124,162,192–197]. Because many patients respond to symptomatic treatment after withdrawal of neuroleptic therapy [181], and because all current knowledge is derived from case reports, not clinical trials, treatment recommendations are difficult to make. The average time to recovery with supportive care only is 9.6 days [165]. Treatment should be guided by clinical judgment. Because of the frequency of coma, renal failure, respiratory insufficiency, and cardiovascular collapse, patients with temperatures greater than 39°C should be initially evaluated and observed in the ICU. Treatment and close observation should be continued for at least 1 week, longer when necessary. The duration of symptoms varies with the rate of excretion of neuroleptic metabolites. In patients receiving long-acting neuroleptic agents such as fluphenazine, symptoms may last for weeks. When therapy is withdrawn, symptoms may recur up to and after 11 days of drug abstinence [187]. Therefore, the duration of treatment must be adjusted according to the metabolism of the inciting agent, but in most cases, it can be tapered over 1 to 2 weeks. Acetaminophen and cooling of IV solutions during the acute period produce few side effects and may be beneficial. Bromocriptine therapy appears safe and effective in reducing temperature and minimizing extrapyramidal reactions. Dantrolene therapy does carry a risk of hepatotoxicity, but in patients with temperatures greater than 40°C, its use is specific and should be beneficial. Electroconvulsive therapy should be considered only for patients who do not respond properly to bromocriptine, dantrolene, and supportive therapy. More aggressive interventions, such as paralysis, use of cooled dialysate, or cardiopulmonary bypass cooling, should be reserved for refractory life-threatening cases.

Prognosis

Although mortality rates as high as 20% to 30% have been reported [115], this rate can probably be reduced to less than 10% with appropriate support and treatment. Age and sex do not appear to influence mortality greatly. Mortality rate does appear to be influenced by peak temperature, inciting neuroleptic drug, and renal failure. No death among patients with maximal temperatures lower than 40°C has been reported. Haloperidol is statistically less likely to result in death than other neuroleptics [123]. Death has been reported as a result of cardiovascular collapse [126], pneumonia [131,161], renal failure [129,145], and hepatic failure [145]. More than 57 cases of acute renal failure due to neuroleptic malignant syndrome have been reported [198]. The development of renal failure is particularly ominous; in some series, 46% of patients with myoglobinuria and 56% of those with renal failure died [123].

Typically, ICU stay is prolonged owing to the frequency of complications and slow response to therapy. Although dopaminergic therapy lowers the mean time to response from 6.8 to 1.1 days [199], the mean time to recovery is long—13 days when the syndrome results from nondepot neuroleptics and 26 days for depot neuroleptics [162]. One patient receiving haloperidol decanoate was symptomatic for months [200]. Rechallenge with neuroleptics may cause the syndrome to recur, but this occurs much more frequently during the first 2 weeks [201,202]. The prognosis among survivors appears to be excellent, and sequelae other than mild extrapyramidal

symptoms compatible with prior neuroleptic treatment appear unusual [203].

DRUG-INDUCED HYPERTHERMIA

Most of our knowledge about drug-induced hyperthermia is derived from case reports. Numerous drugs have been suggested to cause hyperthermia. Drugs that blunt cardiovascular performance, such as beta-blockers, or alter heat dissipation, such as chlorpromazine, are widely used and clearly can contribute to temperature elevation. These drugs rarely result in clinically significant hyperthermia without some other precipitant. Patients on regimens of such agents typically present with heat stroke. This section focuses on drugs that independently produce significant elevations of temperature (Table 66.7).

Commonly abused street drugs may result in severe hyperthermia without other pharmacologic or environmental stimuli. Temperature elevation accompanies phencyclidine use in 2.6% of cases [204]. Temperatures as high as 41.9°C have been reported [205]. Amphetamine use may result in temperatures higher than 43°C [205,206]. Although ecstasy (MDMA, 3,4-methylenedioxymethamphetamine) has resulted in fatal hyperthermia, use is usually associated with a more mild temperature elevation [207]. Hyperthermia (temperatures greater than 37.5°C) was more prevalent (36%) in patients admitted to emergency departments due to overdose of paramethoxyamphetamine than MDMA [208]. Although all these drugs have a low incidence of producing severe hyperthermia, owing to the prevalence of their use, they may account for a large percentage of cases of hyperthermia presenting to an emergency room.

Common prescription drugs that alter central serotonin levels and lysergic acid diethylamine, a serotonin analog, may result in hyperthermia greater than 41°C [209]. These drugs may produce a characteristic constellation of symptoms now known as the *serotonin syndrome* [209–214]. Monoamine oxidase inhibitors and selective serotonin reuptake inhibitors may produce hyperthermia, especially when administered with meperidine or dextromethorphan [177–179], a tricyclic antidepressant [177,215], or each other. Severe hyperthermia is rare. Increasingly combinations of drugs, which independently would not cause serotonin toxicity, act in concert to result in hyperthermia and the serotonin syndrome [216]. For example, a postoperative patient who receives linezolid, a weak monoamine oxidase inhibitor, and tramadol, a weak serotonin reuptake inhibitor, may present with fever, confusion, and clonus. Tramadol, meperidine, fentanyl, dextromethorphan, dextropropoxyphene, pentazocine, brompheniramine, chlorpheniramine, and linezolid in combination with other drugs may cause fever and the serotonin syndrome [180]. In addition, abrupt withdrawal of baclofen, especially after intrathecal administration, has resulted in severe sequelae including hyperpyrexia and potential multiorgan failure and death [180].

Aspirin receives mention as a cause of hyperthermia secondary to increased metabolism, but few hard data are available [217].

TABLE 66.7

DRUGS THAT MAY CAUSE HYPERTHERMIA AND/OR SEROTONIN SYNDROME

Monoamine oxidase inhibitors	
Phenelzine = Nardil	
Tranylcypromine = Parnate	
Linezolid	
Serotonin releasers	
Amphetamines	
Ecstasy (MDMA, 3,4-methylenedioxymethamphetamine)	
LSD	
Serotonin reuptake inhibitors SRI:	
Citalopram = Celexa	
	Fluoxetine = Prozac
	Fluvoxamine = Luvox
	Paroxetine = Paxil
	Sertraline = Zoloft
Tricyclics:	Clomipramine = Anafranil
	Imipramine = Tofranil
	Venlafaxine = Effexor
Analgesics:	Tramadol
	Methadone
	Dextromethorphan
	Dextropropoxyphene
	Pentazocine
	Chlorpheniramine
Antihistamines:	Brompheniramine
Other	Withdrawal of baclofen

Pathogenesis

These drugs are assumed to cause hyperthermia as a result of muscular contracture or hypermetabolism. Virtually all cases of drug-induced hyperthermia mention increased muscle tone, rigidity, or tremor. Cocaine, amphetamine, phencyclidine, and hallucinogens appear to produce hyperthermia by centrally and perhaps peripherally inducing vigorous muscle contractions [218,219]. Repeated cocaine use may elevate temperature by depletion of postsynaptic dopamine [218].

Many drugs such as tricyclics, amphetamines (paramethoxyamphetamine, MDMA), monoamine oxidase inhibitors, and the serotonin reuptake inhibitors may elevate CNS serotonin, resulting in hyperthermia [177,179,219–221]. Buspirone, serotonin agonists, lithium, and carbamazepine stimulate postsynaptic serotonin receptors. Monoamine oxidase inhibitors increase serotonin release and inhibit serotonin metabolism [222]. Selective serotonin reuptake inhibitors, dextromethorphan, and meperidine are believed to inhibit serotonin reuptake and, in susceptible patients, may increase already high serotonin levels and trigger a hyperthermic crisis [200]. In many patients, combination drug therapy contributes to triggering the syndrome. In general, a 2-week, drug-free period after stopping a monoamine oxidase inhibitor before starting a selective serotonin reuptake inhibitor is indicated. Any opiate may trigger the syndrome when another drug already predisposes the patient.

Some patients may have a component of exertional heat stroke, in that they are frequently found running in an agitated or confused manner. Almost all suffer from some loss of voluntary control of temperature. Status epilepticus frequently accompanies drug-induced hyperthermia but is unlikely to contribute greatly to hyperthermia, in that status epilepticus is rarely associated with significant temperature elevation in the absence of drug use [223]. Reactions appear mostly idiosyncratic; they are infrequent in comparison with the total number of persons using the drug; occur by IV, enteral, and nasal insufflation usage; and occur after low-dose use and massive overdose [224].

Pathophysiology

The pathophysiology of drug-induced hyperthermia is most similar to that of exertional heat stroke or malignant

hyperthermia. In the serotonin syndrome, direct stimulation of the 5-HT1A and 5-HT2 receptors in the raphe nuclei may directly result in hyperthermia. Rise in temperature is frequently rapid, and multiple organ failure may rapidly ensue with prolonged elevation of temperature. Patients, however, may also be affected by the direct toxic action of the drug, and it may be difficult to separate the sequelae of hyperthermia from those of direct drug toxicity. Amphetamine overdose, for example, may result in severe rhabdomyolysis, DIC, and renal failure at temperatures of less than 40°C. Hyperthermia can be assumed to have the same physiologic sequelae in these patients as others, but prompt correction of temperature may not be adequate to ensure survival.

Diagnosis

In most case reports, patients are described as agitated, hyperexcited, and diaphoretic and have increased muscle tone. Because nonexertional heat stroke is uncommon in youth, hyperthermia at a young age always suggests possible drug intoxication. The diagnosis of drug-induced hyperthermia should be considered mostly when the patient is young, is an outpatient, has not engaged in recent heavy exertion, has a history of drug abuse, or is on a drug or combination of drugs that may result in the serotonin syndrome.

Patients with the serotonin syndrome typically display tremor, hyperreflexia, myoclonus, tachycardia, diarrhea, confusion, and diaphoresis [210–214]. Serotonin syndrome should be suspected and treated whenever patients have spontaneous clonus and are on a serotonergic agent. Nausea and diarrhea are atypical of the neuroleptic malignant syndrome and may help suggest the serotonin syndrome in complicated cases [225]. The onset of symptoms is within 2 hours of medication ingestion in 50% of cases and within 24 hours in 75% of cases [222]. Myoclonus or rigidity is present in 50% of cases, and mental status changes in 40% of cases. Severe hyperthermia occurs in approximately one third of cases [211]. Diagnosis may be confirmed by toxicologic screen or history.

Treatment

In all cases, treatment should be directed at minimizing the toxicity of the causative drug. Suspected offending drugs should be discontinued. Treatment of hyperthermia should be symptomatic and directed at the underlying physiology. Treatment in general parallels that for exertional heat stroke and is extensively outlined in that section. Evaporative cooling and external cooling with ice are the preferred methods of cooling and should be instituted in any patient with a temperature above 39°C. Many patients may be dehydrated from diaphoresis and require volume replacement. As in malignant hyperthermia and exertional heat stroke, hyperkalemia, acidosis, and myoglobinuria demand careful attention. Because the temperature appears to be generated from muscular contraction, paralysis or use of dantrolene would appear to be useful therapy. Paralysis has been effective in several cases. Paralysis and support with mechanical ventilation should be considered in any patient with a temperature above 40°C not responding promptly to symptomatic cooling. If therapeutic drug levels persist, rebound hyperthermia may occur as paralysis resolves.

When the serotonin syndrome is suspected, therapy with benzodiazepines, propranolol, 50 mg chlorpromazine, cyproheptadine, or postsynaptic serotonin blockers such as methysergide has been advocated, but clinical experience is minimal [218–220,226]. No study to date reports a systematic trial of therapy. As hyperthermia may be mediated by central serotonin receptors, doses of cyproheptadine high enough to block central receptors, 20 to 50 mg, should be considered [227]. One regimen advises 12 mg by mouth or nasogastric tube then 4 to 8 mg every 4 to 6 hours [216].

Prognosis

Hyperthermia owing to amphetamine overdose appears to be well tolerated, with 10 of 11 patients reported in the literature surviving [205,206,228,229]. Hyperthermia in cocaine overdose is frequently accompanied by renal failure [224,230,231], DIC [231,232], and seizure [231,232] and several fatalities [224,231–233] have been reported. Survival despite high temperature has been recorded as well [224,230,234]. Phencyclidine with hyperthermia has resulted in renal failure [235], respiratory and liver failure with coma, and subsequent death [236].

Death and serious morbidity due to the serotonin syndrome appear to be rare [208]. No large series involving significant hyperthermia have been reported, and death and cure with

TABLE 66.8

DISTINGUISHING CHARACTERISTICS OF THE HYPERTHERMIC SYNDROMES

	Heat stroke	Malignant hyperthermia	Neuroleptic malignant syndrome	Acute lethal catatonia	Serotonin syndrome
Inciting factor	Ambient temperature: max >32°C, min >27°C	Triggering anesthetic	Triggering neuroleptic or withdrawal of dopaminergic agent	Excitement and automatisms prior to neuroleptic use	Serotonin active drug(s)
Time to fever	Hours to days	Minutes	Hours to days	Weeks	Minutes to hours
Mental status	Obtunded	Anesthetized	Mute, stuporous	Excited transitioning to catatonia	Confused, agitated
Muscle tone	Flaccid	Rigid, spasm	Extrapyramidal rigid	Variable	Clonus, hyperreflexia, tremor, pyramidal rigidity
Temperature	>40°C	>40°C	>40°C in 40%		>40°C only when late in syndrome

max, maximum; min, minimum.

TABLE 66.9

ADVANCES IN MANAGEMENT OF HYPERTHERMIA BASED ON RANDOMIZED CONTROLLED TRIALS

- No randomized clinical trials have been conducted comparing the effectiveness of different cooling methods for any hyperthermic syndrome [237].
- Dantrolene sodium is ineffective in heat stroke [64]. Dantrolene did not alter survival in heat stroke [65].
- There are no other randomized studies involving the treatment of heat stroke or malignant hyperthermia or drug-induced hyperthermia.
- In neuroleptic malignant syndrome, treatment with dantrolene and bromocriptine may offer no advantage over supportive care [176].
- Solu-Medrol may benefit patients with neuroleptic malignant syndrome due to withdrawal from Parkinson's medications [182].

appropriate treatment have been reported [179]. As severe hyperthermia would likely signify a much more severe case than usual, the physician should always consider the patient at risk of death and ICU level care would always be warranted.

Table 66.8 compares the distinguishing characteristics of the hyperthermic syndromes. Advances in hyperthermia based on randomized, controlled trials or meta-analyses of such trials are given in Table 66.9.

HYPERTHERMIA AND FEVER CONTROL IN BRAIN INJURY

Fever in the neurocritical care is frequent and often results in an adverse outcome for all disease states. Morbidity and mortality is increased among patients who have ischemic brain injury, intracerebral hemorrhage, and cardiac arrest. Fever appears to have a longer impact after subarachnoid hemorrhage and traumatic brain injury. New techniques (see hypothermia chapter 65) have made treatment of fever and maintaining normothermia possible. There are, however, no prospective randomized trials to prove benefit of fever control in these patient populations. In addition, the indication and timing remain unknown. Prospective randomized controlled trials are needed to determine the beneficial impact of secondary injury prevention compared with the potential risks of prolonged fever control [238].

CHAPTER 67 ■ SEVERE UPPER AIRWAY INFECTIONS

STEPHEN J. KRINZMAN, SUNIL RAJAN AND RICHARD S. IRWIN

The components of the upper airway include the nose, mouth, nasopharynx, oropharynx, and hypopharynx. It communicates with the paranasal sinuses and tympanic cavity. Although minor infections in these areas are commonly observed in the outpatient setting, occasionally, they may become severe and life threatening. This class of disease requires intense observation and aggressive management and is the focus of this chapter.

SINUSITIS

In patients on mechanical ventilatory support, sinusitis is one of four common causes of fever, along with pneumonia, catheter-related infection, and urinary tract infection [1–4]. Sinusitis is encountered in the intensive care unit (ICU) in two situations: as an uncommon, potentially fatal complication of a community-acquired sinus infection such as meningitis, osteomyelitis, orbital infection, or brain abscess and as a hospital-acquired sinus infection that may be a frequent cause of occult fever in a critically ill patient.

Incidence

The frequency of nosocomial sinusitis varies greatly from less than 5% to 100% [5,6], depending on the patient population studied and the diagnostic criteria used. In one series, 95% of nasotracheally intubated patients developed radiographic evidence of pansinusitis [7], as did 25% of patients who were orotracheally intubated. Only 40% of patients with "radiographic

sinusitis" were found to have positive cultures, although some cultures may have been sterilized by prior use of broad-spectrum antibiotics. Using stringent diagnostic criteria based on antroscopy, histopathology, and microbiology, the rate of infectious sinusitis may be closer to 10% in patients on long-term mechanical ventilation [4,5].

Pathogenesis

Critically ill patients are predisposed to develop nosocomial sinusitis for several reasons. The diameter of the ostia, normally as small as 1 or 2 mm, has been shown to decrease with recumbency as much as 23% because of venous hydrostatic pressures [8]. In addition, the maxillary sinus ostia are poorly located for gravitational drainage [8]. Nasotracheal and nasogastric tubes strongly predispose patients to develop sinusitis. Patients with orotracheal tubes have a lower incidence of bacterial sinusitis than those with nasotracheal tubes [4,9]. In one series, 73% of mechanically ventilated patients developed culture-proven sinusitis within 7 days of placement of nasogastric or nasotracheal tubes [7]. Larger intranasal tubes (tracheal) will induce radiographic sinus changes more quickly than smaller tubes (gastric) [4]. Using multiple logistic regression analysis, risk factors for nosocomial sinusitis, of strongest association, are sedative use, nasogastric feeding tubes, Glasgow coma scale less than 8, and nasal colonization with enteric Gram-negative bacteria [10].

Etiology

The microbiology of nosocomial sinusitis is quite distinct from that of community-acquired sinusitis. *Haemophilus influenzae* and *Streptococcus pneumoniae* are rarely isolated in the nosocomial setting. Nosocomial sinusitis is polymicrobial in 44% to 58% of cases [11,12], with Gram-negative organisms being the causative agents in two thirds of cases, and Gram-positive organisms being implicated in one third [13]. Anaerobes are isolated in 0% to 15% of cases [11,14]. *Staphylococcus aureus* is the most common Gram-positive organism identified, and *Pseudomonas* species are the leading Gram-negative pathogens [4,13,15]. The organisms isolated in nosocomial sinusitis are the ones frequently identical to those cultured from the lower respiratory tract [3,14]. Such findings support the concept of general colonization of the airways in critically ill patients.

Specific situations warrant consideration of infection with more unusual pathogens. Rhinocerebral mucormycosis, an invasive infection usually caused by the branching fungus *Rhizopus*, a Zygomycetes, is seen most often in association with diabetes mellitus with ketoacidosis, burns, chronic renal disease, cirrhosis, and immunosuppression [16,17]. Other fungal infections, primarily with *Aspergillus* species, can be seen in normal hosts but are usually invasive diseases of immunocompromised patients [18]. *Cryptococcus neoformans* can cause sinusitis with a high relapse rate and significant mortality in immunocompetent and immunocompromised patients [19]. *Candida* species [20], *Pseudoallescheria boydii* and *Cytomegalovirus* species, and other unusual organisms have been isolated in patients with acquired immunodeficiency syndrome with sinusitis [21].

Complications

Complications of acute sinusitis are rare but can be rapidly fatal and are best managed in an ICU. Orbital complications include edema, predominantly of the eyelids, orbital cellulitis, orbital abscess, subperiosteal abscess, and cavernous sinus thrombosis [22,23]. The last one is the most severe, with a mortality of greater than 20% [24–26]. Intracranial complications have an overall mortality of 40% and include osteomyelitis, meningitis, epidural abscess, subdural empyema, and brain abscess [24–26]. In these cases, sinus drainage is imperative and antibiotics directed by culture result. Several investigators have examined the relationship between nosocomial sinusitis and ventilator-associated pneumonia. When *S. aureus* and *Pseudomonas aeruginosa* are isolated in patients with nosocomial sinusitis, the same organisms are identified in lower respiratory tract cultures in one third of cases [12]. Ventilator-associated pneumonia is more frequent in patients with confirmed nosocomial sinusitis [7]. In a prospective, randomized study of a strategy to systematically detect and treat nosocomial sinusitis, both radiographic evidence and bacteriologic evidence of sinusitis were found in 55% of febrile, mechanically ventilated patients [11]. All patients in the study were nasotracheally intubated. Seventy percent of patients with positive radiographs had positive quantitative cultures. Ventilator-associated pneumonia occurred in significantly fewer patients (34% vs. 47%, $p = 0.02$) in the group in which there was systematic screening for and treatment of sinusitis. Taken together, these findings suggest a causal relationship between nosocomial sinusitis and ventilator-associated pneumonia.

Nosocomial sinusitis may also cause fever of unknown origin (FUO) in mechanically ventilated patients. van Zanten and colleagues prospectively studied 351 orotracheally intubated patients with fever for more than 48 hours despite treatment with broad-spectrum antibiotics [3]. In 198 patients, the cause of the fever remained unknown despite initial investigations that included chest radiographs. Based on the results of sinus radiographs and subsequent sinus cultures, infectious sinusitis was confirmed in 105 of 198 (53%) patients with FUO and was found to be the sole cause of fever in 16% of cases.

Diagnosis

Computed Tomography Scans and Radiographs

Computed tomography (CT) scanning has become the imaging modality of choice for the diagnosis of nosocomial sinusitis. Compared with plan sinus radiographs, sinus CT scans can more accurately visualize the ethmoid and sphenoid sinuses and are also superior in differentiating mucosal thickening from air–fluid levels [27]. Portable sinus radiographs performed in the supine position have been recommended to identify sinus infections in critically ill patients who cannot travel for standard sinus films or a CT scan [28]. As discussed earlier, patients may have sterile cultures despite radiographic evidence of sinusitis.

Ultrasonography

With the increasing use of ultrasound in the ICU, there has been a renewed interest in this modality to diagnose nosocomial sinusitis. Although bone often presents obstacles to ultrasound imaging, the anterior walls of the maxillary sinuses are flat bones composed of compact tissue, allowing adequate ultrasound penetration. Prior investigations had demonstrated that ultrasound was 67% sensitive and 87% specific for maxillary sinusitis visualized on CT scans [29]. Accuracy is improved when the patient is in the semi-recumbent position, and not supine [30].

More recent investigations have shown further improvements in diagnostic accuracy. Vargas and coworkers used B-mode ultrasound in the semi-recumbent position in

120 patients with suspected sinusitis [30]. They found that in 36 patients with negative sinus ultrasounds, none had evidence of maxillary sinusitis on CT scan. Extensive maxillary sinus disease is indicated by hyperechogenic visualization of the posterior wall and extension to the internal and and external walls was, in one investigation, found to be 100% specific for total opacification of the sinus on CT scan [31]. On transnasal puncture, fluid could be aspirated from all such patients, and the cultures were positive in 67% of patients [30]. In patients where only the posterior wall of the maxillary sinus is hyperechogenic, 80% of transnasal punctures yield fluid, and cultures are positive in half of those where fluid is obtained.

Rhinoscopy and Antral Aspiration

As reviewed earlier, opacification of the paranasal sinuses in the critically ill patient does not necessarily indicate infectious sinusitis; in some series, a majority of such patients have sterile cultures. Endoscopically obtained cultures from the middle meatus do not correlate with the cultures from the antral lavage aspirate in the febrile ICU patient [32]. Rhinoscopy can add significantly to the diagnostic yield in patients with suspected sinusitis. In patients with both purulent secretions in the middle meatus by rhinoscopy and radiographic evidence of sinusitis, 92% have positive cultures by antral lavage. Although cultures obtained from the maxillary sinus by antral puncture have been considered the gold standard for diagnosis of nosocomial sinusitis, the high correlation between culture findings from the sinuses and those obtained from endotracheal specimens [14] suggests that performing antral puncture to obtain sinus secretions for culture may not be necessary in most cases.

Treatment

Nosocomial sinusitis is most often related to the presence of nasopharyngeal and oropharyngeal catheters and tubes [4,12,33]. Therefore, in addition to antibiotics and decongestants, treatment includes removal of all nasal tubes to eliminate the source of obstruction and irritation in addition to decongestants and antibiotics. Because the spectrum of bacteria causing nosocomial sinusitis is similar to that causing other nosocomial respiratory infections [4,13,15], broad-spectrum Gram-positive and Gram-negative coverage is indicated. With removal of nasal tubes and antibiotic therapy, 67% of patients become afebrile within 48 hours [34]. Because the majority of patients respond to these conservative measures, consideration of surgical drainage can be reserved for patients who fail to respond to medical therapy and in whom no other source of infection is identified.

SPHENOID SINUSITIS

Sphenoid sinusitis deserves separate mention because of its potentially fulminant nature and difficulty in diagnosis. Delay in its diagnosis has been associated with serious morbidity and mortality [35,36]. The typical presentation of acute infection is severe headache that interferes with sleep, often accompanied by fever and nasal discharge [35,36]. Neurologic deficits can be prominent features; trigeminal hyperesthesia or hypoesthesia occurs in one third of cases [36]. Gram-positive organisms have been isolated from the cultures of most patients with acute sinusitis, whereas equal numbers of Gram-positive and facultative Gram-negative pathogens have been cultured from those with chronic sphenoid sinusitis [35,36]. Serious sequelae including permanent neurologic deficits and death can result from the spread to nearby structures (e.g., cavernous sinus, pituitary gland, optic chiasm). When findings suggest extension of the infection, early CT scan of the sinuses is essential. Surgical drainage may be necessary if symptoms persist or neurologic signs develop while the patient is receiving appropriate antibiotic therapy.

OTOGENIC INFECTIONS

Serious complications of otologic infection occur rarely [37,38]. Anatomically, the external auditory canal is one-half cartilaginous, and the medial half tunnels through the temporal bone. The auditory tube (pharyngotympanic tube) passes into the nasopharynx along the superior border of the lateral pharyngeal space (LPS). Other structures that are accessible by infection include the mastoid air cells, the jugular foramen, cranial nerves (especially the facial nerve), the internal carotid artery, and the dura mater of the posterior cranial fossa.

Mastoiditis

Acute mastoiditis is an uncommon complication of otitis media, seen primarily in children and young adults. Inflammation spreads from the middle ear to the modified respiratory mucosa lining of the mastoid air cells. The closed space infection leads to accumulation of purulent exudate, increased pressure, and bony necrosis. Pain, typically postauricular, fever, and abnormal tympanic membranes are the most common findings on presentation [39]. In approximately 50% of patients with mastoiditis, acute otitis media was diagnosed within days to weeks of admission [40]. Radiographic abnormalities of the mastoid are common and demonstrate opacification or cloudiness of the mastoid air cells and, less frequently, evidence of bone destruction [40]. CT scan of the temporal bone can identify and confirm intracranial complications [40]. Up to 25% of patients have complications on presentation, including subperiosteal abscess with or without epidural abscess, meningitis, cranial nerve involvement, and sigmoid sinus thrombophlebitis [41]. Lateral sinus thrombosis secondary to mastoiditis [42] has also been associated with septic pulmonary emboli [43,44]. The most common bacterial organisms isolated include *S. pneumoniae*, group A streptococci, and *S. aureus; Pseudomonas* may be commonly isolated as well [39]. Treatment includes broad-spectrum antibiotics that can adequately penetrate cerebrospinal fluid and surgical intervention for those who fail to improve within 24 to 72 hours.

Chronic mastoiditis and chronic otitis media result from a progressive inflammatory process that usually leads to obstruction of the communication between the middle ear and mastoid (aditus) or the middle ear and nasopharynx (eustachian tube) [39]. Often a cholesteatoma or epidermal inclusion cyst within the tympanomastoid compartment may be involved and may become secondarily infected [39]. Presenting symptoms include hearing loss, painless otorrhea, and tympanic membrane perforation [39]. Other symptoms (e.g., facial nerve paresis, headache, ear pain, fever) may be present if complications have occurred. Uncomplicated chronic otitis media and mastoiditis are treated medically with local hygiene, topical antibiotics often including a corticosteroid, and oral, or infrequently parenteral, antibiotics [39]. Broad-spectrum antibiotics are required to cover a wide range of aerobic and anaerobic organisms. Surgery is usually reserved for recurrent disease, often associated with a cholesteatoma, which can be identified by CT scan of the temporal bone [39].

Malignant External Otitis

Malignant, or necrotizing, external otitis (MEO) most often affects elderly diabetic patients. Diabetic microangiopathy, an altered immune response, the biochemistry of diabetic cerumen, and characteristics of the usual etiologic organism have been implicated in the pathogenesis of MEO [45]. MEO most commonly presents with otalgia; granulation tissue in the external auditory canal, most prominently at the osteocartilaginous junction; and often purulent and fetid otorrhea [45]. Spread of infection is anteriorly toward the parotid compartment or downward into the temporal bone; spread to the mastoid is less common [37]. Extension leads to pain and tenderness of the tissues around the ear. In MEO, *P. aeruginosa* is the most commonly implicated pathogen [45]. Patients with acquired immunodeficiency syndrome may develop infection from a wider variety of organisms and may accumulate less granulation tissue in the external auditory canal [46]. *Aspergillus* species have been identified, primarily in immunocompromised patients [47,48]. Osteomyelitis [49], cranial nerve paralysis [50], and central nervous system (meningitis) and vascular (thrombophlebitis) spread [51] are potential severe and fatal complications of MEO.

CT and magnetic resonance imaging scanning, along with technetium-99 bone scans, are valuable components of the diagnostic evaluation of MEO [51]. The therapy for MEO includes prolonged antibiotics directed against *P. aeruginosa* unless the culture data suggest otherwise. This may include a semisynthetic penicillin or ceftazidime with an aminoglycoside. Oral fluoroquinolones have also been used successfully [51]. The duration of treatment is not clearly defined. Surgical intervention can be complementary and is based on the response to conservative treatment and the presence of complications.

SUPRAGLOTTITIS (EPIGLOTTITIS)

Acute supraglottitis is an uncommon infection of the structures located above the glottis. These structures include the epiglottis, aryepiglottic folds, arytenoids, pharynx, uvula, and tongue base. The true vocal cords are rarely involved. The infection may progress to abrupt and fatal airway obstruction. This entity is well described in children, in whom the presentation and course are usually fulminant. In the pediatric population, increased awareness and prophylactic airway control have reduced overall mortality to less than 1% [52,53]. In children, *H. influenzae* type B is the most identifiable causative organism. Since the introduction of a vaccine against *H. influenzae* type B in 1995, the incidence of pediatric epiglottitis has decreased substantially [54–56]. As a result, it appears supraglottitis is becoming a disease of adults, in whom the course is frequently indolent but with a mortality rate that may reach 5%, mostly because of misdiagnosis and unexpected airway obstruction [52,56–59].

Incidence

In the post–*H. influenzae* type B vaccine era, the annual incidence of acute supraglottitis is estimated between 0.6 and 0.78 cases per 100,000 immunized children [58]. In adults, the incidence of acute supraglottitis has increased from 0.79 cases per 100,000 adults in 1986 to 2.1 cases per 100,000 adults in 2005 [58]. Adults with acute supraglottitis usually present in their 40s and 50s, with a male preponderance, and children usually present between the ages of 2 and 5 years [58].

TABLE 67.1

ORGANISMS IMPLICATED IN ACUTE EPIGLOTTITIS

Organism	References
Haemophilus influenzae	[3,5,15,17]

Herpes simplex virus type 1[b]	[34,35]

[a] Cultured from epiglottic swab or seen on autopsy; all others recovered from blood.
[b] Epiglottis biopsy specimen histology and viral culture.

Pathogenesis and Pathophysiology

In children, the inflammation is mainly restricted to the epiglottis because of loose mucosa on its lingual aspect. This provides a readily available space for edema to collect within. Swelling reduces the airway aperture by curling the epiglottis posteriorly and inferiorly, accentuating the juvenile omega shape. When edema spreads to involve the aryepiglottic folds, respiratory distress can occur as inspiration draws these structures downward, further exacerbating the obstruction and resulting in stridor. The adult airway is relatively protected because the larynx is larger and the epiglottis is shaped more like a spatula.

Etiology

Although various bacteria, viruses, and *Candida* species have been recognized as causes of acute supraglottitis (Table 67.1) [60–68], *H. influenzae* type B is the most common cause identified in pediatric and adult cases [60,68]. Although vaccine failure has been reported in children who had received an early polysaccharide vaccine [61], significant declines in the incidence of this infection have been noted with the use of conjugated vaccines that can be administered to even younger children [60]. In adults, blood cultures are positive in less than 20% of cases, and *H. influenzae* is the isolate in one third of these cases [62,68].

Noninfectious causes of acute supraglottitis have been described and include thermal injuries related to inhalation drug use, ingestion of hot food, apparent caustic injury from aspiration, and posttransplant lymphoproliferative disorder [63,64]. McKinney and Grigg [66] described a case of epiglottitis after general anesthesia administered via a laryngeal mask.

Diagnosis

History and Physical Examination

In children, the classic presentation is of a 3-year-old child who initially complains of a sore throat followed by dysphagia and/or odynophagia, which then progresses within hours to stridor. The child prefers to sit, leaning forward, and usually appears pale and frightened. Breathing is slow and quiet

with characteristic drooling noted. These symptoms may lead to sudden respiratory depression and arrest. The progression of symptoms can be remembered as the four "Ds": dysphagia, dysphonia, drooling, and distress.

In adults, the classic presentation is more the exception than the rule, and as such, the frequency of misdiagnosis has been reported as high as 60% to 75% [52,58,59]. More than 90% of adults seek medical attention complaining of sore throat with or without dysphagia [63,67]. Many patients report antecedent upper respiratory tract infections [60,68]. Other less common signs and symptoms are respiratory distress, muffled voice, drooling, fever, and stridor [52,53,63,67,68]. Hoarseness or true dysphonia is not observed because the process usually spares the true vocal cords. Children and adults often prefer an upright posture with the neck extended and mouth slightly open [69].

The duration of symptoms varies, ranging from hours to several days [70]. Patients presenting within 8 hours of the onset of symptoms are more likely to have signs of upper airway obstruction [71]. In general, patients who present early in their disease course have more severe symptoms, fever, and leukocytosis. They are also more likely to be infected with *H. influenzae* [70]. These patients are at increased risk of needing artificial airways and of dying [72].

Evaluation of patients with suspected supraglottitis depends, in part, on their age and the severity of their symptoms. In young children with a classic presentation, pharyngeal examination should not be attempted. An artificial airway should be established in the controlled setting of an operating room, where an examination can be performed with less risk of airway obstruction. When there is doubt about the diagnosis in a stable child, a lateral neck radiograph to look for the classic, "thumb sign" of a swollen epiglottis is the proper first step (Fig. 67.1).

In older children and adults, supraglottitis should be considered when sore throat and dysphagia seem to be out of proportion to visible signs of pharyngitis. In this situation, if the patient has no respiratory distress, examination of the larynx and supralaryngeal structures is recommended. The epiglottis may appear cherry red in color but more commonly is pale and edematous. Other supraglottic structures may be edematous as well, resulting in the inability to visualize the vocal cords [60].

Diagnostic Tests

A lateral soft tissue radiograph of the neck has frequently been used to diagnose acute supraglottitis [60]. The radiograph should be taken in the upright position to avoid pooling of secretions posteriorly and potentially increasing the obstruction. Because the disease is unpredictable, the patient must be observed at all times by someone skilled in airway management. Characteristic radiographic changes (see Fig. 67.1) have been detected in most endoscopically proven infections [72]. These changes include epiglottic thickening of more than 8 mm (producing the thumb sign) [73], swelling of the aryepiglottic folds of more than 7 mm [73], ballooning of the hypopharynx [74], and narrowing of the vallecula [74]. However, it is important to remember that a normal radiograph is inadequate to exclude the diagnosis of supraglottitis, and direct visualization of the structures should be performed if suspicion is high [75].

Few laboratory tests are helpful at the time of initial evaluation. An elevated white blood cell count and C-reactive protein level may identify a patient at higher risk. Throat cultures are positive in less than 33% of the cases and blood cultures detect a causative agent in less than 20% of the cases [58,63]. Direct visualization guided swab culture of the epiglottis may reflect more closely the causative agent and has been positive in up to 75% of the cases [59,63].

Differential Diagnosis

Supraglottitis in children is a clinical diagnosis. Since immediate airway control is a priority, recognizing other pediatric illnesses presenting with a sore throat and not requiring this intervention is important [76,77]. The most common infection is croup, a predominantly viral laryngotracheobronchitis that occurs up to 40 times more frequently than epiglottitis [77]. Typically, the child is younger than 3 years and has had an upper respiratory tract infection of at least 48 hours' duration. Hoarseness develops initially and is followed by a distinctive

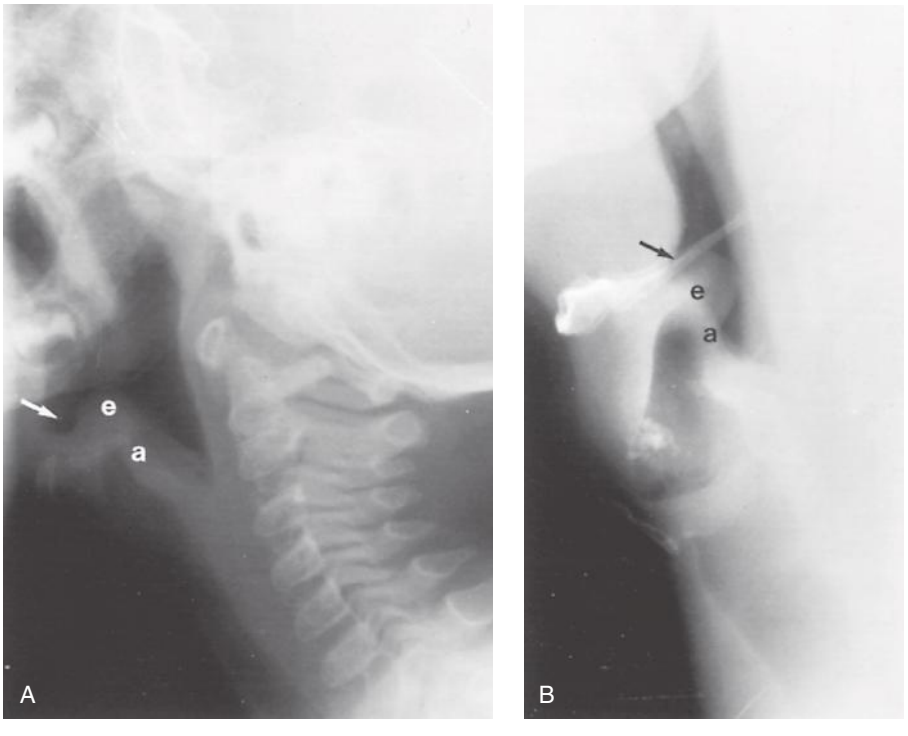

FIGURE 67.1. Acute supraglottitis. Lateral radiographs of the neck obtained with soft tissue technique in a 2-year-old child (**A**) and a 42-year-old adult (**B**). There is epiglottic (*e*) swelling (thumb sign), thickening of the aryepiglottic folds (*a*), and narrowing of the vallecula (*arrow*) in both patients. Compare with normal epiglottis in Figure 67.11(*a*).

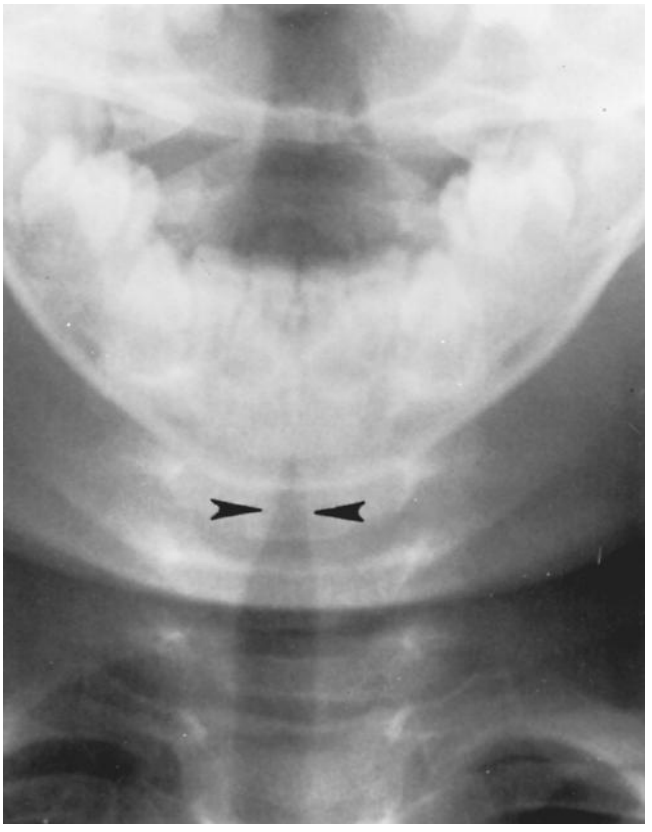

FIGURE 67.2. Croup. Anteroposterior radiograph of the neck in a 19-month-old child. Subglottic edema produces smooth tapering (*arrowheads*) of the tracheal air column (the steeple sign).

barking cough. Although respiratory distress with stridor is common, intubation is rarely needed [76,77]. Anteroposterior and lateral views of the neck may show the classic, "steeple sign" (Fig. 67.2), a gradual narrowing of the proximal tracheal air column secondary to subglottic edema. Other less common infectious considerations in children include pseudomembranous croup (bacterial laryngotracheobronchitis), retropharyngeal abscess, lingual tonsillitis, and diphtheria [76,77].

In adults, infectious mononucleosis, often with massive tonsillar hypertrophy leading to stridor, and a unilateral pharyngeal mass should be considered when patients complain of sore throat and dysphagia. Pharyngitis may present a picture indistinguishable from that of mild or early supraglottitis [72].

Bacterial tracheitis is a potentially life-threatening illness with features similar to those of supraglottitis and viral croup. Although more often seen in the pediatric population, adults can also be affected [78]. These patients present with a brief, progressive upper respiratory tract prodrome including a brassy cough, stridor, high fever, and toxicity but do not exhibit dysphagia or drooling [76,77]. Airway obstruction is due to subglottic mucosal edema and thick, inspissated, mucopurulent tracheal secretions [78]. Bacterial superinfection of a preceding viral tracheitis occurs most commonly with *S. aureus* and *H. influenzae* [77]. Rare cases of membranous tracheobronchitis due to a fungal agent have been described in immunocompromised hosts [79], but these infections have involved primarily the lower respiratory tract. Lateral neck radiographs demonstrate subglottic narrowing and may show mucosal irregularities or membranes in the tracheal air column [80]. Chest radiographs may show signs of atelectasis due to central bronchial obstruction by mucus or necrotic debris [81]. Management is similar to that for supraglottitis, and bronchoscopy should be performed for diagnosis [82]. Intubation or tracheostomy is usually necessary to relieve obstruction and provide adequate tracheal suctioning [78,82]. Antibiotic therapy should be directed against *S. aureus* and other common causative respiratory pathogens.

Rhinoscleroma should also be considered in the differential diagnosis. *Klebsiella rhinoscleromatis* is the etiologic agent of this chronic granulomatous disorder [83,84]. Although nasal and oral mucous membranes are the most common sites of infection, patients have presented acutely with upper airway obstruction due to indolent spread to the larynx and tracheobronchial tree. This condition may be seen in immigrants to the United States from endemic areas such as Central America, Central Europe, Africa, and Asia. The nodular and indurated endoscopic appearance is nondiagnostic, so multiple biopsy specimens for culture and histologic examination are required. Treatment is with a prolonged course of oral antibiotics. Repeated cultures of biopsy specimens may be needed to ascertain whether bacteriologic cure has been achieved [84].

Noninfectious causes of acute upper airway obstruction are usually suggested by the history obtained and by the patient's nontoxic appearance. These include foreign body aspiration, allergic edema, chemical laryngitis from gastroesophageal reflux, and necrotizing tracheobronchitis as a complication of mechanical ventilation [85]. Paraquat poisoning can cause a pharyngeal membrane similar to diphtheria that is accompanied by signs of shock and sepsis [86].

Treatment

The treatment of supraglottitis has two major components: airway management and medical therapy. The early placement of an artificial airway in children has significantly reduced mortality. Moreover, because airway obstruction is the most common cause of death in adults in whom airways are not secured when the diagnosis of supraglottitis is made, some authors favor establishing an artificial airway prophylactically, as is performed in children [53,58,69]. We tend to agree that intubation should be reserved for adult patients with early signs of airway obstruction [63,69,87]. Predictors of the need for an artificial airway in adults include drooling, diabetes mellitus, rapid onset of symptoms, and abscess formation [57]. All patients should be observed in an ICU with the immediate availability of equipment and personnel for emergent intubation.

Both tracheostomy and translaryngeal endotracheal intubation have been performed. No difference in mortality has been noted when comparing these two modalities [88,89]. Significant reductions in duration of airway control, incidence of upper airway complications, and length of hospital stay have been observed in patients with endotracheal intubation when compared with tracheostomy [89,90]. The acute complications of tracheostomy, including pneumothorax, hemorrhage, and subcutaneous or mediastinal emphysema, occur with increased frequency in patients younger than 12 years [88]. Accidental extubation, particularly in children, is the greatest risk of endotracheal intubation [88,89]. Much of the morbidity of the artificial airway is associated with its prolonged maintenance, which is unlikely to occur in supraglottitis. In one large series, 90% of children were extubated in less than 24 hours [91]. The choice of an artificial airway should be determined by the skill of available personnel in placing and maintaining the airway. Endotracheal intubation is preferred, with surgical backup, should the attempt fail.

The appropriate time for extubation in a patient recovering from acute supraglottitis varies. Some physicians remove the artificial airway when the patient's general toxic appearance and fever have subsided [91]. Others wait until repeat laryngoscopy or lateral neck radiographs show decreased edema of

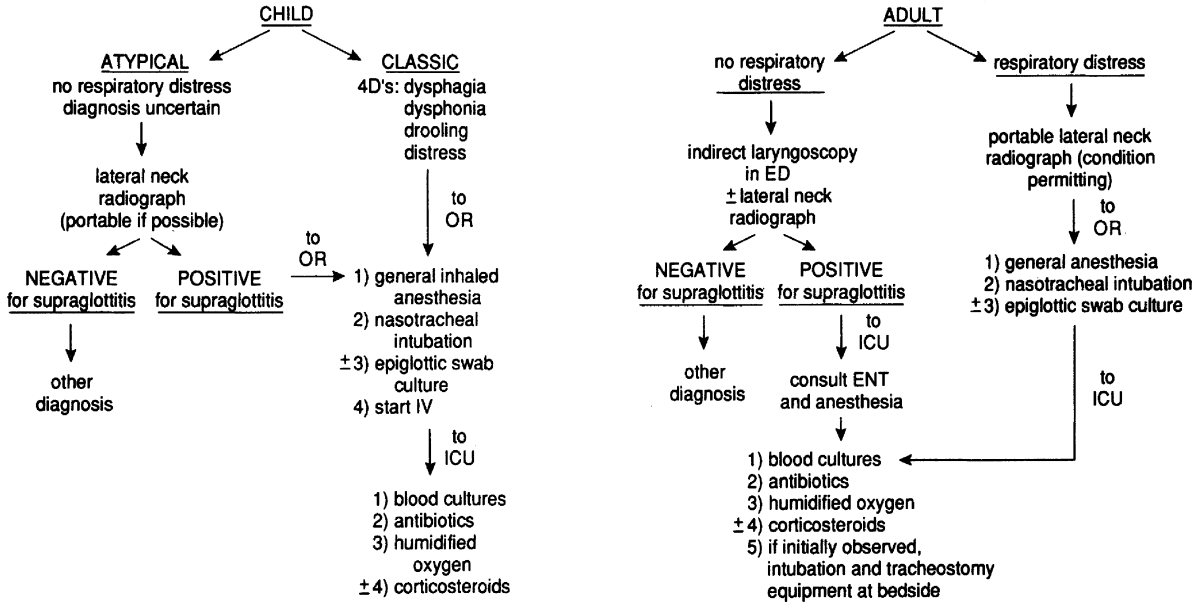

FIGURE 67.3. Management algorithm for acute supraglottitis; ± for epiglottic swab relates to questionable use; for corticosteroids reflects inconclusive study data. ED, emergency department; ENT, ear, nose, and throat specialist; ICU, intensive care unit; OR, operating room.

the involved structures [92]. One can deflate the cuff to test for an air leak around the tube or the patient's ability to breathe with the tube plugged for a brief moment [93]. It is important to remember that if the tube fills the trachea, the patient may not be able to breathe even if supraglottitis has completely resolved.

Medical therapy is crucial for rapid recovery from supraglottitis. All patients require close observation, humidification, and, often, mild sedation [60]. Many antibiotics are effective, and the regimens must cover *H. influenzae* infection. With the high frequency of β-lactamase–producing strains of *H. influenzae*, ampicillin is no longer adequate as an initial single agent. The initial drug of choice is a second- or third-generation cephalosporin that covers ampicillin-resistant *H. influenzae* as well as the other possible pathogens in adults: *S. aureus*, *S. pneumoniae*, and other streptococcal species [72]. Cefotaxime has been considered the antibiotic of choice; ceftriaxone and ampicillin/sulbactam have also been found to be effective [60]. Trimethoprim–sulfamethoxazole can be used as an alternative agent in penicillin-allergic patients. With the rising frequency of penicillin-resistance and multidrug-resistant *S. pneumoniae*, one may need to modify the initial antibiotic regimen based upon culture data. The antibiotics should be initially administered intravenously for several days, depending on the response, and then continued by mouth for 7 to 10 days [93].

Corticosteroid therapy is controversial in patients with infectious supraglottitis. Many authors, finding no contraindications, use steroids empirically [60,88]. There have been no randomized, controlled trials assessing the effectiveness of corticosteroids in patients with acute epiglottitis. Steroids have been noted to be effective in a large, randomized, controlled trial of children with moderate-to-severe croup, lending some support to the hypothesis that steroids may be beneficial in infectious upper airway disease [94]. The use of a helium–oxygen mixture (Heliox) could be considered to diminish the work of breathing and provide a bridge to avoid intubation while antibiotics take effect.

Complications of the disease differ between the pediatric and adult populations. The former has a higher incidence of pneumonia and accidental extubation [95]. Pulmonary edema immediately after intubation for severe stridor has been described in children [96]. In adults, an epiglottic abscess may be suggested by a persistent or deteriorating clinical condition [57,87]. CT scan of the neck may be helpful in making this diagnosis, particularly if direct visualization is not adequate [57,97]. Both groups face risks and complications associated with intubation and tracheostomy [90]. Treatment recommendations are outlined in Figure 67.3.

INFECTIONS OF THE DEEP SPACES OF THE NECK

Deep neck infections can be fatal extensions of upper airway infections. These potentially catastrophic infections are infrequently encountered today due to the prompt treatment of pharyngitis, tonsillitis, odontogenic, and otologic infections with antibiotics. Whenever a delay in diagnosis or treatment occurs, life-threatening complications such as airway compromise, jugular vein thrombosis, pneumonia, pericarditis, mediastinitis, and arterial erosion may develop [98]. Tonsillitis remains the most common cause of this disease in children, whereas poor dental hygiene and injection drug abuse are the most common causes in adults [99]. Some other causes include trauma, surgical trauma, esophageal perforation, laryngopyocele, infected branchial cleft, infected thyroglossal duct cysts, thyroiditis, and mastoiditis with Bezold's (mastoid tip) abscess [99]. An understanding of the complex interconnections between anatomic spaces is essential for early diagnosis and timely intervention of these conditions.

General Pathogenesis and Anatomy

Knowledge of the cervical fasciae is a prerequisite to understanding the etiology, manifestations, complications, and treatment of deep neck infections. The fascial planes separate and connect distant areas, thereby limiting and directing the spread of infection (Fig. 67.4). Suppurative processes in the submandibular, lateral pharyngeal, and retropharyngeal spaces (RPSs) are considered life threatening and are the focus of this discussion.

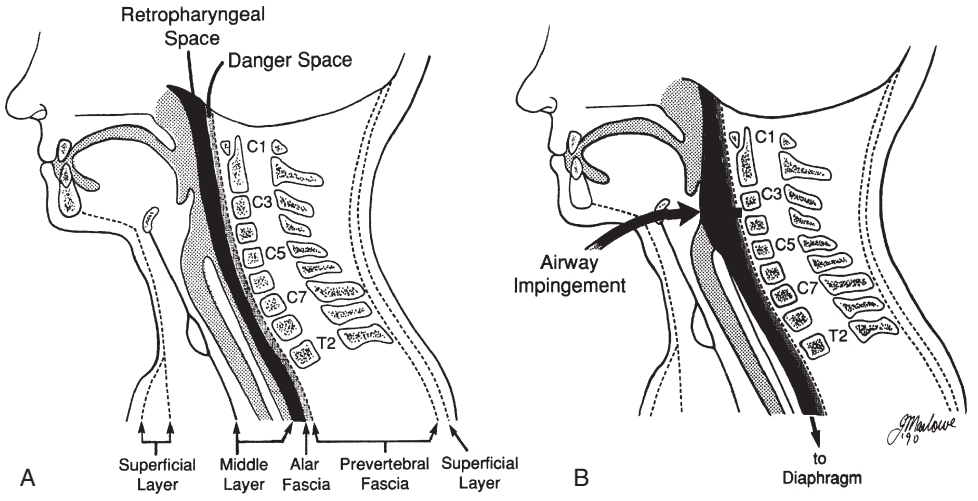

FIGURE 67.4. Schematic representation of cervical fascial planes and spaces. **A:** Normal. **B:** Retropharyngeal space abscess. [Adapted from Netter FH: *Atlas of Human Anatomy*. Summit, NJ, Ciba-Geigy, 1989.]

The submandibular space (SMS) (Fig. 67.5) consists of the sublingual and submylohyoid spaces, which communicate around the free posterior border of the mylohyoid muscle. It extends from the mucous membrane of the floor of the mouth above to the superficial layer of the deep cervical fascia below. It is bounded by the mandible both anteriorly and laterally. Superolaterally is the buccopharyngeal gap, an important opening behind the styloglossus muscle, which connects the SMS to the LPS.

The LPS (Fig. 67.6), also called the *pharyngomaxillary* or *parapharyngeal space*, is shaped like an inverted cone with its apex at the hyoid bone and its base at the base of the skull. The styloid process penetrates the space and divides it into two functional units: anterior (muscular) and posterior (neurovascular) compartments. The former lies lateral to the tonsillar fossa and connects inferomedially to the SMS. The latter contains the carotid sheath and its contents (internal carotid artery, internal jugular vein, vagus nerve, and lymph nodes), cranial nerves IX through XII, and the cervical sympathetic trunks. Both compartments abut the RPS.

The RPS, also called the *posterior visceral space*, (see Fig. 67.4) lies between the middle layer of the deep cervical fascia, which surrounds the pharynx and esophagus anteriorly, and the alar layer of the deep cervical fascia posteriorly. It extends from the base of the skull to the level of T1 or T2 in the superior mediastinum. Laterally, it abuts the LPS. Two chains of lymph nodes that drain many structures of the head are located on either side of midline.

Immediately posterior to the RPS is the *danger space* (see Fig. 67.4), so named because it is the pathway into the chest for all neck infections. It extends from the base of the skull to the diaphragms and is bounded posteriorly by the prevertebral layer of the deep cervical fascia. Involvement of this space by infection is a result of extension from the RPS or prevertebral space and can result in life-threatening complications.

The prevertebral space (see Fig. 67.4) lies between the vertebral bodies and the prevertebral layer of the deep cervical fascia. Infections in this location most often represent chronic processes arising from cervical spine injuries or infections.

Etiology

Bacteria found in normal oral flora are primarily responsible for deep cervical infections. When mucosal barriers are interrupted, bacteria can penetrate into the deeper spaces. Infections are typically polymicrobial with anaerobes predominating over aerobes. Fungi and mycobacteria are uncommon etiologic agents in these infections.

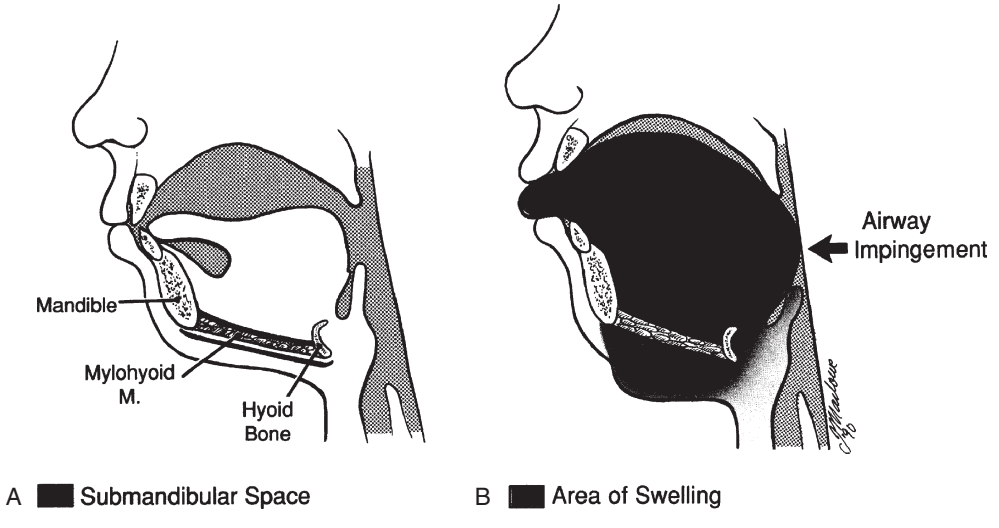

FIGURE 67.5. Schematic representation of submandibular space. **A:** Normal. **B:** Ludwig's angina. The submandibular space consists of sublingual and submylohyoid spaces. Area of swelling in **B** fills the submandibular space.

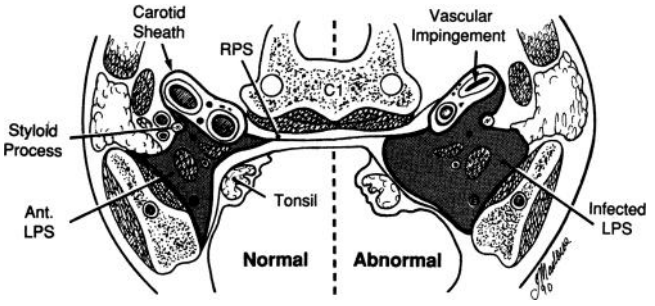

FIGURE 67.6. Cross-sectional view of lateral pharyngeal space (LPS), showing normal anatomic landmarks and effects of space infection on them. RPS, retropharyngeal space.

Correct identification of the causal pathogen requires careful culture techniques. Several factors contribute to the difficulty in obtaining meaningful bacteriologic data. Most patients receive antibiotics before hospitalization, many deep infections resolve with empiric antibiotic therapy without the need for aspiration procedures, and cultures obtained perorally are often contaminated by nonpathogenic organisms colonizing the oropharynx [98–102]. With proper anaerobic collection and transport techniques, three anaerobic isolates are most commonly identified: *Peptostreptococcus*, *Fusobacterium* (mostly *F. nucleatum*), and *Bacteroides* (mostly *B. melaninogenicus*) [98–101]. Although obligate anaerobes as a class are recovered most often, aerobic streptococci (mostly *Streptococcus viridans*) [100] and staphylococci are the most frequent individual isolates [100].

Facultative Gram-negative bacilli colonize the oropharynx in 6% to 18% of healthy adults [102] but are less common causes of deep neck infections. Rates of colonization may be as high as 60% in hospitalized and institutionalized patients and in individuals with diabetes and alcoholism [103]. *Escherichia coli*, *P. aeruginosa*, *Klebsiella pneumoniae*, *H. influenzae*, *Enterobacter*, *Proteus mirabilis*, *Citrobacter freundii*, and *Actinomyces* species have been isolated from deep cervical infections [98–103]. *Eikenella corrodens*, a facultative anaerobic Gram-negative rod, is an emerging pathogen in head and neck infections that is uniformly resistant to clindamycin [104]. Staphylococci should be considered in deep neck infections, particularly with cases of penetrating trauma, including cervical intravenous (IV) drug use [105], deep infections that originate from osteomyelitis of the cervical spine [106], and those infections that spread from acute suppurative parotitis [107].

When microbiologic confirmation is lacking, clinical clues may help suggest the presence of anaerobes. A foul-smelling discharge, gas production, tissue necrosis, and abscess formation can be suggestive, but the sensitivity of these findings is low [108]. Gram's stain may reveal anaerobic organisms with specific morphologic characteristics (e.g., *Clostridia*, *Fusobacterium*). Because anaerobes are more fastidious, failure of the more rapidly available aerobic cultures to reveal a causative organism may suggest an anaerobic pathogen.

Diagnosis

It is important to distinguish the space or spaces involved in deep neck infections to allow for early recognition and prevention of potentially devastating complications. The clinical picture may be confusing because of involvement of multiple spaces and interference with the physical examination by trismus. Fever and systemic toxicity are common early symptoms. Other signs and symptoms may be helpful to localize the primary site of infection (Table 67.2) [109]. Serologic testing contributes little to the diagnostic evaluation. Initial assessment should include a lateral neck radiograph.

Submandibular Space Infection

Infection in the SMS is exemplified by Ludwig's angina. This is a potentially life-threatening, bilateral cellulitis originating in the SMS. It spreads rapidly by direct extension, rather than via lymphatics, and can involve the submental and sublingual spaces [110]. Glandular structures are spared, and gangrene is produced without abscess formation. (see Fig. 67.5) [111]. Most patients are young, previously healthy adult men (male to female ratio, 2 to 3:1) [112]. The presenting symptoms are neck pain and swelling, tooth pain, and dysphagia [109,113]. Odontogenic infections are implicated in 70% to 90% of cases of Ludwig's angina [113]. Dyspnea, tachypnea, and stridor have been reported in as many as 27% of cases [113]. Other

TABLE 67.2

COMPARATIVE FEATURES OF INFECTIONS OF THE DEEP CERVICAL SPACES

	Clinical features					
Space infections	**Usual site of origin**	**Pain**	**Trismus**	**Swelling**	**Dysphagia**	**Dyspnea**
Submandibular	Second and third mandibular molars	Present	Minimal	Submandibular	Absent	Absent
Sublingual	Mandibular incisors	Present	Minimal	Floor of mouth (tender)	Present if involvement is bilateral	Present if involvement is bilateral
Lateral pharyngeal						
Anterior	Masticator spaces	Intense	Prominent	Angle of jaw	Present	Occasional
Posterior	Masticator spaces	Minimal	Minimal	Posterior pharynx (unilateral)	Present	Severe
Retropharyngeal (and danger)	Lateral pharyngeal space; distant via lymphatics	Present	Minimal	Posterior pharynx (often unilateral)	Present	Present
Prevertebral	Cervical vertebrae	Present	None	Posterior pharynx (usually midline)	Occasional	Occasional

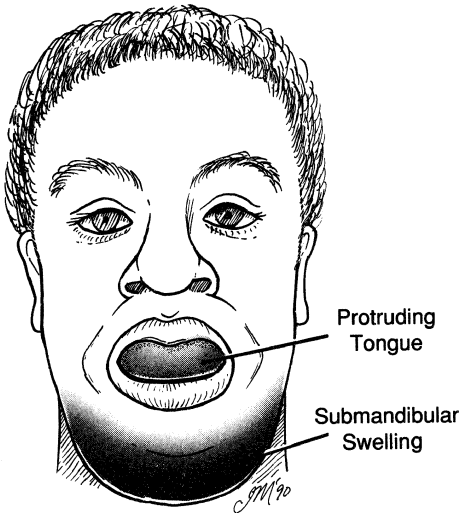

FIGURE 67.7. Schematic representation of salient clinical findings of Ludwig's angina.

symptoms include a muffled voice, drooling, and swelling of the tongue [109,113].

Ludwig's angina is essentially a clinical diagnosis. Physical examination (Fig. 67.7) reveals bilateral, firm submandibular swelling [111,113]; distortion of the mouth secondary to enlargement of the tongue, which is elevated and often protruding [112,114]; fever; and general toxicity [113]. Up to 51% of patients develop trismus, which indicates that the infection has spread to the LPS [113,114]. Airway obstruction can be a frequent and life-threatening complication of Ludwig's angina. Respiratory compromise can result from obstruction by the swollen, displaced tongue; edema of the neck and glottis; extension of edema to involve the epiglottis; and poor control of pharyngeal secretions [115,116]. Most patients with SMS involvement demonstrate soft tissue swelling (Fig. 67.8) [117]. Such a finding should prompt radiographic examination of the mandible in patients without a clear odontogenic source [118]. Mortality rates have decreased significantly due to more effective antibiotic therapy and early airway control [112,115].

Lateral Pharyngeal Space Infections

The signs and symptoms of LPS infections are determined by which of the two compartments is affected (see Fig. 67.6). The four major clinical signs of anterior compartment involvement include systemic toxicity with high fever and rigors; unilateral trismus due to irritation of the internal pterygoid muscle; induration and swelling along the angle of the jaw; and medial bulging of the lateral pharyngeal wall with the palatine tonsil protruding into the airway [113,114] (Fig. 67.9). Other symptoms may include dysphagia and pain involving the jaw or side of the neck. Pain may be referred to the ipsilateral ear and may worsen with turning the head to the unaffected side, which compresses the inflamed space by contraction of the sternocleidomastoid muscle. A history of recent upper respiratory tract infection is common [119]. Other sites of initial infection, especially in children, include the teeth, adenoids, parotid gland, middle ear with associated mastoiditis, and lymph nodes draining the nose and pharynx [113,114]. Extension from the SMS and RPS has also been implicated.

In infection of the posterior compartment, signs of sepsis—fever, leukocytosis, and often hypotension and respiratory alkalosis—are the cardinal features. Trismus and tonsillar prolapse are notably absent [120]. Dyspnea may be present as edema descends to involve the larynx and epiglottis [112]. External swelling may be visible when it spreads to the parotid space (see Fig. 67.9), but most patients have no localizing signs.

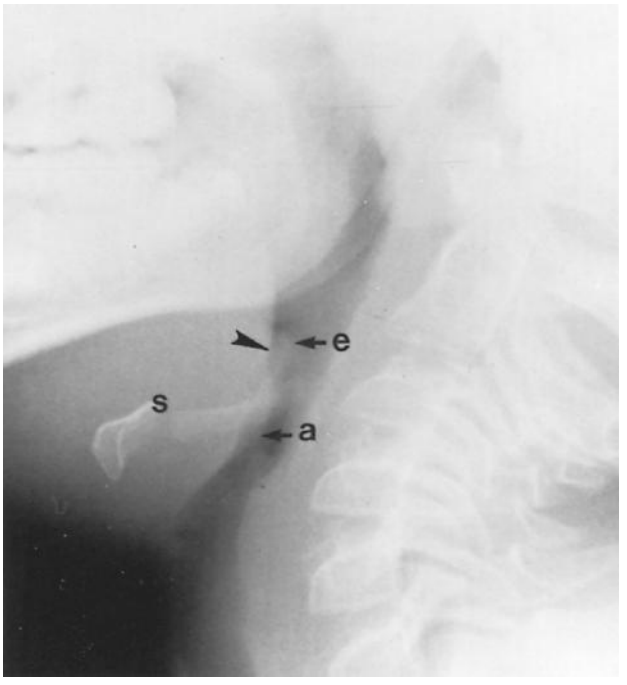

FIGURE 67.8. Ludwig's angina. Lateral radiographs of the neck obtained with soft tissue technique in a 7-year-old child. There is soft tissue swelling of the submandibular space (*s*), producing a smooth impression on the airway anteriorly, compressing and practically ablating the vallecula (*arrowhead*): the epiglottis (*e*) and aryepiglottic folds (*a*) are normal.

Many symptoms and signs in LPS infections are due to involvement of the neurovascular structures. Suppurative jugular venous thrombosis is the most common complication. Bacteremia and septic emboli, the most frequent consequences of

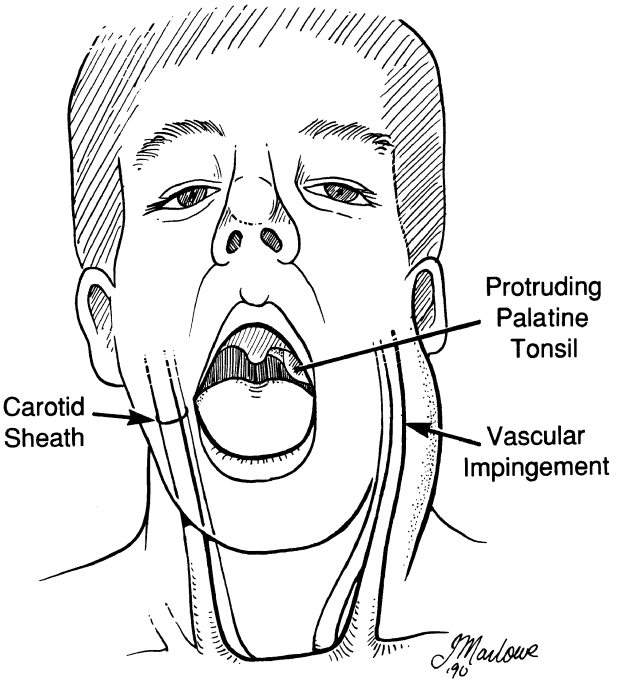

FIGURE 67.9. Schematic representation of salient clinical findings of lateral pharyngeal space abscess.

this entity, occur in one half of the cases [113,121]. Suppurative subclavian thrombosis, lateral sinus thrombosis, cavernous sinus thrombosis, and metastatic infections have also been reported [113,121–123].

Involvement of the carotid artery has the highest morbidity and mortality of any vascular complication in the LPS [112,113]. Carotid artery rupture carries a mortality of 20% to 40%, regardless of treatment [124]. The internal carotid is the most likely to rupture (62%), followed by the external carotid and its branches (25%) and the common carotid (13%) [125]. Arteritis develops from contiguous inflammation and results in false aneurysm formation [126]. Because the carotid sheath is not easily invaded, 1 or 2 weeks of illness usually precedes arterial erosion [124]. Signs suggestive of carotid sheath involvement include persistent tonsillar swelling after resolution of a peritonsillar abscess, ipsilateral Horner's syndrome, and cranial nerve palsies [126]. Impending rupture of a carotid aneurysm may be signaled by recurrent bleeds from the nose, mouth, or ears; hematoma in the surrounding tissue; a protracted clinical course; and the onset of shock [124]. Death after carotid hemorrhage is more likely from asphyxiation by the aspiration of blood than from exsanguination [124].

CT scan has been used to define neck masses, particularly in the LPS, with excellent results (Fig. 67.10) [127,128]. A retrospective study of 38 patients found a sensitivity of approximately 88% for CT scan in distinguishing parapharyngeal space (LPS) or RPS abscesses from cellulitis [129]. In another study, contrast-enhanced scans yielded an accuracy of 100% in separating abscess, cellulitis, and neoplastic lymphadenopathy [130]. Additional CT findings suggestive of an abscess are cystic or multiloculated masses with central air or fluid, soft tissue air, and surrounding edema [112,128]. Because the complications of deep neck abscesses are potentially fatal, CT scan of the neck is indicated in all cases, especially when surgical intervention is contemplated. The scan can be extended inferiorly to include the chest and mediastinum. IV contrast is helpful to enhance the abscess capsule and better evaluate the vascular structures of the LPS, but it may not specifically identify thrombosis of the internal jugular vein [131].

Ultrasonography of the neck has been used to identify fluid-filled masses and guide needle aspiration for culture material and surgical drainage techniques [132]. Ultrasonography has identified abscesses of the neck with a sensitivity of 95% [133], although its specificity is not as high as that of the CT scan, and therefore CT is preferable [134]. Magnetic resonance imaging can be complementary to CT scan with its multiplanar capability, particularly sagittal sections in the evaluation of RPS infections [135,136].

If arterial involvement is suggested and time permits, carotid artery angiography is recommended to locate the aneurysm before surgery [124,126]. With the exception of carotid angiography, studies used to identify vascular complications in the LPS are plagued by false-negative findings. Doppler venous flow studies [126,131], gallium scans [112], and retrograde venography [112] have been used to diagnose internal jugular vein thrombosis with mixed results and cannot be recommended at this time.

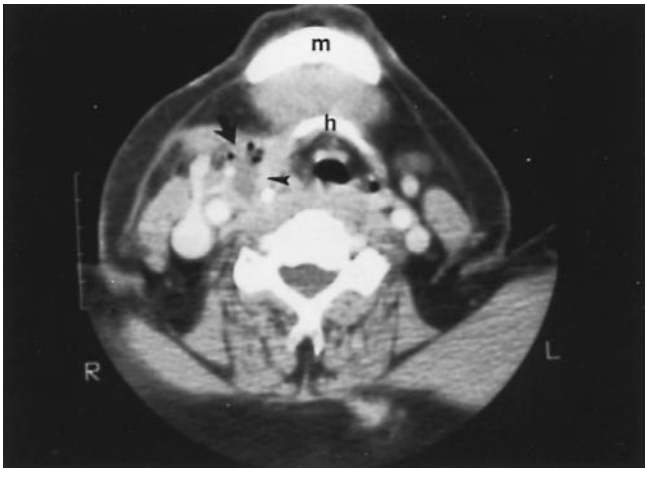

FIGURE 67.10. Abscess in the lateral pharyngeal space. Computed tomography at the level of the hyoid bone (*h*), at the apex of the inverted lateral pharyngeal space cone. There is a cystic mass (*arrow*) with floating air bubbles and enhancing rim (*arrowhead*), findings virtually pathognomonic of abscess caused by gas-forming organisms. *m*, base of mandible.

Retropharyngeal Space Infections

RPS abscesses are uncommon but potentially fatal infections, most often seen in children younger than 6 years [137,138]. The two chains of lymph nodes in this space drain adjacent muscles, nose, nasopharynx, pharynx, middle ear, eustachian tubes, and paranasal sinuses and are the source of most RPS abscesses. Their regression by approximately 4 years of age explains the higher frequency of this process in young children [113]. In children, the initial symptoms include fever, irritability, and refusal to eat [101]. The neck is often stiff and sometimes tilted away from the involved side [137]. Dyspnea and dysphagia occur as the swelling increases. Respiratory distress can occur as the abscess protrudes anteriorly (see Fig. 67.4). This may impair the child's ability to handle secretions [112].

In children, spontaneous rupture of a retropharyngeal abscess may result in aspiration and asphyxiation or upper airway obstruction from a combination of a child's high larynx and anterior displacement of the pharyngeal wall [101]. This can occur in adults as well, but the larger airway offers some protection from rapid airway occlusion. Uncommon complications include meningitis and epiglottitis [139].

Adults generally exhibit signs and symptoms directly referable to the pharynx. There may be a history of trauma to the posterior pharynx by intubation [113], ingestion of a foreign body [140], or an external penetrating injury [140]. Fever, sore throat, dysphagia, nasal obstruction, noisy breathing, stiff neck, and dyspnea are most common [112,113,137,138]. Pain originating in or radiating to the posterior neck that increases with swallowing is also most suggestive [137]. Severe respiratory distress, particularly if accompanied by chest pain or pleurisy, suggests mediastinal extension.

The lateral neck radiograph can aid in making the diagnosis by its ability to detect prevertebral soft tissue swelling (Fig. 67.11) [141]. The radiograph should be a true lateral view, with the neck in full extension, and should be made during inspiration. Exhalation, crying, and swallowing, especially in children, may cause thickening of the upper cervical soft tissues. Normal dimensions have been defined as less than 7 mm in all age groups at the C2 (retropharyngeal) level and less than 14 mm in children or 22 mm in adults at the C6 (retrotracheal) level [142]. Loss or reversal of the normal cervical lordosis secondary to inflammation-induced muscle spasm also suggests an RPS infection. CT scans can be valuable as well in the diagnosis of retropharyngeal abscess [135].

Descending Infections

Any deep neck infection can have access to the posterior mediastinum and diaphragms by the common pathways of the RPS and danger space [112,143,144]. Descending necrotizing mediastinitis can carry a mortality of greater than 40% [144]. The process can develop within 12 hours to as long as 2 weeks from the onset of the primary infection. An early diagnosis is difficult to make. Severe dyspnea and pleuritic or retrosternal chest

FIGURE 67.11. Retropharyngeal abscess. Lateral neck radiograph. There is marked swelling of the prevertebral soft tissues extending from the base of the skull to the base of the neck, with bulging and anterior displacement of the airway. There is mild reversal of the normal lordosis of the neck secondary to muscle spasm. The epiglottis (*e*) and aryepiglottic folds (*a*) are normal.

pain concomitant with or subsequent to the onset of symptoms of an oropharyngeal infection suggest this process. Manifestations include a widespread necrotizing process extending to the diaphragms and occasionally into the retroperitoneal space, a mediastinal abscess that may rupture into the pleural cavity, or purulent pleural and pericardial effusions [144]. Suggestive physical findings include diffuse, bulky induration of the neck and upper chest associated with pitting edema or crepitation [101,113].

Cervical necrotizing fasciitis, fascial infection with muscle necrosis, often without pus or abscess formation, can progress superficially along the fascial planes of the neck and chest wall [145–147]. Early in the course of this disease, the physical appearance may be deceptively benign. Skin erythema occurs initially and progresses to dusky skin discoloration, blisters, or bullae and eventually to visible skin necrosis [148]. Crepitation may be absent, but gas in the tissues can readily be seen using CT. Surgical exploration with wide excision is essential to determine the full extent of necrosis and to improve prognosis [145–147].

Differential Diagnosis

Few clinical entities must be distinguished from deep cervical infections. Common causes of submandibular swelling include cervical adenitis and submandibular sialoadenitis. In the proper settings, the differential diagnosis includes anticoagulant overdose with sublingual hematoma, tumor of the floor of the mouth, superior vena cava syndrome, and angioedema. None of these presents with the classic physical findings or respiratory symptoms of SMS infection due to Ludwig's angina.

The major entities from which LPS infection must be differentiated are peritonsillar abscess, anaerobic tonsillitis, and masticator space infections. In the latter, the patient presents with fever, trismus, pain, and swelling over the mandible, and the oropharyngeal examination is normal [112]. Peritonsillar abscess becomes evident with fever and tonsillar prolapse but without extreme toxicity, trismus, or parotid swelling [149]. Vincent's angina is an anaerobic tonsillitis due to *Fusobacterium necrophorum*, which produces a foul smelling discharge that forms a pseudomembrane and can be associated with bacteremia and metastatic abscesses [107].

Acute suppurative parotitis can occur as a complication of pharmacologic therapy (e.g., diuretics, anticholinergics) [149]. Reduced salivary flow allows normal oral flora to spread to Stensen's duct and into the gland. The most common pathogen is *S. aureus*, but infection is also seen with hemolytic streptococcus, Gram-negative bacilli, and anaerobes [114,149]. The mainstays of therapy are hydration, sialagogues, and often a broad-spectrum antibiotic with anti–β-lactamase activity. Despite appropriate treatment, complications may include spread to the mastoid, entrapment of the facial nerve, severe swelling of the pharynx and neck resulting in airway obstruction, and problems typical of involvement of the LPS [114,149]. Mortality may approach 25% [114,149].

The septic complications of LPS infection can mimic right-sided bacterial endocarditis [112] and be misdiagnosed as community-acquired pneumonia, pancreatic abscess, periorbital cellulitis, and temporomandibular joint pain [131]. Lemierre's syndrome, first described in 1900, but given its eponym in 1936, is the occurrence of suppurative thrombophlebitis, sepsis, and metastatic abscesses in the setting of an acute oropharyngeal infection [121,150]. With the widespread use of antibiotics for the treatment of tonsillitis/pharyngitis, there has been a dramatic decrease in the occurrence of the syndrome. As such, clinicians must be aware of its existence. The time of onset from the initial infection to sepsis is usually 1 week. Clinical evidence of internal jugular vein thrombophlebitis includes severe neck pain at the angle of the mandible and along the anterior border of the sternocleidomastoid muscle, trismus, and dysphagia [146]. Infectious emboli most commonly result in pleuropulmonary infection, although metastatic infections of the joints, bones, meninges, and liver have been reported [121,150]. *F. necrophorum* is the primary pathogen in the great majority of cases. Although penicillins had been the treatment of choice, the increasing frequency of β-lactamase–producing organisms may warrant the use of an antibiotic with β-lactamase resistance.

Retropharyngeal swelling might be due to tumors [151], hematomas [152], lymphadenopathy [153], enlargement of the prevertebral space as can occur with a cervical spine fracture [153], or tendinitis of the prevertebral muscles [151]. In children presenting with fever, sore throat, nuchal rigidity, drooling, or respiratory distress, all components of RPS abscess, severe croup, epiglottitis, and meningitis must also be considered.

Treatment

All patients with deep neck infections require hospitalization. Therapy has three components: airway management, IV antibiotics, and timely surgical exploration.

Airway Management

Establishment of an artificial airway is not universally required, but it should be done when evidence of airway obstruction

exists, such as dyspnea and stridor or inability to handle secretions. The method of airway protection in patients with deep cervical infections must be individualized for the patient and to the expertise of the available personnel [154]. Upper airway obstruction is most often a complication of infections involving the SMS, for which the standard method of airway control has been tracheostomy [115,116]. Because of the proximity of the tracheostomy to submandibular wounds created for drainage, there is a potential risk of aspiration pneumonia and anterior mediastinitis [113]. Moreover, the surgical risks of tracheotomy may be increased by the distortion of the neck with edema. Because of these concerns, cricothyroidotomy has been recommended as an alternative, particularly in emergent situations [155], because of the low immediate and delayed complication rates and because it can be performed rapidly. Distortion of neck landmarks may equally complicate this procedure, but fewer critical structures are in proximity, which may reduce some procedure-related risks.

Endotracheal intubation can be difficult to achieve because of trismus and intraoral swelling. Trismus may be a more significant problem when infection has spread to the LPS. Blind intubation is unsafe because of the risk of trauma to the posterior pharyngeal wall, rupture of abscesses in the LPS or RPS, and possibly laryngospasm precipitating lower airway obstruction [115,116]. Intubation over a fiberoptic laryngoscope may be useful but requires a cooperative, stable patient and may therefore be useful only in certain cases [154]. Inhaled anesthesia to relieve trismus, along with an antisialagogue, may allow for intubation under direct vision [115,116]. If this is attempted, skilled personnel should be available to establish an emergent surgical airway if needed.

Antimicrobial Therapy

Antibiotic therapy should be given intravenously for all neck infections. Optimum empiric coverage is recommended with either penicillin in combination with a β-lactamase inhibitor (such as amoxicillin, ticarcillin with clavulanic acid, piperacillin/tazobactam) or a β-lactamase–resistant antibiotic (such as cefoxitin, cefuroxime, imipenem, or meropenem) in combination with a drug that is highly effective against most anaerobes (such as clindamycin or metronidazole) [101]. Vancomycin should be considered in patients with immune dysfunction, neutropenia, and in IV drug abusers at risk for infection with Methicillin-resistant Staphylococcus aureus [101]. If needed, other agents including linezolid, daptomycin, and quinupristin/dalfopristin can be substituted in place of vancomycin. The addition of gentamicin for effective Gram-negative coverage against *K. pneumoniae*, which is resistant to clindamycin, is highly recommended for diabetic patients with intact renal function [101]; an alternative for the seriously ill patient with penicillin allergy is chloramphenicol [112]. Parenteral antibiotic therapy should be continued until the patient has been afebrile for at least 48 hours, followed by oral therapy using amoxicillin with clavulanic acid, clindamycin, ciprofloxacin, trimethoprim–sulfamethoxazole, or metronidazole [101]. The antibiotic regimen can be de-escalated based on culture data.

Anticoagulation for septic internal jugular thrombosis has been used and recommended [124], but its efficacy as an adjuvant to antibiotic therapy has not been conclusively demonstrated [156]. Resection of a thrombosed vein is not widely recommended but may be unavoidable in a patient who deteriorates despite drainage of the LPS, or in one whose vein is frankly suppurative [131].

Surgery

Surgical intervention is most important when infections involve the RPS and LPS and can rarely be avoided. Conservative therapy using antibiotics and selective needle aspirates has been successful at times [127,157,158]. In general, if signs of clinical improvement are not observed after receiving IV antibiotics for 24 to 48 hours, then reimaging and surgical intervention are likely warranted [113]. Most recommendations are for broad-spectrum antibiotics and surgical treatments consisting of cervical drainage, thoracotomy with radical surgical debridement of the mediastinum and excision of necrotic tissue, decortication, and irrigation [159,160]. A less invasive thoracoscopic approach has also been described [161]. In contrast to LPS and RPS infections, up to one half of the cases of Ludwig's angina are cured without surgical drainage [120]. Dental extraction may be required [162]. Specific surgical approaches are reviewed elsewhere [159–161,163,164].

CHAPTER 68 ■ ACUTE INFECTIOUS PNEUMONIA

VERONICA BRITO AND MICHAEL S. NIEDERMAN

Pneumonia is a common community- and hospital-acquired infection that is managed in the intensive care unit (ICU) when it leads to acute respiratory failure or septic shock and complicates the course of an otherwise serious illness. Modern medical technology has not been able to eliminate this infection. Rather, it has promoted its emergence by the application of novel, life-sustaining therapies that lead to specific at-risk populations who have impairments in respiratory tract host defenses. This chapter reviews the scope of the problem in seriously ill patients.

Pneumonia occurs in up to 6 million outpatients annually (community-acquired pneumonia, CAP), with up to 1 million requiring hospitalization [1]. Pneumonia also develops in the hospital (nosocomial pneumonia or hospital-acquired pneumonia [HAP]), particularly in those patients with underlying serious illnesses, at the rate of approximately five to ten cases per one thousand hospital admissions [2]. In the hospital, the incidence of pneumonia is directly related to the degree of underlying systemic illness in a given patient, with the incidence being higher in medical than in surgical patients, and in those requiring prolonged mechanical ventilation than in those managed by short-term ventilatory support [2]. Recently, the distinction between CAP and HAP has become blurred, because patients with chronic illness often live in complex environments out of the hospital (nursing homes), or patients are repeatedly admitted to the hospital, or they receive treatments in healthcare settings such as dialysis centers. These individuals come in contact with the healthcare environment, even when they are not hospitalized, and can become infected with hospital-associated drug-resistant pathogens, and when they develop pneumonia, it is termed healthcare-associated pneumonia (HCAP) [2].

Certain patient populations are at increased risk for pneumonia, primarily as a result of disease-associated impairments in lung host defenses. These include the elderly and those with cardiac disease, alcoholism, chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), malnutrition, head injury, cystic fibrosis, bronchiectasis, malignancy, splenic dysfunction, renal failure, liver failure, diabetes mellitus, and any immunosuppressive illness or therapy [2,3]. In addition, hospitalized patients often receive therapeutic interventions that predispose them to pneumonia, including antibiotic therapy, enteral feeding, endotracheal intubation, tracheostomy, and the use of certain medications (such as corticosteroids, aspirin, digitalis, morphine, and pentobarbital) [3].

The mortality implications of pneumonia (along with influenza) rank it as the eighth leading cause of death in the United States, the sixth leading cause of death in those older than 65 years, and the number one cause of death from infectious diseases [4]. Although CAP can vary from a mild to a severe illness, those who enter the ICU with this infection have a mortality rate that can vary from 20% to greater than 50% [5]. Older studies questioned whether use of the ICU was even beneficial for severe CAP, but that was at a time when the ICU was only used when the disease was far advanced. In more recent studies, an effort has been made to identify patients with severe CAP at the earliest possible time point, and thus while as many as 90% of ICU admitted CAP patients in older studies were intubated and mechanically ventilated, more recently, only about 60% to 70% of CAP patients in the ICU receive this intervention. This means that the indications for ICU admission and the definitions of severe CAP are changing, and with good reason, since the later in the hospital course that the ICU is used, the higher the mortality [6]. Recently, Woodhead et al. [6] found that CAP accounted for 5.9% of all ICU admissions, but that early admission (within 2 days of hospitalization) appeared to be preferable and was associated with a lower mortality (46.3%) than late admission (>7 days in the hospital, 50.4% mortality). Thus, the mortality associated with severe CAP is a reflection of how accurately the ICU is used, what organisms are causing the infection, what complications develop in the hospital, and how effective is the initial empiric therapy [7] (Table 68.1).

In data from the National Nosocomial Pneumonia Infection Surveillance System, pneumonia is the most common, ICU-acquired infection, with 86% of episodes being associated with mechanical ventilation [8]. Patients usually develop HAP because of an underlying chronic illness, and thus the question arises, if they die, whether their death was due to the pneumonia itself or a result of the underlying, predisposing illness. This issue of "attributable mortality" has been studied, and as many as 60% of those who die do so as a direct result of their pneumonia [9]. Not all studies report attributable mortality, particularly those involving surgical and trauma patients, a group that seems to acquire pneumonia commonly but usually without a major direct effect on mortality [10]. In those with acute respiratory distress syndrome (ARDS), the mortality rate of pneumonia has been reported to be high, with only 12% of patients with pneumonia surviving in contrast to 67% survival in the absence of infection [11]; however, more recent data report lower death rates from pneumonia in patient with ARDS.

Bacteriology is another important factor adding to mortality in HAP, with Kollef et al. [12] reporting a high attributable mortality for late-onset ventilator-associated pneumonia (VAP) caused by potentially drug-resistant organisms such as *Pseudomonas aeruginosa*, *Acinetobacter* spp, and *Stenotrophomonas maltophilia*. Rello et al. [13] matched patients with VAP caused by methicillin-resistant *Staphylococcus aureus* (MRSA) with controls having caused by other organisms. They found that the mortality for MRSA VAP was 48%, compared with 25% for control patients ($p < 0.01$). Heyland et al. [14] compared 177 patients with VAP to a matched control group of critically ill ventilated patients without pneumonia and found that patients with pneumonia had a longer duration of mechanical ventilation, longer stay, and a trend toward increased mortality, particularly with the use of initially inappropriate empiric antibiotic therapy. Thus, similar to the data with severe CAP, mortality in HAP is also affected by patient characteristics, bacteriology, and the accuracy of therapy. In studies of HCAP, when patients are admitted to the ICU, mortality can also be high, and it is increased if patients do not receive appropriate initial antibiotic therapy [15].

TABLE 68.1

RISK FACTORS FOR PNEUMONIA MORTALITY IN PATIENTS WITH CAP

Physical findings
Abnormal vital signs
Respiratory rate >30/min
Hemodynamic compromise: systolic or diastolic hypotension
Tachycardia (>120/min)
Afebrile or high fever (>38°C)
Altered mental status or coma
Laboratory findings
Respiratory failure: hypoxemic or hypercarbic
Multilobar infiltrates
Rapidly progressive infiltrates
Positive blood culture
Multiple organ failure
Hypoalbuminemia
Renal insufficiency
Polymicrobial infection
Historical information
Serious comorbidity or advanced age
Poor functional status at presentation
Recent hospitalization
Immunosuppression (including systemic corticosteroids)
Nonrespiratory clinical presentation
Delayed or inappropriate therapy
Prolonged mechanical ventilation

TYPES OF PNEUMONIA ENCOUNTERED IN THE INTENSIVE CARE UNIT

Serious pneumonia occurs when a potential pathogen overwhelms a patient's host defenses, and then, because of either overwhelming infectious challenge or an excessive inflammatory response to infection, the patient develops respiratory failure or septic shock. Certain pathogens are so virulent that they can even overcome an intact, and normal, host defense system, as is the case with epidemic viral illness. Normal host defenses can also be overcome if the inoculum of the pathogen is large (as with massive aspiration), but smaller inocula can be pathogenic if disease-associated factors interfere with immune function. Certain patients seem to become ill because of an excessive inflammatory response to a localized infection, and genetic polymorphisms in the immune response are being identified to explain this phenomenon.

Community-Acquired Pneumonias Leading to Intensive Care Unit Admission

Although less than 20% of all patients with CAP require hospitalization, those patients ill enough to enter the hospital may have a substantial mortality rate. As classically described by Austrian and Gold [16], for certain patients with advanced illness, even penicillin therapy could not eliminate the mortality of pneumococcal pneumonia, because the disease process was too advanced at the time of presentation.

When CAP leads to ARDS, a complication that occurs in less than 5% of cases, the mortality rate can exceed 70% [17]. For a general ICU population, the mortality rate of CAP, reported in a meta-analysis of 788 patients, was just more than 35%, and other series have reported even lower rates [18]. Pneumonia caused by bacteria, viruses, fungi, and protozoa can occasionally be severe enough to prompt admission to the ICU. Pathogens that have been described as causing severe CAP include *Streptococcus pneumoniae* (pneumococcus), *Legionella pneumophila*, *Haemophilus influenzae*, enteric Gram-negative bacteria, *S. aureus* (including community-acquired methicillin-resistant strains), *Mycoplasma pneumoniae*, *Pneumocystis jiroveci*, *Mycobacterium tuberculosis*, *Chlamydophila pneumoniae*, endemic fungi (blastomycosis, histoplasmosis) influenza virus, respiratory syncytial virus, varicella, severe acute respiratory syndrome virus (SARS, caused by a coronavirus), and the bacteria associated with aspiration pneumonia [4].

Definition of Severe CAP and Prognostic Factors/Scoring Systems

Although "severe" CAP does not have a uniform definition, the term has been used to refer to patients with CAP who require ICU care, although, recently, some investigators have focused on defining patients with CAP who need invasive respiratory or vasopressor support (IRVS), independently of site of admission [4,5]. Torres et al. [19] estimated that CAP accounted for 10% of all admissions to an ICU over a 4-year period, and that these patients were admitted directly to the ICU 42% of the time, after admission to another ward 37% of the time, and in transfer from another hospital 21% of the time.

There are some patients in whom pneumonia is such a virulent infection that survival may have already been determined when they reach the ICU because the patient is already "too far gone." Some older studies questioned whether treating CAP patients in the ICU could even impact mortality, since as many as 75% of patients with pneumococcal pneumonia managed in the ICU died. However, in older series, most of these patients were mechanically ventilated when admitted to the ICU so that the ICU may have been used very late in the course of illness. In more recent studies, only about 60% to 70% of patients with CAP in the ICU receive mechanical ventilation [6]. In these series of severe CAP, the mortality rates have varied from 21% to 54%, with the lower mortality rates being found when not all patients were mechanically ventilated, and the higher mortality rates being seen when nearly 90% were being ventilated [5]. These findings suggest that there is value in defining the need for ICU care at the earliest possible time point, and not reserving the ICU for extreme circumstances such as overt respiratory failure and shock.

Poor prognostic factors in CAP are as follows: multilobar pneumonia, respiratory rate greater than 30 breaths per minute, severe hypoxemia, abnormal liver function, low serum albumin, signs of clinical sepsis, and delayed or inappropriate antibiotic therapy [4,18]. While sepsis increases CAP mortality, bacteremia by itself is not a mortality risk. In a recent study [20], bacteremia was not an independent mortality risk or a predictor of delayed clinical response, after controlling for other variables such as age, comorbidities, and abnormal vital signs at presentation.

Over the past decade, a number of studies have examined prognostic scoring systems for patients with CAP. In general, there are two widely used approaches, the Pneumonia Severity Index (PSI) and the British Thoracic Society approach (CURB-65). Each uses a point scoring system to predict a patient's mortality risk, with the CURB-65 being simpler and more focused on acute illness parameters, whereas the PSI is a more complex system that incorporates measurements of both chronic and acute disease factors [5]). While both tools predict mortality risk, neither is a direct measure of severity of illness. For example, as many as 37% of those admitted to the ICU in one study [21] were in PSI classes I–III, pointing out that even those with a low risk for death (which PSI can measure) may benefit from aggressive intensive care support [21]. Conversely, patients in

higher PSI classes do not always need ICU care if they fall into these high mortality risk groups because of advanced age and comorbid illness in the absence of physiologic findings of severe pneumonia.

In one recent study [22], both tools were applied to the same patients, and each was similarly accurate for identifying low-risk patients. However, the CURB-65 was more discriminating in predicting mortality risk for patients with more severe illness. This approach gives one point for each of five abnormalities: **c**onfusion, elevated blood **u**rea nitrogen (BUN) (>19.6 mg per dL), **r**espiratory rate 30 per minute or more, low **b**lood pressure (BP) (either systolic ≤90 mm Hg or diastolic ≤60 mm Hg), and whether the patient is at least **65** years old. If three of these five criteria are present, the predicted mortality rate is greater than 20%, and these patients are generally considered for ICU admission [23]. A similar approach has been developed by the Japanese Respiratory Society, the A-DROP scoring system, that assesses **A**ge (male ≥70 years, female ≥75 years); **D**ehydration (BUN ≥210 mg per L); **R**espiratory failure (Sao(2) ≤90% or Pao(2) ≤60 mm Hg); **O**rientation disturbance (confusion); and low blood **P**ressure (systolic BP ≤90 mm Hg) [24].

Another scoring system, developed by España et al., based on data from 1,057 patients in Spain, suggested that the need for ICU admission could be defined by the presence of one of two major criteria (arterial pH <7.39 or a systolic BP <90 mm Hg), or the presence of two of six minor criteria, which included confusion, BUN greater than 30 mg per dL, respiratory rate greater than 30 per minute, PaO_2/FiO_2 ratio less than 250, multilobar infiltrates, and age 80 years or older. This approach gave different point values to each abnormality, and when severity criteria were met, the tool was 92% sensitive for identifying those with severe CAP and was more accurate than the PSI or the CURB-65 [25]. Another tool, the SMART-COP approach [26], was developed in Australia to predict the need for IRVS using eight clinical features, in which the acronym referred to systolic BP less than 90 mm Hg, multilobar infiltrates, albumin less than 3.5, respiratory rate elevation (>25 for those younger than 50 years, and >30 for those older than 50 years), tachycardia (>125 per minute), confusion, low oxygen (<70 mm Hg if younger than 50 years or <60 mm Hg if older than 50 years), and arterial pH less than 7.35. The abnormalities in the systolic BP, oxygenation, and arterial pH each received 2 points, whereas the five other criteria received 1 point each, and with this system, the need for IRVS was predicted by a SMART-COP score of at least 3 points. Using this cutoff, the sensitivity for the need for IRVS was 92.3% and the specificity of 62.3%, with a positive and negative predictive value of 22% and 98.6%, respectively. Both PSI and CURB-65 did not perform as well overall.

The adverse prognostic factors discussed above are particularly applicable to the elderly, and those with nursing home–acquired pneumonia often have a higher mortality rate than those with simple CAP [5]. One factor that may explain this finding is that older patients often have atypical clinical presentations of pneumonia, which may lead to their being diagnosed at a later, more advanced stage of illness, resulting in an increased risk of death [5]. Older patients from nursing homes presenting with pneumonia are now included in a separate category, called HCAP.

Recently, the accuracy of prognostic scoring systems has been enhanced by biomarker measurements. Salluh et al. [27] and others have found that baseline cortisol levels showed a good correlation with CAP outcome. The most data have focused on procalcitonin (PCT), a "hormokine" that has increased plasma concentrations in the presence of severe bacterial infections, but not in viral illness. Masia et al. [28] found that PCT levels correlated well with the PSI score and the development of complications such as empyema, mechanical ventilation, and septic shock in a study of 185 patients. In another study performed in patients with severe CAP, a rise in PCT during hospitalization correlated with mortality. In other studies, PCT data have supplemented the information provided by prognostic scoring tools. Krüger et al. [29] found that PCT identified low-risk patients in all severity classes, and that the finding of a low PCT value had a 98.9% negative predictive value for mortality, regardless of the results of prognostic scoring tools. Similarly in a study of 1,651 patients admitted with CAP, there were 546 in high PSI classes (IV and V), but in the 126 of these who had low PCT levels, only 2 died [30], suggesting the advantage of combining serum markers with the commonly used prognostic indices.

Although there are no absolute criteria for severe pneumonia, or need for ICU admission, in the 2007 American Thoracic Society/Infectious Society Diseases of America (ATS/IDSA) guidelines, [4] severe CAP was defined as the presence of one of two major criteria (need for mechanical ventilation, or septic shock requiring pressors) or the presence of three of nine minor criteria. These minor criteria were a PaO_2/FiO_2 ratio of 250 or less, respiratory rate 30 per minute or more, confusion, multilobar infiltrates, systolic BP less than 90 mm Hg despite aggressive fluid resuscitation, BUN greater than 20 mg per dL, leukopenia (<4,000 cells per mm^3), thrombocytopenia (<100,000 cells per mm^3), and hypothermia (<36°C) [4]. This approach requires further validation, but in one study of 2,102 patients, of which 235 were admitted to the ICU, this predictive rule had a sensitivity of 71% and a specificity of 88% for determining need for ICU admission. This degree of accuracy was similar to the 2001 ATS guideline rule [31]. The use of only minor criteria to define need for ICU care is uncertain, since in that study, only 47 of 219 patients meeting only minor criteria needed ICU admission, and the presence of minor criteria alone did not increase mortality risk.

CAP Prognostic Factors Defined After Initial Management

The above discussion has focused on data available on admission that can be used to guide the site of care decision. However, after admission, the results of cultures become available, and therapy (accurate or not) is given, and these events can impact prognosis. Garau et al. [32] have found that late and overall CAP mortality are reduced if patients have negative blood cultures, and if antibiotic therapy is given according to guidelines. Among patients with severe CAP, the most important prognostic finding during therapy is radiographic progression [19]. Ineffective initial empiric therapy has also been identified as a potent predictor of death, being associated with a 60% mortality rate, compared with an 11% mortality rate when patients received initial effective therapy [33]. Similarly, in other studies of CAP, the use of a combination of a β-lactam and a macrolide antibiotic was associated with a lower mortality than if other therapies were given [4], and the use of guideline compliant therapy was associated with a reduced duration of mechanical ventilation [34]. In the setting of pneumococcal bacteremia, the use of combination therapy is associated with reduced mortality, compared with monotherapy, particularly for patients treated in the ICU [4]. Not only must initial therapy be accurate, it must be timely, and in patients with septic shock (from all sources, including pneumonia), mortality increases by 7% for each hour in the delay of initiating therapy [35]. Retrospective data have also shown a reduced mortality for admitted CAP patients who are treated within 4 hours of arrival to the hospital compared with those who are treated later [4].

The interaction between prognostic factors related to therapy and bacteriology is most evident when patients with CAP are infected with drug-resistant organisms, particularly drug-resistant pneumococcus. Pneumococcal resistance to penicillin

is increasing and is present in more than 40% of all pneumococci by older definitions of in vitro resistance [4]. Studies have defined the clinical features of patients at risk for drug-resistant pneumococcus (drug-resistant *S. pneumoniae* [DRSP]) [4] and these include older than 65 years, β-lactam therapy in the past 3 months, multiple medical comorbidities, alcoholism, nosocomial acquisition, and contact with a child in day care. Recently, the criteria for resistance in nonbacteremic infection have changed, and fewer organisms are defined as resistant, compared with the past, since many available therapies are known to be effective [36]. Studies of bacteremic pneumococcal pneumonia have shown that the presence of resistance is not itself a predictor of a poor outcome or a risk factor for mortality. In the absence of meningitis, clinical failure with high-dose β-lactam therapy is currently unlikely [4,36]. Most investigators have found no difference in mortality for patients infected with resistant or sensitive organisms, after controlling for comorbid illness [36,37], although patients with resistant organisms may have a more prolonged hospital stay, and suppurative complications such as empyema [38], and in HIV infection, the presence of high-level penicillin resistance has been associated with increased mortality [39]. The breakpoint for clinically significant penicillin resistance is a minimum inhibitory concentration value of 4 μg per mL or more, with increased mortality in patients with invasive disease (bacteremia) and this degree of resistance, who do not die in the first 4 days of illness [40].

Nosocomial Pneumonia in the Intensive Care Unit: Hospital-Acquired Pneumonia

Risk Factors for HAP and VAP

As mentioned, pneumonia is the nosocomial infection most likely to contribute causally to the death of patients, particularly those treated with mechanical ventilation (VAP). Risk factors for this infection fall into four categories: the underlying primary critical illnesses leading to ICU admission; coexisting medical illness; factors associated with therapies that are frequently used in the ICU; and malnutrition. Thus, some of the common conditions associated with nosocomial pneumonia include risk factors present on admission such as immunesuppressive illness, risk of aspiration (coma, impaired consciousness), serious comorbid illnesses (chronic heart or lung disease, renal failure, malignancy, diabetes mellitus), ARDS, malnutrition (serum albumin <2.2 mg per dL), obesity, older than 60 years, smoking and drug abuse, need for major surgery, and recent major trauma or burns. Other nonmodifiable risk factors that increase the risk of nosocomial pneumonia are treatment related such as prior antibiotic therapy, immune suppressive therapy (including corticosteroids), need for multiple transfusions, transport out of the ICU, mechanical ventilation with PEEP, tracheostomy, nasogastric tube use, supine position in the first 24 hours after admission, and intestinal bleeding prophylaxis [2,41]. The most important risk factor for nosocomial pneumonia is probably mechanical ventilation, explained later in the chapter.

HAP is currently the second most common nosocomial infection in the United States and is associated with high mortality and morbidity [2]. HAP accounts for up to 25% of all ICU infections and for more than 50% of the antibiotics prescribed [2]. The presence of HAP increases hospital stay by an average of 7 to 9 days per patient and VAP leads to an excess cost of more than $40,000 per patient [2]. Available data suggest that it occurs at a rate of between five and ten cases per one thousand hospital admissions, and that critically ill patients who develop VAP appear to be twice as likely to die compared with similar patients without VAP (pooled odds ratio [OR], 2.03; 95% confidence interval, 1.16 to 3.56) [9].

In ICU patients, nearly 90% of episodes of HAP occur during mechanical ventilation, referred to as VAP, when the illness develops after 48 hours of endotracheal intubation and ventilation. Intubation increases the risk of acquiring pneumonia by as much as 6- to 20-fold [2]. Older studies estimated that the risk of nosocomial pneumonia was 1% per day of mechanical ventilation, but other data show a risk of 3% per day for the first 5 days, 2% per day for days 6 to 10 days, and 1% per day for days 11 through 15 [42]. Although VAP occurs in 9% to 27% of all intubated patients [2], since many patients are intubated for only a short time, up to half of all VAP episodes begin within the first 4 days of mechanical ventilation (early-onset pneumonia) [2]. In the past, mortality rates were high in mechanically ventilated patients, with Craven et al. [43] reporting a 55% mortality rate in 49 patients with nosocomial pneumonia treated with mechanical ventilation, and Bryan and Reynolds [44] finding a 58% mortality rate in patients with bacteremic nosocomial pneumonia.

Recently, in the United States, there has been a focus on prevention of VAP, through the use of "ventilator bundles," and there have been numerous reports of "zero VAP" as a consequence of these efforts [45]. These bundles, which include daily assessment for weaning, daily interruption of sedation, elevation of the head of the bed, prophylaxis of deep vein thrombosis, and gastrointestinal bleeding, have been quite successful, but most studies have reported a reduction in the frequency of VAP, without associated reductions in mortality or antibiotic use. Thus, it is unclear if VAP is really being prevented, or if the disease is being diagnosed less often, especially given the subjective nature of the VAP definition, and the possibility of treating patients for another diagnosis. If VAP does occur, proper management can impact outcome, with several studies showing that management with a guideline-concordant therapy can improve outcomes [46,47].

The relation between pneumonia and ARDS is particularly interesting. In older studies, as many as one third of all cases of ARDS were the result of pneumonia [48], but secondary pneumonia was the most common nosocomial infection acquired by patients with established ARDS [2,11]. When patients with ARDS develop pneumonia, it is generally a late event, occurring after at least 7 days of mechanical ventilation [2], and when it occurs [11], it can be the start of a progressive downhill course characterized by multiple organ failure. In a European collaborative study of 583 patients with ARDS, pneumonia was the cause in 33% of cases and a complication in 34% [49]. When quantitative diagnostic methods were used in ARDS patients, Chastre et al. [50] found an incidence of 55% of VAP in patients with ARDS; however, there were no significant changes in survival between ARDS patients with VAP and those without VAP. All patients who developed VAP had a significantly longer duration of mechanical ventilation, regardless of whether they had coexisting ARDS.

Healthcare-Associated Pneumonia

The other type of pneumonia that has been described recently and may require ICU admission is HCAP. This entity refers to patients who develop infection while having contact with the healthcare environment, such as those residing in nursing homes, those treated in dialysis units, patients who have been in the hospital in the past 90 days, and those getting home infusion therapy of home wound care (Table 68.2), and some of these patients are at risk for infection with multidrug resistant (MDR) organisms. This has also been addressed in the ATS/IDSA guidelines as a form of HAP [2]. However, recent studies have shown that patients who qualify has having HCAP are a heterogeneous population, and that when HCAP patients

TABLE 68.2

HOSPITAL-ACQUIRED PNEUMONIA AND HEALTHCARE-ASSOCIATED PNEUMONIA: RISK FACTORS FOR MULTIDRUG RESISTANT ORGANISMS

Current hospitalization of ≥5 d
Antibiotic treatment in prior 90 d
High frequency of antibiotic resistance in the community/specific hospital unit
Immunosuppressive disease/therapy
Presence of multiple risk factors for healthcare-associated pneumonia
Hospitalization for 2 d or more in the preceding 90 d
Residence in a nursing home or extended care facility
Home infusion therapy (including antibiotics)
Chronic dialysis within 30 d
Home wound care
Family member with multidrug-resistant pathogen

Adapted from Niederman MS, Craven DE, Bonten MJ, et al: Guidelines for the management of adults with hospital-acquired, ventilator-associated, and healthcare-associated pneumonia. *Am J Respir Crit Care Med* 171:388–416, 2005, with permission.

are managed in the ICU, the frequency of MDR pathogens is much greater than when they are not as ill and do not need ICU care [51].

PATHOGENESIS OF PNEUMONIA

Normal Host Defenses

When an organism enters the respiratory tract, it encounters a host defense system designed to repel and remove it from every anatomic site in the airway. Pneumonia develops when the size of the organism inoculum overcomes the host defense system, when the organism is so virulent that it cannot be repelled, or when the patient is so impaired that he or she is unable to resist an organism type or inoculum size that could ordinarily be handled by a fully functioning host defense system.

The oropharynx is ordinarily free of enteric Gram-negative bacilli because salivary proteases, secretions, and local immunoglobulin-A (IgA) antibody prevent these bacteria from establishing a foothold on the mucosal surface. The intrinsic ability of the oral epithelium to bind or adhere to Gram-negative bacteria is poor in healthy people [52]. With a variety of acute illnesses, such as malnutrition, uremia, and general surgery, Gram-negative bacteria can bind more avidly to the oral epithelium, and colonization can occur [52].

The lower respiratory tract (starting beneath the vocal cords) has a complex host defense system that keeps this site sterile in normal people [2,3]. For this area to become infected, organisms must overcome the physical barrier of the vocal cords and the tracheobronchial protective mechanisms of cough, bronchoconstriction, airway angulation, and the upward transport of the mucociliary blanket [3]. As in the oropharynx, bacterial adherence is necessary for Gram-negative bacteria to colonize the tracheobronchial tree. Protective substances in respiratory secretions include IgA, the predominant immunoglobulin of the upper airway; IgG, which dominates in the lower respiratory tract; complement; lysozymes; surfactant; and fibronectin [3]. The resident phagocytic cell of the lower respiratory tract is the alveolar macrophage, but its function can be augmented by the production of inflammatory cytokines which can promote the recruitment of blood neutrophils and the development of cell-mediated and humoral immunity.

In the setting of focal lung infection, the cytokine inflammatory response is normally localized to the site of initial infection [53]. Severe pneumonia occurs when the inflammatory response is unable to be localized (due to overwhelming infection or inappropriate bilateral inflammation) or if the inflammatory response extends to the systemic circulation (sepsis syndrome). The innate immune response of the lung is organized to recognize pathogens and once this occurs, a cytokine response follows. Pathogen recognition is mediated by toll-like receptors for Gram-negative bacteria or by pathogen-stimulated production of interleukin 1 (IL-1) or tumor necrosis factor (TNF). Once pathogens are recognized through these mechanisms, nuclear factor κB is produced by inflammatory cells, which in turn leads to cytokine production that can recruit more inflammatory cells. In addition, the lower airway handles individual pathogens in specific ways. For example, *S. aureus* is removed by resident alveolar macrophages, whereas certain enteric Gram-negative bacteria and the pneumococcus require the recruitment of neutrophils (presumably in response to interleukin-8) to be cleared [53]. Cell-mediated immunity is required to resist infection with *L. pneumophila* and *M. tuberculosis*. Viruses are handled somewhat differently from bacteria, and important factors in defense against these agents include the alveolar macrophage, neutralizing antibodies (IgG, IgA, IgM), cytotoxic T lymphocytes, and cytokines such as interferon. Specific genetic immune impairments or acquired immune dysfunction can cause specific aspects of the inflammatory response to malfunction and lead to infection with specific, predictable pathogens.

How Microorganisms Reach the Lung

Bacteria and other infectious agents can reach the lung by inhalation from ambient air, hematogenously from distal sites of infection, by direct extension or exogenous penetration, and by aspiration from a colonized oropharynx and nasopharynx [2,3]. Inhalation is an uncommon route of organism entry except for pathogens such as *L. pneumophila*, viruses, and *M. tuberculosis*. Hematogenous spread can occur with septic emboli from such sites as the valves of the right cardiac chambers. Exogenous penetration is an unlikely route of bacterial entry but can occur, for example, with extension of an abdominal infection into the pleural space and then the lung parenchyma. Most pneumonias result when microorganisms are aspirated from a previously colonized oropharynx [2]. Nosocomial pneumonia is frequently preceded by Gram-negative bacillary colonization of the oropharynx [2]. The source of bacteria that colonize the upper airway is most likely the patient's own lower intestinal flora, but the nasal sinuses and stomach can also harbor bacteria that can subsequently reach the lung. The coexistence of nosocomial sinusitis and pneumonia has been documented, often with the same organisms, and both infections can be promoted by the presence of a nasogastric or nasotracheal tube [2].

In addition to promoting sinusitis, the endotracheal tube and the nasogastric tube can also serve as additional pathways for bacterial entry to the lung. Insertion of an endotracheal tube allows organisms direct access to the lung from the hands of the ICU staff, thereby avoiding the defense mechanisms present above the vocal cords. Any organisms that reach the inside of the endotracheal tube can proliferate to large numbers because this site is free from host defenses, and a biofilm commonly lines the interior of the endotracheal tube and can contain as many as 10^6 organisms per cm of the tube surface [54]. These organisms can reach the lung every time an intubated patient is suctioned [2]. Recently, this problem has been addressed by

developing new materials for endotracheal tubes that are antibacterial, one such device is a silver-coated endotracheal tube, which may be able to reduce the incidence of VAP, but has had no impact on mortality [55]. Another factor in VAP pathogenesis is the ventilator circuit tubing, which can easily be contaminated by large numbers of bacteria [2]. Interestingly, the ventilator circuits are usually not contaminated by the ventilator but rather by the patient, as the circuit becomes colonized in large numbers, as bacteria proliferate in the water condensate in the tubing. If handled carefully, the circuits are not a major source of pneumonia pathogens, and the incidence of pneumonia is not increased even if ventilator circuit tubing is never changed during the course of therapy [2]. The presence of an endotracheal tube can promote infection, and studies [2] have shown that when an endotracheal tube is present, some bacteria, particularly *P. aeruginosa*, can colonize the lower airway directly without first colonizing the oropharynx.

The gastrointestinal tract, particularly the stomach, can serve as a reservoir for bacteria, and several investigators have shown that Gram-negative bacilli can move retrograde from the stomach to the oropharynx and then antegrade into the lung [56]. The stomach can be the source of 20% to 40% of the enteric Gram-negative bacteria that colonize the trachea of intubated patients [56], but it is difficult to determine if these colonizing gastric bacteria also lead to pneumonia. One of the ways that the stomach can be an important source of pneumonic organisms is through the mechanism of reflux and aspiration. When a nasogastric tube is used for feeding, it can promote aspiration, especially if a large-bore tube is used with a bolus feeding method rather than with a continuous infusion of enteral nutrients, and if the patient is kept in a supine position [57]. When a nasogastric tube is present, it may promote pneumonia if the gastric contents have a pH above 4 to 6, as can occur with the use of antacids, H_2 blockers, and enteral feeding. An elevated pH can increase the number of Gram-negative bacteria in the stomach, increases to as many as 1 to 100 million per mL of gastric juice, and elevation of gastric pH has been reported as a risk factor for nosocomial pneumonia, although not in all studies [43,58]. The Canadian Critical Care Trials Group reported that acidified enteral feeds preserve gastric acidity and substantially reduce gastric colonization in critically ill patients; however, in this study, there was no impact on the incidence of pneumonia with this intervention [58]. Increases in gastric volume can be detrimental and promote aspiration, thus accounting for the observation that when continuous enteral feeding leads to an elevation of gastric pH (and presumably an elevation of gastric volume), the incidence of pneumonia is higher than when continuous feeding is used but does not raise pH [59]. Placing the feeding tube into the jejunum to avoid an elevation in gastric pH did not reduce the risk of pneumonia [60]. Another way to minimize the impact of the stomach and to avoid aspiration is to keep patients in a semierect position whenever possible, particularly because the supine position can favor aspiration when a nasogastric tube is in place [57].

Airway Colonization and Nosocomial Pneumonia

Colonization (the persistence of organisms in the absence of a host response and without an adverse effect to the host) of the respiratory tract by enteric Gram-negative bacilli is the first step toward the development of nosocomial pneumonia [2]. Risk factors for Gram-negative colonization of the upper and lower respiratory tract are similar and include antibiotic therapy, endotracheal intubation, smoking, malnutrition, general surgery, and therapies that raise gastric pH [3,52]. Additional risk factors for oropharyngeal colonization include azotemia, diabetes, coma, hypotension, advanced age, and underlying lung disease [52]. Additional risk factors for tracheobronchial colonization include chronic bronchitis, cystic fibrosis, ciliary dysfunction, tracheostomy, bronchiectasis, acute lung injury, and viral infection [52]. The distinction between colonization and infection in mechanically ventilated patients is less clear than in the past, with recognition and focus on ventilator-associated tracheobronchitis (VAT) [61]. Some patients who are mechanically ventilated can have high concentrations of pathogenic organisms in the tracheobronchial tree, in the absence of pneumonia, yet some may be clinically ill, and therapy could potentially prevent some from progressing to VAP.

One pathogenetic mechanism that links many of the clinical risk factors for upper and lower airway colonization is a cell–cell interaction termed bacterial mucosal adherence. Many clinical disease states can alter the oropharyngeal or tracheal epithelium, making the cell surface more receptive for binding by such bacteria as *P. aeruginosa* [52]. Diseases that result in an increased number of oropharyngeal and tracheal cell bacterial receptors are many of the same processes that promote colonization of these sites [52]. One study of intubated patients demonstrated the rapidity with which the endotracheal tube itself became colonized with enteric Gram-negatives and found that colonization took place despite the use of bacterial filters in the ventilator circuit [62]. Colonization is a common finding in intubated patients, and the presence of potential pathogens in the respiratory secretions of intubated patients is to be expected, and does not require therapy unless there are clinical signs of infection.

Host Defense Impairments in Acute and Chronic Illness that Predispose to Pneumonia

Many systemic diseases increase the risk of pneumonia as a result of disease-associated malfunctions in the respiratory host defense system, including ARDS, sepsis, CHF, malnutrition, renal failure, diabetes mellitus, chronic liver disease, alcoholism, cancer, and collagen vascular disease [63]. For example, sepsis can lead to a number of inflammatory events that interfere with respiratory tract immune defenses. In addition, many illnesses can be complicated by pneumonia because they require therapy with medications that interfere with immune function. Several studies have shown that acute and chronic malnutrition (Table 68.3) can increase the risk of bacterial and viral infections both in and out of the hospital. Genetic polymorphisms may explain why patients who have certain inherited patterns of immune response are more prone to severe forms of pneumonia than others, and even mortality. CAP severity is increased with genetic changes in the IL-10-1082 locus that are often present along with changes in the TNF-α-308 locus. Another genetic change associated with an increased risk of septic shock from CAP is a modification in heat shock protein 70-2

TABLE 68.3

LUNG HOST DEFENSE IMPAIRMENTS WITH MALNUTRITION

Increased tracheal and buccal cell adherence
Altered macrophage function and migration
Reduced recruitment of neutrophils
Impaired cell-mediated immunity and T-cell depletion
Diminished secretory immunoglobulin A
Complement deficiency

[64]. Currently, there are large number of genes that can affect the severity and outcome of CAP, but the clinical application of this is not defined. One recent observation about gender differences in the immune response was that men have a higher degree of systemic inflammation on admission for CAP (higher levels of TNF, IL-6, and IL-10), and that higher levels of these mediators increased pneumonia mortality risk [65].

ETIOLOGY OF PNEUMONIA

Community-Acquired Pneumonia

Even with extensive diagnostic testing, a specific etiologic agent can be identified in only approximately 50% of pneumonias that develop outside of the hospital, although the rate of pathogen recovery may be higher in intubated and mechanically ventilated patients [66,67]. Although the exact incidence of viral pneumonias is unknown, these agents may account for up to one third of all community-acquired cases. The most common pathogen identified in pneumonias arising out of the hospital is the pneumococcus, followed by *M. pneumoniae*, *L. pneumophila*, *H. influenzae*, *C. pneumoniae*, anaerobes, *S. aureus*, and enteric Gram-negative bacilli, although the exact incidence of each pathogen varies depending on a number of factors. These include the severity of the acute illness, the age of the patient, and the types of comorbidity present in a given patient population [4,67]. In the elderly, although pneumococci are still the most common pathogens, enteric Gram-negative organisms may be responsible for 20% to 40% of all cases of pneumonia, and anaerobes and *H. influenzae* are other common agents [68]. However, age alone has little impact on the bacterial etiology of CAP, but rather, the comorbid illnesses that become more common in the elderly affect bacteriology [69]. The most common CAP pathogens leading to ICU admission (severe pneumonia) are pneumococcus, *L. pneumophila*, epidemic viruses (influenza), *S. aureus* (including MRSA), and enteric Gram-negative bacilli, including, in some patients, *P. aeruginosa* [4,67,68]. The incidence of CAP caused by community-acquired MRSA (CA-MRSA) is on the rise, but the exact frequency and the impact on mortality and other outcomes remain to be defined [70]. Although Gram-negatives are more common in VAP and HCAP than in CAP, risk factors for Gram-negative pneumonia (in addition to nursing home residence, an HCAP risk factor) are cardiac disease, smoking history, and clinical features of severe illness including hyponatremia, septic shock, and severe tachypnea [71].

Other pathogens that can lead to respiratory failure include *H. influenzae*, pathogens associated with aspiration (such as anaerobes), *P. jiroveci*, *tuberculosis*, varicella, and respiratory syncytial virus. Mixed infection occurs in more than 10% of patients with CAP requiring hospitalization, and in one study, in patients with mixed CAP, *S. pneumoniae* was the most prevalent microorganism (44 out of 82; 54%) [72]. In that study, the most frequent combination was *S. pneumoniae* with *H. influenzae* (17 out of 82; 21%), and influenza A occurred with *S. pneumoniae* in 5 out of 28 (18%). Of note, patients with mixed pyogenic pneumonia more frequently developed shock when compared with patients with single pyogenic pneumonia (18% vs. 4%) [72].

When evaluating a patient with pneumonia, it is important to understand the status of each individual's respiratory host defense system to predict which possible pathogen is most likely (Table 68.4). Thus, CAP in a previously healthy person is most likely due to a pathogen of such intrinsic virulence that it can overcome even an intact host defense system. These pathogens include *S. pneumoniae*, *Legionella* sp, *S. aureus*, and *M. pneumoniae*. Certain agents should be suspected in specific clinical settings. If the patient has a serious underlying illness, then organisms of less intrinsic virulence that would ordinarily be eliminated by a normal host can be responsible. When an alcoholic has pneumonia, anaerobes and *Klebsiella pneumoniae* become more likely; those with chronic bronchitis may be infected with nontypeable *H. influenzae* and *Moraxella catarrhalis*; cardiac patients commonly have pneumococcal infection; those with cystic fibrosis are commonly infected by *S. aureus* and *P. aeruginosa*; and those with risk factors for aspiration can have enteric

TABLE 68.4

LIKELY PATHOGENS FOR PNEUMONIA IN THE CRITICALLY ILL

Database	Suspected pathogen
Alcoholism—acute or chronic	*Streptococcus pneumoniae* (including DRSP), anaerobes, Gram-negative bacilli, *Mycobacterium* sp
Chronic obstructive pulmonary disease	*S. pneumoniae, Haemophilus influenzae, Moraxella catarrhalis*
Recent viral infection	*S. pneumoniae, Staphylococcus aureus* (including MRSA), *H. influenzae*, Gram-negative bacilli
Nursing home (age >75 y)	Gram-negative bacilli (including resistant ones such as *Pseudomonas aeruginosa, Acinetobacter* spp), *S. pneumoniae, H. influenzae*, aspiration (anaerobes), *S. aureus, Chlamydophila, Mycobacterium tuberculosis*
AIDS (risk groups: intravenous drug abuser, hemophilia, homosexual)	*S. pneumoniae, Salmonella*, cytomegalovirus, *H. influenzae, Cryptococcus, P. jiroveci*, anaerobes, *M. tuberculosis*
Hospital acquired	Gram-negative bacilli (including *P. aeruginosa*), *S. aureus* (including MRSA)
High-risk aspiration	Anaerobes (if aspirate while not intubated), Gram-negative bacilli, chemical pneumonitis
Cardiac disease	*S. pneumoniae*, Gram-negative bacilli
Neutropenia	*P. aeruginosa, Aspergillus* sp, Gram-negative bacilli
Recent antibiotic therapy	DRSP, *P. aeruginosa*, MRSA (especially in HAP)
Postinfluenza	Pneumococcus, *S. aureus* (including MRSA), enteric Gram-negatives
Endobronchial obstruction	Anaerobes, Gram-negative bacilli
Structural lung disease (cystic fibrosis, bronchiectasis)	*P. aeruginosa, P. cepacia, S. aureus*

AIDS, acquired immunodeficiency syndrome; DRSP, drug-resistant *S. pneumoniae*; HAP, hospital-acquired pneumonia; MRSA, methicillin-resistant *S. aureus*.

TABLE 68.5

HISTORICAL AND PHYSICAL FEATURES USEFUL IN PNEUMONIA DIAGNOSIS

Clinical setting	Organisms
Environmental contact	
Birds, bats	*Chlamydophila psittaci, Cryptococcus neoformans, Histoplasma capsulatum*
Bird droppings	*C. psittaci, H. capsulatum* (histoplasmosis)
Ungulates	*Coxiella burnetii* (Q fever)
Hunting (animal and insect bites)	*Yersinia pestis* (plague), *Francisella tularensis* (tularemia)
Infected hides	Anthrax
Travel or location	
Southeast Asia	*Pseudomonas pseudomallei*, SARS (coronavirus)
Southwestern United States	*Coccidioides immitis* (coccidioidomycosis)
Midwestern United States	*H. capsulatum* (histoplasmosis)
Prison environment	*Mycobacterium* sp (tuberculosis)
Poor dental hygiene	Anaerobes

SARS, severe acute respiratory syndrome.

Gram-negative bacterial or anaerobic lung infection. Other associations are listed in Table 68.4. Certain historical information can be valuable, such as an appropriate travel or exposure history that suggests specific etiologic pathogens (Table 68.5).

Nosocomial Pneumonia

Both VAP and HCAP may be caused by a variety of Gram-positive and Gram-negative bacteria, many of which are multidrug resistant (MDR). These infections may be polymicrobial and are seen more often in patients with ARDS than in other ventilated patients [73]. Viral or fungal pathogens are rarely causative in immunocompetent hosts [74,75]. Nosocomial viral infections can occur if infected staff members come to work when their illness is incubating. Common pathogens include aerobic Gram-negative bacilli, such as *P. aeruginosa*, *Escherichia coli*, *K. pneumoniae*, and *Acinetobacter* species. Gram-positive infections include *S. aureus*, particularly MRSA, which has been increasing in the United States [76]. Pneumonia due to *S. aureus* is more common in patients with diabetes mellitus, head trauma, and ICU patients. In the National Nosocomial Infections Surveillance (NNIS) system data examining changes in the organisms from 1986 to 2003, Gram-negative aerobes persisted as being the most frequent organisms in HAP (65.9%), with little change in their distribution over this period, except for a rise in the proportion of *Acinetobacter* in 2003, from 1.5% in 1975 to 6.9% in 2003. The commonest Gram-negative organism reported was *Pseudomonas* (18.1%), and others included *Klebsiella* spp (7.2%), *Acinetobacter* spp (6.9%), and *E. coli* (5%). The Gram-positive organisms included *S. aureus* (included *Enterobacter* spp (10%), 27.8%), coagulase-negative *Staphylococcus* (1.8%), and *Enterococci* (1.3%) [77]. Among patients who have a prolonged hospital stay, therapy with corticosteroids or antibiotics, need for long-term mechanical ventilation, and in those with ARDS, the pathogen most likely to cause pneumonia is *P. aeruginosa*, but in many hospitals, *Acinetobacter* is becoming an increasing concern. Contamination with *Legionella* sp in the water system can lead to infection, especially if patients are being treated with corticosteroids. Another pathogen that should be considered when nosocomial pneumonia arises in the setting of corticosteroid therapy for COPD is *Aspergillus* sp. [78]. HAP involving anaerobic organisms may follow aspiration in nonintubated patients but is rare in patients with VAP [2]. Gram-negative organisms are more common with aspiration, especially in the healthcare environment, including the nursing home [51,68]. Oropharyngeal commensals such as viridans group streptococci, coagulase-negative staphylococci, *Neisseria* species, and *Corynebacterium* species can produce infection in immunocompromised hosts and some immunocompetent patients [2]. The identity of specific MDR pathogens causing HAP varies from one ICU to another, and depends on the patient population treated and the degree of prior antibiotic exposure, but the dominant organisms change over time [2,77]. Risk factors for infection with MDR pathogens are summarized in Table 68.2.

Elderly patients represent a diverse population of patients with pneumonia, particularly HCAP. Elderly residents of long-term care facilities have been found to have a spectrum of pathogens similar to late-onset HAP and VAP [2,51,79].

In patients aged 75 years and older with severe pneumonia, El-Solh et al. found *S. aureus* (29%), enteric Gram-negative rods (15%), *S. pneumoniae* (9%), and *Pseudomonas* species (4%) as the most frequent causes of nursing home–acquired pneumonia [74]. In this population, MDR organisms are most likely in patients with a history or prior antibiotic therapy and poor functional status. Scant data are available about HAP in patients who are not mechanically ventilated. In general, the bacteriology of nonventilated patients is similar to that of ventilated patients, including infection with MDR pathogens. The frequency of resistant Gram-negative bacilli is often high enough in nonventilated patients that they should be accounted for in designing an empiric therapy regimen. Sopena et al. [80] looked at a multicenter population of non–ICU admitted patients with HAP in Spain and described that the most common etiologies were *S. pneumoniae*, *L. pneumophila*, *Aspergillus* sp, *P. aeruginosa*, and several Enterobacteriaceae. Another study therapy for nonsevere HAP and HCAP [81] found among 303 patients, 53.5% had an identifiable etiology, with *Enterobacteriaceae* in 19.5%, followed by *S. pneumoniae* in 12.9% and *S. aureus* in 11.6%. In a study that examined both HAP and VAP in the same hospital, patients with VAP had infection with non-Enterobacteriaceae Gram-negatives (*P. aeruginosa* and *Acinetobacter* spp) more commonly than HAP patients, while *S. pneumoniae* was more common in HAP patients [82].

The bacteriology of HCAP is widely variable depending on which study is examined [51]. Current data show that HCAP is a heterogeneous disease, including a wide range of patients,

some severely ill and others not. In the severely ill population, often treated in the ICU, MDR Gram-negatives and MRSA are common and must be considered when designing empiric therapy. These resistant organisms are a particular concern in severely ill patients with other risk factors, including poor functional status, prior antibiotic therapy, immune-suppressive therapy, and a history of recent hospitalization. In one study, focusing on HCAP with nearly half of the patients treated in the ICU [15], the most common pathogens were *S. aureus*, then *S. pneumoniae*, followed by *P. aeruginosa*.

CLINICAL FEATURES OF PNEUMONIA

General Features of Community-Acquired Pneumonia

The signs and symptoms of pneumonia depend on both host and bacterial factors, and in the past, the presentation was classified as being either "typical" or "atypical," but data have shown that this approach is not clinically useful [4]. In several studies, the clinical presentations of CAP (including severe CAP) have overlapped enough among all etiologies that clinical features could not be used to identify the likely etiologic pathogen or to guide initial antibiotic therapy [4,7,69]. The common clinical features of CAP include fever, cough, sputum production, dyspnea, and occasionally pleuritic chest pain. Gastrointestinal symptoms that may be seen include nausea, vomiting, and diarrhea, which were regarded previously as "atypical features." In the elderly patient, pneumonia can have a nonrespiratory presentation with symptoms of confusion, falling, failure to thrive, altered functional capacity, or deterioration in a preexisting medical illness, such as CHF.

Because many of the symptoms of pneumonia result from the host inflammatory response, patients who have altered immune function have less dramatic symptoms. Thus, those with advanced age, chronic lung disease, cardiac disease, renal failure, diabetes, immunosuppressive therapy, and other chronic illnesses have not only an increased incidence of pneumonia but also a less distinct and subtler clinical presentation. In this patient population, fever has been absent in up to 10% of those with bacteremic pneumonia [83].

General Features of Nosocomial Pneumonia

One of the major controversies in critical care medicine is how to determine when hospital-acquired (particularly ventilator-associated) pneumonia is present. On clinical grounds alone, the diagnosis is imprecise and is a particular problem in those with ARDS or lung contusion. Fagon et al. [84], using quantitative cultures collected with a protected specimen brush (PSB) to define this infection in mechanically ventilated patients, have reported that up to two thirds of cases that are diagnosed based on clinical criteria alone are not truly pneumonia. Most clinical definitions of nosocomial pneumonia require the patient to be hospitalized 48 to 72 hours before the onset of purulent sputum, leukocytosis, fever, and a new and persistent infiltrate. If these features exist along with isolation of a potential pathogen from the sputum, then this organism is deemed to be responsible for the infection. The findings of a positive blood culture or radiographic cavitation add to the likelihood of pneumonia being present. Positive blood cultures in nosocomial pneumonia can support the diagnosis, but if the organism present in the blood culture is different from the one in the respiratory tract, the bacteremia may be secondary to an extrapulmonary infection [2]. One approach to the clinical definition of VAP, developed by Pugin et al. [85], has been to use a scoring system that weights the likelihood of pneumonia using six clinical variables: fever, white blood cell count and differential, the presence of pathogens in the sputum, sputum purulence, radiographic patterns, and oxygenation changes. When this clinical pulmonary infection score (CPIS) has been used, the clinical and quantitative bacteriologic definitions of pneumonia have correlated very well. These observations suggest that there may still be a role for careful clinical judgment in the diagnosis of this confusing infection.

In the presence of diseases such as ARDS, atelectasis, pulmonary embolism, lung contusion, and CHF, all of which may be associated with lung infiltrates, pneumonia may be overlooked, or these processes may be incorrectly diagnosed as lung infection. In addition, the elderly and immunosuppressed may have few clinical findings when pneumonia develops in the hospital. Limited sputum production due to impaired immunologic status and mobilization of leukocytes compound the difficulties in diagnosis. Conversely, those on a mechanical ventilator with VAT may have purulent sputum, fever, and pathogens colonizing the sputum but not have invasive parenchymal lung infection. The use of biomarkers, both in the serum and in the respiratory secretions, may help in making this difficult diagnosis. In patients with VAP, the role of biomarkers to corroborate the clinical diagnosis is being studied. To date, studies have used PCT [86], C-reactive protein [87], soluble triggering receptors expressed on myeloid 1 (STREM) [88], and IL-6 [89], among others.

DIAGNOSTIC APPROACH TO THE PATIENT WITH SEVERE PNEUMONIA

Once the presence of severe pneumonia has been defined, the patient should be categorized by place of origin of infection, defining the illness as CAP, HCAP, or HAP (including VAP). Then the immune competence of the patient, the types of comorbid diseases present, and the existence of risk factors for specific pathogens should be defined to identify the most likely etiologic pathogens. Historical data, physical examination, and laboratory findings pertinent to diagnoses will also be helpful in determining which etiologic agent is responsible and what specific therapy should be instituted (see Tables 68.4 and 68.5). For example, contact with animals, especially birds, rats, and rabbits, can suggest the diagnosis of psittacosis, tularemia, and plague, respectively.

Historical Information

The history can be used to determine if the patient has pneumonia as the cause of his or her acute illness, recognizing that certain populations, such as the elderly, may have an altered, nonclassical presentation of pneumonia. In the elderly and compromised host, the infection may be heralded only by lethargy and confusion [69]. In the compromised host with malignancy or immunosuppressive therapy, the presentation may be so stunted that pneumonia may be discovered only serendipitously at autopsy.

Hemoptysis is an important historical feature, since it implies tissue necrosis and is most common with pyogenic streptococcal pneumonia (groups A to D), anaerobic lung abscess, *S. aureus*, necrotizing Gram-negative organisms, and invasive aspergillosis. Microaspiration of anaerobic organisms leading to pneumonia is more likely with a history of preexisting severe periodontal disease or with a history of seizure disorder,

TABLE 68.6

EXTRAPULMONARY FINDINGS IN PNEUMONIA

Findings	Organisms
Dermatologic findings	
Herpes labialis	*Streptococcus pneumoniae*
Erythema multiforme	*Mycoplasma* sp, *Chlamydophila psittaci*
Erythema nodosum	*Mycobacterium tuberculosis, Coccidioides immitis*
	Histoplasma capsulatum
Skin nodules	*Nocardia* sp
	Aspergillus sp
	Coccidioides immitis
	Blastomyces sp
Pharyngitis, bullous myringitis	*Mycoplasma* sp
Splenomegaly	*Francisella tularensis*
	C. psittaci
	Coxiella burnetii (Q fever)
Pleural effusion	*Haemophilus influenzae*
	S. pneumoniae
	Pyogenic streptococci
	Aspergillus sp
	F. tularensis

altered consciousness, or esophageal obstructive disease. Extrapulmonary symptoms may give clues to specific etiologic agents, with diarrhea and abdominal discomfort being seen in patients with *Legionella* sp and otitis media and pharyngitis with *M. pneumoniae* (Table 68.6).

In the patient with nosocomial pneumonia, the history should focus on whether the patient has recently received antibiotics and how long the patient has been in the hospital prior to the onset of infection. Both are risk factors for infection with MDR Gram-positive and Gram-negative bacteria. In addition, the specific antibiotics used in the past 2 weeks should be recorded, since the pathogens causing the current infection are likely to be resistant to those agents [2,4]. Other risk factors for MDR pathogens that can be present in those with HAP and HCAP include hospitalization in the past 90 days, poor functional status, and immunosuppressive therapy (including corticosteroid use).

Physical Examination

The physical examination is valuable for suggesting the presence of pneumonia and in grading its severity. Tachypnea (>20 breaths per minute) may be the earliest sign of pneumonia in the elderly, and findings of consolidation are more specific for pneumonia than crackles, especially in the ICU [90]. In patients with CAP, an admission respiratory rate greater than 30 breaths per minute is an important negative prognostic feature, and in some studies mortality increases dramatically when respiratory rate exceeds this level [91]. Signs of pleural effusion are particularly common in *H. influenzae*, pneumococcal, streptococcal, and aspergillus pneumonia, where pleural friction rubs may be detected. Pleural involvement can be seen, although less often, in *Legionella* and *Mycoplasma* pneumonia. Relative bradycardia is a frequent finding in many pneumonias caused by *Mycoplasma*, *Legionella*, and *Chlamydophila* organisms [92].

Dermatologic manifestations (erythema nodosum, erythema multiforme, and skin nodules) may be observed with *Mycoplasma*, fungal, *Nocardia*, and tuberculous infections. Horder's spots (pale macular rash), long considered part of the presentation of psittacosis, should lead the clinician to look for other evidence of this infection. Ecthyma gangrenosum, an indurated, round skin lesion with a central dark area surrounded by erythema, is characteristic of Gram-negative septicemia, especially with *P. aeruginosa*. Central nervous system abnormalities can be found in infections with pneumococcus, *M. tuberculosis*, *H. influenzae*, Gram-negative organisms, cryptococci, *Aspergillus* sp, *Legionella* sp, *Toxoplasma gondii*, varicella zoster, and cytomegalovirus (CMV). Other physical findings that narrow the differential diagnosis include splenomegaly in the case of psittacosis and tularemia, herpes labialis in pneumococcal infection, bullous myringitis with *M. pneumoniae* infection, and lymphadenopathy with tularemia. The predictive value of many of these observations has not been evaluated rigorously (Table 68.6).

Routine Diagnostic Testing

Routine Laboratory Testing

The IDSA/ATS guidelines for CAP recommend a relatively streamlined evaluation, including chest radiograph, routine blood chemistries and blood counts, blood cultures (in the critically ill), assessment of oxygenation (oximetry or blood gas), and a clinical evaluation of severity of illness. The routine use of sputum culture or Gram stain of sputum is not recommended, reserving these tests for the patient who is at risk for infection with unusual or drug-resistant organisms. If a sputum sample is obtained, it should be prior to therapy, rapidly transported to the lab, and of good quality with little evidence of oral contamination. For the critically ill, intubated patients should have an endotracheal aspirate sent for culture, and *Legionella* and pneumococcal urinary antigen testing should be considered. The routine use of serologic testing is not encouraged [4]. The impact of diagnostic testing in patients with severe CAP remains uncertain, and several studies have shown that even if the etiologic diagnosis is known, outcome may not be affected, whereas the use of early and effective empiric therapy has been associated with an improved outcome [4,33]. However, Rello et al. [92] have shown that knowing the etiologic pathogen can help to focus and simplify treatment in nearly one third of cases of severe CAP.

Most routine laboratory results are not specific for individual pathogens, and the focus of diagnostic testing is to assess disease severity. Extremes of white blood cell count (<4,000 or >30,000 per mm^3) may indicate overwhelming sepsis and may be a poor prognostic finding [4]. Elevated liver function tests are not a specific finding but can be seen in a variety of viral and bacterial pneumonias, including those associated with *Legionella* sp, *M. tuberculosis*, *Mycoplasma* sp, Q fever, tularemia, and psittacosis, as well as in pneumococcal infection. Similarly, electrolyte disturbances, including hypophosphatemia and hyponatremia, are not predictive of a specific pathogen in the individual patient with pneumonia, but hyponatremia (<130 mEq per L) on admission may predict a poor outcome [93].

Serology, Urinary Antigen, and PCR Testing

As mentioned earlier, routine serologic testing is not recommended because results are rarely positive at the time of presentation (i.e., convalescent serologic testing is usually needed), and even if positive, results are usually not available during the first 24 to 48 hours of critical illness [4]. Serologic responses are useful for retrospective epidemiologic purposes to document viral and so-called atypical pathogen infection and may be useful

if the patient is not responding to appropriate empiric therapy (discussed later). Many patients with CAP have serologic evidence for recent atypical pathogen infection, but in the setting of an illness like *Legionella* pneumonia, convalescent titers are essential and less than 10% of those with acute illness have a positive serologic result. To make the diagnosis of *Legionella* pneumonia acutely, urinary antigen testing has the highest yield (approximately 50%), but is specific for serogroup I infection, and is the test that is most likely to be positive early in the disease [4]. The direct immunofluorescent stain of sputum for *L. pneumophila* has a sensitivity of between 25% and 50% and a specificity of more than 90% for this organism. The urinary antigen for the detection of pneumococcal pneumonia has also been described for patients with severe disease, asplenia, liver disease, alcoholism, or leukopenia. Genetic probes for specific viral DNA and RNA are available for CMV, varicella zoster, herpes simplex, influenza virus, and adenovirus. In one study, real-time polymerase chain reaction (PCR) for viruses and atypical pathogens was more sensitive than conventional methods, and results were obtained in a clinically relevant time period. Microbiological diagnoses were determined for 52 (49.5%) of 105 patients by conventional techniques and for 80 (76%) of 105 patients by real-time PCR, and the time to obtain the result of real-time PCR could be reduced to 6 hours. In addition, patients with more severe infection had mixed infection identified more commonly by PCR than by conventional techniques (10.2% with conventional techniques, compared with 35% with PCR diagnosis), and some of these mixed infections involved viral pneumonia [94]. Further development of this technology may change the diagnostic approach to CAP in the future.

Chest Radiographic Interpretation

The chest radiograph is essential for the diagnosis of pneumonia in the critically ill patient (Table 68.7), and the use of pattern reading can help to narrow the differential diagnosis of CAP and HAP, particularly when used in concert with other available information. For example, the rapid development of a diffuse alveolar pattern frequently implies a hematogenously disseminated infection such as varicella or CMV, or the development of ARDS as a pneumonic complication. Hyperinflation is characteristic of respiratory syncytial virus pneumonia. A more subacute presentation of diffuse alveolar infiltrates may represent hematogenous dissemination of tuberculosis. *P. jiroveci* must be considered in the setting of a diffuse alveolar or reticulonodular pattern in groups at risk for HIV infection. Noninfectious causes of pulmonary infiltrates such as heart failure, bronchiolitis obliterans and organizing pneumonia (BOOP), drug toxicity, and lymphangitic carcinomatosis can also frequently present in this fashion. Focal infiltrates (i.e., confined to single segments or lobes) are most likely to represent bacterial pneumonia related to microaspiration into a particular area of the lung.

Acute bacterial pneumonias generally progress more rapidly (hours to days) than fungal or mycobacterial infections (days to weeks). Pleural effusions occur commonly in *H. influenzae* pneumonia (>50%) and pneumococcal infection (25%) but can also be seen in patients with group A streptococcal pneumonia. Cavitation can occur in both infectious and noninfectious lung disease, but the finding of multiple cavitary nodules suggests septic embolization from right-sided endocarditis. Rapid cavitation is also common in Gram-negative pneumonias, whereas a subacute course with cavitation suggests anaerobic or mycobacterial infection. Cavitations and necrotizing pneumonia also are present in CA-MRSA pneumonia, and its presence is often used to guide initial empirical antibiotic treatment. Occasionally, ventilator-associated bacterial pneumonia can progress rapidly and fatally, emphasizing the need for timely recognition and therapy. Chronic cavitation (weeks to months) is more likely due to a noninfectious problem, such as carcinoma, lymphoma, or Wegener's granulomatosis, especially in the absence of the systemic signs of acute infection.

The limitation of the chest radiograph in the critically ill patient is considerable, especially for the detection of VAP, when the clinician must rely on a portable film, which may not show findings very clearly. Also, in the ICU, coexisting and preexisting lung disease may obscure the findings of pneumonia. A recent study showed that chest radiographs are of limited value in predicting the causative pathogen in CAP, but are useful in determining the extent of pneumonia and detecting complications such as parapneumonic effusion [95].

Sputum Examination and Evaluation of Other Respiratory Secretions

Although Gram stain of the sputum has been the traditional first step in the evaluation of patients with suspected

TABLE 68.7

RADIOGRAPHIC PATTERNS IN DIAGNOSIS OF PNEUMONIA

Diffuse infiltrates

		Wegener's granulomatosis

pneumonia, this is problematic in the critically ill patient who is not intubated and may be unable to expectorate. When a specimen is obtained, interpretation depends on the quality of the sample and on the criteria used to define a "positive" sample. Although no studies correlate Gram stain findings to alveolar cultures in patients with pneumonia, the goal is to evaluate respiratory secretions from deep in the lower airway, and such a specimen from a nonintubated patient should have more than 25 polymorphonuclear cells and less than 10 epithelial cells per low-power field. When such criteria are met and intracellular organisms are identified, a bacterial density above 10^5 colony-forming units per mL of secretions is usually present [4]. The presence of elastin fibers on potassium hydroxide staining, along with a positive Gram stain, is more suggestive of pneumonia than airway infection or colonization. In addition to not always being able to distinguish airway colonization from pneumonia, the sputum Gram stain may be falsely negative up to 50% of the time compared with blood cultures. Some findings in sputum may suggest specific etiologies. For example, an inflammatory Gram stain (polymorphonuclear cells) without organisms in a patient with pneumonia is presumptive evidence of an atypical (*Legionella* or *Mycoplasma*) or viral cause. Gram stain may be best used to broaden initial empiric therapy, rather than to narrow it, especially if an unusual pathogen that is not routinely treated is thought to be present. For example, the finding of Gram-positive cocci in clusters in a patient with influenza would lead to empiric therapy for *S. aureus*. The use of special stains for tuberculosis and silver or Giemsa staining for *P. jiroveci* may provide definitive evidence for these organisms. With the use of rapid point-of-care diagnostic tests for influenza virus, treatment and chemoprevention can be offered. Rapid influenza can sometimes differentiate influenza A from influenza B and this can guide treatment decision. Other diseases caused by agents of bioterrorism and endemic diseases can be identified with the use of examination of respiratory secretions.

Culture

A definitive etiologic diagnosis of pneumonia can be made if cultures of blood, pleural fluid, or spinal fluid are positive in the presence of a lung infiltrate and a compatible clinical picture. Bacteremia is uncommon in most pneumonias, occurring in less than 15% of patients with CAP, in 20% of pneumococcal infections, and in only 8% to 15% of nosocomial pneumonias [44]. In nosocomial pneumonia, the presence of bacteremia may imply an extrapulmonary infection, especially if the organism present in the blood culture is different from the one in the respiratory tract. Blood cultures are indicated in all patients admitted to the ICU with a diagnosis of pneumonia but are most valuable if collected prior to antibiotic therapy. In patients without severe illness, the yield is lower, and findings can be misleading (false-positive rate may exceed the true positive rate) [96]. Sputum cultures can be difficult to interpret because of the problem in separating infection from colonization in the critically ill. In a study of bacteremic nosocomial pneumonia, sputum culture yielded both false-positive and false-negative findings compared with blood cultures, with only 49% of the cases having the same organism recovered from both blood and sputum [44]. Sputum cultures are sensitive but not specific and are often unable to distinguish colonizing from infecting pathogens. In intubated patients, colonization is present after several days, so the culture should be interpreted in the clinical context of the patient, and a sample should not be cultured in the absence of clinical signs of infection.

Viruses may be cultured from respiratory secretions, but this procedure may take up to 20 days, depending on the virus. Thus, cytologic evidence of viral infection that can be recognized sooner may provide helpful information. For example, inclusion bodies and multinucleated giant cells are suggestive of CMV or herpesvirus infection.

Invasive Diagnostic Sampling and Quantitative Cultures

Because of the inherent problems distinguishing colonizing from infecting pathogens in samples of lower respiratory tract secretions, investigators have advocated for the collection of deep respiratory secretions through invasive (bronchoscopic) or semi-invasive (catheter-lavage) means, combined with analysis of the results using quantitative cultures. Early efforts at invasive sampling involved transtracheal aspiration in a nonintubated patient, using a polyurethane catheter, but the technique was difficult and potentially dangerous and led to false-positive results more than 20% of the time.

Percutaneous needle aspiration of the lung in an area of infiltrate has also been studied, but it is limited by a high incidence of false-negative results and an unacceptable complication rate, including pneumothorax in up to 30% of patients and a 10% rate of hemoptysis. Although open lung biopsy is the unequivocal standard for the diagnosis of infection, it has been applied primarily in the immunocompromised host with rapidly advancing, life-threatening infections. *Aspergillus*, CMV, herpes simplex, and *T. gondii* infections are more readily diagnosed by open lung biopsy than by other described techniques. In patients with CAP, open lung biopsy is rarely needed, and its potential for demonstrating a treatable infection that will alter outcome is low, and similar findings have been reported when it is used in patients with HAP [97] (Table 68.8) (see Chapter 69).

Bronchoscopic sampling has been used in the critically ill, particularly in those who are immunosuppressed or who already have an endotracheal tube in place, such as patients with VAP and severe CAP [2,84,98]. Cultures are obtained by using the bronchoscopically directed PSB, or bronchoalveolar lavage (BAL), and the samples cultured quantitatively. When PSB samples are cultured quantitatively, patients with nosocomial pneumonia will have greater than 10^3 organisms per mL of respiratory secretions. When BAL is used, a threshold concentration of 10^4 to 10^5 organisms per mL is used to define pneumonia [98]. In some studies, lower airway cells recovered by lavage have been examined for the presence of intracellular organisms, and the finding of more than 5% to 25% of cells with intracellular bacteria may predict the diagnosis of pneumonia, confirmed by PSB. Quantitative endotracheal aspirates have also been used, particularly patients with severe nursing home pneumonia, and this technique has a very good correlation with results of BAL if a threshold of 10^4 colony-forming organisms per mL is used [2,99]. Although the role of bronchoscopy in patients with suspected VAP is still controversial, most investigators agree that BAL is valuable in establishing a nonbacterial cause of infection, especially in the immunocompromised host or the patient with HIV infection, where it can reliably diagnose *P. jiroveci* pneumonia and CMV infection [100].

Quantitative cultures have been proposed as the most accurate way to establish the presence of VAP and to define the etiologic pathogen. Although the clinical diagnosis of VAP has been much maligned, it may be very accurate, particularly if it is objectively defined by calculating the CPIS and if the score incorporates a Gram's stain of a lower respiratory tract sample [101]. Once the clinical diagnosis of VAP is made, a culture is needed to identify the etiologic pathogen, but this culture could be quantitative or semiquantitative (light, moderate, or heavy growth), and collected as an endotracheal aspirate or via bronchoscopy or catheter lavage. Quantitative culture-based diagnosis may not be more accurate than clinical diagnosis, and quantitative cultures have a number of methodologic

TABLE 68.8

DIAGNOSTIC TECHNIQUES IN PNEUMONIA

Test	Advantages	Disadvantages
Expectorated sputum Gram stain	Easy to perform; rapidly available; inexpensive	High false-positive and false-negative rates
Expectorated sputum culture	Easy to obtain	High false-positive and false-negative rates
Blood culture	High specificity	Low sensitivity, not always a lung source
Transtracheal aspiration	Less contamination than expectorated sputum	High false-positive rates in colonized patients; bleeding; impractical to do
Needle aspiration (percutaneous)	High specificity; useful for children and malignancy	High risk of pneumothorax especially in patients with chronic obstructive pulmonary disease and in ventilated patients; not widely done
Bronchoscopy (protected brush, bronchoalveolar lavage [BAL])	Low morbidity and mortality; useful in ventilated patients and for nonbacteriologic diagnosis and in compromised host	"Invasive"; requires special training; less useful if patient already on antibiotics; wide range of sensitivity; may bias against the treatment of early infection
Nonbronchoscopic BAL	May give quantitative culture data in ventilated patients; can be done any time of the day by respiratory therapists or physicians	Variable accuracy, assumes that random sampling is reflective of bacteriology throughout the lung; same benefits/ disadvantages of relying on other quantitative methods
Open lung biopsy	Excellent for nonbacterial diagnosis and in compromised host	Most invasive; critically ill may not be able to undergo procedure; may not change prognosis

limitations that can cause both false-positive and false-negative results. Some studies have reported false-positive results in patients on long-term ventilation, even in the absence of infection [102], and the reproducibility of the sampling technique is also questionable. False-negative results are also common, particularly with sampling errors, and in the presence of prior effective antibiotic therapy. Finally, a number of studies have suggested that clinical management without quantitative cultures may be accurate, and that outcomes such as mortality and change in antibiotics to a focused regimen are not improved by the use of quantitative cultures [103].

The impact of quantitative sampling on patient outcome is controversial. One study suggested that the data from bronchoscopy can lead to antibiotic changes, but these changes are made too late to affect mortality [2]. Another study concluded that bronchoscopic culture results are frequently associated with changes in antibiotic therapy, but there was increase in mortality as a result of inappropriate early antibiotic therapy despite a subsequent microbiologically guided change [104]. Other studies have demonstrated the importance of getting initial therapy correct, and the use of quantitative cultures has never been shown to aid in this goal [2].

Studies of the impact of quantitative culture methods on VAP outcome have been mixed, but a recent meta-analysis showed no effect on mortality [105]. An early study by Fagon et al. [106] reported that a bronchoscopic-based invasive management strategy, with quantitative cultures, compared with a clinical approach based on endotracheal aspirate cultures, led to improved mortality at 14 days, reduced organ failure at 7 days, and reduced antibiotic usage. However, another study by Singh et al. [107] used clinical diagnosis and management with the CPIS and showed that patients with suspected VAP and a low score could be safely managed with a short course of antibiotics, and that these patients did as well as those treated with standard regimens [107]. In a large multicenter trial, Heyland et al. [108] compared management of VAP using cultures obtained via endotracheal aspirates with those obtained by BAL. They found no difference in mortality between the two groups, and similar rates of adjusting antibiotic therapy after initial empiric management. Unlike the earlier study, in this investigation, all patients initially received antibiotic therapy, so cultures were used to adjust antibiotics but never to withhold them. One of the limitations on the applications of these data is that patients with known colonization with *Pseudomonas* sp and MRSA were initially excluded from the study so that less than 15% had MDR pathogen pneumonia. Fewer studies have been done to investigate the impact of quantitative lower respiratory secretion cultures in patients with severe CAP, but Rello et al. [92] have shown that information from bronchoscopic sampling can help to narrow and focus antibiotic therapy in patients with severe CAP. However, in patients with severe CAP, PSB and BAL only give an etiologic diagnosis in one quarter to one third of all patients (which is less than with sputum or endotracheal aspirate cultures), but in this group, antibiotics were changed in nearly 75%.

Reconciling these different views, the ATS/IDSA guidelines for nosocomial pneumonia have recommended that all patients have a lower respiratory tract sample collected prior to starting therapy, and that the technique and culture method be one that the clinician is expert at performing and interpreting. Lower respiratory tract cultures can be obtained bronchoscopically or nonbronchoscopically and can be cultured quantitatively or semiquantitatively. Quantitative cultures increase specificity of the diagnosis of HAP but may potentially delay the initiation of therapy in patients with early pneumonia. Nonquantitative cultures are sensitive but may lead to some colonizing organisms being treated. Regardless of which method is used, it should only be initiated once the clinician has made a clinical diagnosis of pneumonia and is ready to initiate therapy. Therapy should be prompt and not delayed for the purpose of collecting diagnostic sample, especially in patients who are clinically unstable or septic from pneumonia [2,106]. Extrapulmonary infection should be ruled out prior to the administration of antibiotic therapy.

Differential Diagnosis

In the evaluation of a patient with lung infiltrates, it is necessary to determine (a) if pneumonia, or another infiltrative or

inflammatory process, is responsible for the constellation of symptoms and signs being evaluated and (b) if it is pneumonia, what is the etiologic pathogen. Since the features of pneumonia are nonspecific, it is necessary to consider such alternative noninfectious processes such as aspiration with chemical pneumonitis, acute pulmonary embolism, pulmonary infarction, pulmonary hemorrhage, ARDS, CHF, bronchiolitis obliterans organizing pneumonia, radiation pneumonitis, bronchoalveolar carcinoma, and atelectasis. An increasingly common problem is the differentiation of acute infectious pneumonia from drug-induced pneumonitis caused by agents such as amiodarone, bleomycin, busulfan, and methotrexate, and eosinophilia may be an important clue. Amiodarone pneumonitis may be indistinguishable from CAP, producing focal changes on chest radiography and occasionally pleural effusion; the illness generally occurs only in patients receiving more than 400 mg per day, and there is a subacute presentation, a low or declining diffusing capacity, and abnormal lipid-laden cells in BAL.

In immunocompromised patients, a new lung infiltrate may represent infection, progression of the underlying primary disease, or drug-induced lung disease. As in all patients, the nature of the immune impairment determines which pathogens are most likely. Although *P. jiroveci* pneumonia is a cause of rapidly progressive hypoxemic respiratory failure in the patient with HIV infection, a similar picture may be seen with tuberculosis, and pneumococcus is also a common respiratory pathogen in these patients [109]. Many have suggested that tuberculosis is poorly recognized in the intensive care setting and should be considered in patients with a history of inadequately treated tuberculosis or radiographic evidence of previous infection. The use of corticosteroid therapy in doses more than 20 mg per day increases the risk of opportunistic fungi, with reports stressing the occurrence of invasive aspergillosis in patients receiving high-dose steroid therapy for exacerbations of COPD [78]. Patients with B-cell–specific problems such as multiple myeloma are particularly prone to pneumonia with encapsulated organisms, including pneumococcus and *H. influenzae*. A similar organism profile can be seen in the splenectomized patient and in those with complement defects. Even in the setting of established pneumonia, patients may have a second infectious process such as extrapulmonary infection (catheter-associated bacteremia) or complications of antibiotic therapy, such as antibiotic-induced colitis.

THERAPY

Supportive Therapy

The role of supportive therapy in pneumonia in the critically ill is crucial because the use of antibiotics may not alter outcome during the first 24 to 72 hours of treatment. Many of the commonly applied measures are based on traditional practice, with little documentation of efficacy.

Nutritional Support

Evidence implicating malnutrition as a cofactor in pneumonia is substantial [69], but the evidence that nutritional intervention alters the outcome of severe pneumonia is lacking. Catabolic stress may be expected in the septic syndrome and has been related to progressive multiorgan failure if the patient survives the acute phase of critical illness. Enteral nutrition is preferred, if this can be practically accomplished, because data suggest better preservation of immune function using this route compared with total parenteral nutrition [110]. When enteral feedings are given, a small-bore tube, preferably placed in the small bowel, should be used along with a continuous infusion method to prevent aspiration and to optimize the delivery of calories [111]. The use of large-bore tubes placed in the stomach with bolus feeding has been associated with an increased risk of aspiration. All patients should be kept semierect and not supine as much as possible, to reduce the risk of reflux and aspiration [57]. The optimal time for initiating enteral feeding has not been determined.

Chest Physiotherapy

There is little support for the routine application of chest physiotherapy in patients who have an effective cough and scant amounts of respiratory secretions. Such maneuvers have the potential to worsen hypoxemia and mucociliary clearance when applied to routine pneumonia, and have not been demonstrated to affect duration of hospitalization [112,113]. Because of the labor-intensive nature of this intervention, techniques such as percussion, vibration, and postural drainage should be specifically targeted at patients with large volumes of purulent secretions (>30 mL per day) and an ineffective cough (see Chapter 62). In patients at bed rest in the ICU, the use of positioning and rotation may be helpful in clearing secretions [114]. In several studies, particularly in surgical trauma patients, the use of beds that rotate patients from side to side, and presumably accelerate mucus clearance, has led to a reduced incidence of nosocomial pneumonia [114].

Aerosols and Humidification

Humidification has been a traditional practice of respiratory therapy aimed at reducing sputum viscosity and promoting mucociliary clearance. Because the deposition of water vapor depends on particle size and the degree of airway obstruction, however, it is likely that most such aerosols are deposited above the glottis and act only to stimulate cough. Although mucolytic agents such as acetylcysteine offer the theoretic benefit of reducing the viscosity of purulent secretions, they may act as irritants that can provoke bronchospasm, and thus must be used selectively. Bronchodilator therapy with β_2 agents can enhance mucociliary clearance and ciliary beat frequency, but there have been no controlled trials that have demonstrated improved outcome with their use in pneumonia, in the absence of underlying bronchospasm. The greatest benefit of bronchodilator therapy may be expected in the patient with COPD in whom pneumonia develops (see Chapter 62).

Other Supportive Modalities

Other routine ICU care is applicable to the patient with severe pneumonia. Since many patients with severe pneumonia have signs of systemic sepsis, it is important to provide adequate early volume resuscitation. In addition, control of hyperglycemia may be beneficial, especially in surgical patients, and BP support with vasoactive medications may also be needed if the patient has septic shock. Other nonantibiotic, pharmacologic therapies for pneumonia patients with septic shock, including activated protein C and systemic corticosteroids, are discussed below.

Antibiotic and Other Pharmacologic Therapy

In the critically ill patient, the timely initiation of appropriate antimicrobial therapy has been shown to improve survival for patients with both severe CAP and VAP [2,4,33]. Because it is often impossible to identify a specific etiologic agent at the time that therapy is started, initial therapy is necessarily empiric

but can be modified and focused (de-escalated) once the results of diagnostic testing become available. The ATS and IDSA have developed algorithms for initial empiric therapy of severe pneumonia arising in both the community and the hospital [2,4].

Community-Acquired Pneumonia

Because the use of clinical syndromes or sputum Gram stain to guide therapy is often inaccurate and not recommended, initial therapy is empiric, based on the likely etiologic pathogens. For patients treated in the ICU, monotherapy is not recommended, using any agent, and all patients require initial therapy directed at pneumococcus (including DRSP), atypical pathogens (especially *Legionella*), *H. influenzae*, and enteric Gram-negatives (including *P. aeruginosa* in some patients). In selected patients, particularly following influenza or other viral infections, empiric therapy for *S. aureus*, including MRSA, is necessary. Aspiration pneumonia, including anaerobic pathogens, can occasionally present as severe illness, needing ICU care. Endemic viruses can also cause severe CAP, and the use of antiviral agents depends on local epidemiology and whether influenza or another viral agent is prevalent at the time that the patient is being evaluated. In the ICU, initial therapy is determined by whether the patient has risks for *P. aeruginosa*, which include structural lung disease (bronchiectasis), therapy with broad-spectrum antibiotics for more than 7 days in the last month, use of corticosteroids (>10 mg of prednisone daily), malnutrition, or HIV infection [2,4].

For the patient with severe CAP, mixed infection, involving a bacterial pathogen and an atypical pathogen, is also common and should be accounted for in the initial empiric regimen. Every patient should receive therapy directed at these organisms, which can be either primary pathogens or copathogens, but studies have shown that the use of a macrolide may be of specific value. In patients with bacteremic pneumococcal pneumonia, particularly in those with severe illness, dual therapy including a macrolide has been associated with improved outcomes [115,116]. A quinolone can also be used to treat atypical pathogen infection and may have an advantage in the patient with suspected *Legionella* infection, where the outcomes using quinolones are exceptionally good [117].

If the patient has no risk factors for *Pseudomonas*, then therapy should be with an intravenous β-lactam (ceftriaxone, cefotaxime, or ertapenem) with activity against DRSP plus either intravenous azithromycin or an intravenous quinolone (levofloxacin 750 mg or moxifloxacin 400 mg). When the patient has risk factors for *Pseudomonas*, then therapy should involve two antipseudomonal agents, in addition to providing coverage for DRSP and *Legionella* [4]. For these patients, therapy can be a two-drug regimen, using a selected antipseudomonal β-lactam (cefepime, piperacillin/tazobactam, imipenem, meropenem, doripenem), in combination with an antipseudomonal quinolone (ciprofloxacin, high-dose levofloxacin 750 mg daily). Alternatively, the above-mentioned β-lactams can be combined with an aminoglycoside and either azithromycin or an antipneumococcal quinolone (levofloxacin 750 mg or moxifloxacin 400 mg). In the penicillin-allergic patient, aztreonam can be combined with an aminoglycoside and an antipneumococcal fluoroquinolone [4].

As mentioned earlier, no patient with severe CAP should receive monotherapy, even with a quinolone, since studies have not proven the efficacy of this approach [118]. Moxifloxacin is safe and efficacious for CAP, even in the elderly, but few patients with severe CAP have been studied. In the Community-Acquired Pneumonia Recovery in the Elderly (CAPRIE) study, comparing moxifloxacin with levofloxacin for CAP in the elderly who were hospitalized outside of the ICU, although the cure rate for moxifloxacin (94.7%) was greater than levofloxacin (84.6%) in the severe CAP subgroup, the difference was not statistically significant [119]. One study of nearly 400 patients with severe CAP compared monotherapy with high-dose levofloxacin (500 mg twice daily) with the combination of ceftriaxone/ofloxacin, and although an equivalent clinical response was observed in both treatment groups (79.1% with levofloxacin compared with 79.5% with combination therapy), patients with shock were excluded from the study, and in patients with mechanical ventilation, treatment with levofloxacin resulted in a lower clinical cure rate (63% compared with 72% with combination therapy) [118]. Therefore, quinolone monotherapy is not recommended in severe CAP, especially in the setting of septic shock and respiratory failure.

Although quinolones are acceptable as monotherapy for patients not admitted to the ICU, it is currently uncertain if the outcome is different if a quinolone is used in place of macrolide, as part of a combination regimen for patients in the ICU. In one report, the use of initial empiric therapy with a β-lactam plus a fluoroquinolone for severe CAP was associated with increased short-term mortality (OR, 2.71; 95% confidence interval, 1.2 to 6.1), in comparison with other guideline-recommended antimicrobial regimes [120]. On the other hand, a recent meta-analysis of 23 randomized trials of CAP therapy outside the ICU compared the use of fluoroquinolones with other antibiotics, including β-lactams, macrolides, or both. Although there was no mortality difference in favor of the fluoroquinolones, for patients with more severe pneumonia, those who required hospitalization and those requiring intravenous therapy, the quinolones were more effective [121].

Occasionally, these broad-empiric approaches should be modified, particularly if clinical or culture data suggest an organism that is not included in the initial regimen (e.g., *S. aureus* or MRSA). In addition, certain comorbidities predispose to specific pathogens, and these should be covered by any empiric regimen (see Table 68.4). Thus, those with recent influenza should be treated for *S. aureus*, including CA-MRSA, in addition to the other usual severe CAP pathogens. CA-MRSA is different from nosocomial MRSA, as it occurs in previously healthy people, carries the Panton-Valentine leukocidin gene (a virulence factor which causes tissue necrosis), and causes a necrotizing, often bilateral severe pneumonia [70]. The best therapy for CA-MRSA is unclear, but the options include vancomycin, linezolid, or the combination of vancomycin and clindamycin. The latter two regimens have the ability to inhibit bacterial toxin synthesis (by linezolid or clindamycin), which may be part of the pathogenesis of severe CA-MRSA infection, but current recommendations are not definitive about whether antitoxin therapy is needed [4]. Anecdotal reports suggest a benefit to this approach [122].

If DRSP is present, any of the recommended regimens will be effective. Although pneumococcal resistance to multiple agents is present at rates up to 40%, using older definitions of resistance, the outcome in CAP is generally not worsened by the presence of penicillin-resistant organisms, compared with penicillin-sensitive organisms, and that these resistant organisms can still be effectively treated by high doses of penicillin, amoxicillin, amoxicillin/clavulanate, the third-generation cephalosporins (ceftriaxone or cefotaxime), or the antipneumococcal fluoroquinolones [4]. If highly resistant pneumococcus (but not cephalosporin resistant) is documented and meningitis is present, therapy should be initiated with vancomycin, cefotaxime, or ceftriaxone. Discordant therapy of DRSP usually has no impact on outcome, but even in studies when it was independently associated with death (OR, 27.3), it was very unlikely that discordant therapy would be given with ceftriaxone or cefotaxime [123]. Ceftriaxone is usually used at doses of 1 to 2 mg per day, but if DRSP and severe infection are present, the dose can be increased to 2 g every 12 hours. A notable exception to using cephalosporins in

severe CAP is cefuroxime. Yu et al. [124] studied the impact of concordant antibiotic therapy (using an antibiotic with in vitro activity against *S. pneumoniae*) versus discordant therapy (inactive in vitro) on mortality in bacteremic pneumococcal pneumonia. Discordant therapy with penicillins, cefotaxime, and ceftriaxone did not result in a higher mortality rate, but this did not apply to cefuroxime, which did increase mortality in the presence of in vitro resistance. *H. influenzae* is also becoming increasingly resistant to common antimicrobials because of the production of β-lactamases, and these organisms can be treated with second- or third-generation cephalosporins, quinolones, macrolides, or ampicillin/sulbactam.

Recent advances in the treatment of sepsis and septic shock, such as activated (activated drotrecogin α) and possibly steroids, are applicable to CAP as well. In severe CAP, patients treated with drotrecogin α had a relative risk reduction in mortality of 28% at 28 days, with a relative risk reduction in mortality of 14% observed at 90 days from the start of study drug infusion. The survival benefit was greatest in severe CAP patients with *S. pneumoniae* and in those at high risk of death as indicated by an Acute Physiology and Chronic Health Evaluation II score of 25 or more. Therefore, in addition to antibiotics, activated protein C could be considered as a potential therapeutic intervention, but its value was limited in patients already receiving appropriate therapy, and it was not useful in nosocomial pneumonia [125].

The role of low-dose (replacement) steroids in septic shock has been the topic of numerous studies, and relative adrenal insufficiency occurs in a high proportion of patients with severe CAP [27,126]. Salluh et al. [27] have shown that in patients with severe CAP, median cortisol levels were 15.5 μg per dL, and 65% of patients met the criteria for adrenal insufficiency (cortisol levels <20 μg per dL). When patients with septic shock were evaluated, 63% had adrenal insufficiency. Higher doses may also have value to modify the inflammatory response in patients with severe CAP. A recent placebo-controlled, randomized study of 46 patients used hydrocortisone as an intravenous 200-mg bolus followed by infusion at a rate of 10 mg per hour for 7 days. The treatment arm had a significant improvement in the PaO_2/FiO_2 ratio and chest radiograph score and a significant reduction in C-reactive protein levels, multiple-organ dysfunction syndrome score, and delayed septic shock, compared with the control group. Hydrocortisone treatment was associated with a significant reduction in length of hospital stay ($p = 0.03$) and mortality ($p = 0.009$) [127]. A recent systematic review of the use of systemic steroids in the treatment of CAP showed that in two studies, there was a significant clinical benefit [128], but two other trials failed to demonstrate a positive effect [129]. These results suggested that at least, steroid use in the setting of severe CAP does not appear to be harmful, but routine use in severe CAP is not recommended. One other setting in which corticosteroids may have benefit is when pneumococcal pneumonia is complicated by meningitis. In this setting, pretreatment with corticosteroids, prior to antibiotic therapy, may lead to more favorable neurologic outcomes [130].

Other new antibiotics may become available for the therapy of CAP. Tigecycline is a novel glycylcycline antibacterial agent, with an expanded broad spectrum of activity including proven utility against Gram-positive, Gram-negative, anaerobic, and atypical pathogens. It is effective in vitro against clinically important community- and hospital-acquired resistant organisms—*Acinetobacter*, MRSA, DRSP, vancomycin-resistant *Enterococcus* spp, *E. coli*, and *K. pneumoniae* expressing extended-spectrum β-lactamases (ESBLs). Currently, it is approved for CAP, but not nosocomial pneumonia [131]. New anti-Staphylococcal agents are also being developed, and may have utility in severe CAP, including telavancin, ceftaroline, and ceftobiprole [132].

Hospital-Acquired Pneumonia, Including VAP and HCAP

Although Gram-negative bacterial infection is the most common cause of nosocomial pneumonia, the frequency of Gram-positives, including MRSA, is rising, and in the impaired host, opportunistic fungi and mycobacterial infections are also possible. Defining the underlying disease and knowledge of patterns of bacterial infection and antibiotic resistance in a given ICU are important for selecting a therapy regimen that is likely to be active against the responsible pathogens.

In most patients, initial therapy is empiric, and if that therapy is "inappropriate" (i.e., not active against the etiologic pathogen), then mortality is higher than if the therapy was appropriate [2,4]. The approach to VAP in the 2005 ATS/IDSA guidelines [2] provides therapy recommendations for patients with HAP, VAP, and HCAP and focuses on multiple areas of management including the need for early diagnosis, prompt and accurate treatment, avoiding unnecessary antibiotics, and efforts to avoid future increases in antibiotic resistance. The key decision point in initial empiric therapy is to determine whether the patient has risk factors for MDR organisms, as outlined in Table 68.2. In the most recent guidelines, and unlike earlier guidelines, "early" onset of HAP, within the first 4 days of hospitalization, was only one factor to consider when defining whether the patient is at risk for MDR pathogen infection [2]. To be considered not at risk for MDR pathogens, the patient must have both early onset of infection, and no risks for HCAP such as recent hospitalization, treatment in a healthcare-associated facility (nursing home, dialysis center, etc.), and the patient should not have received antibiotic therapy in the past month. On the other hand, patients with either late-onset infection or the presence of any of the other MDR risk factors are treated empirically for infection with MDR Gram-negative and Gram-positive pathogens. Some patients with healthcare-associated infections are bacteriologically similar to hospital-acquired infections and also at risk for infection with MDR pathogens [51,79], but recent studies have shown that not all HCAP patients are at the same risk [51,133]. In the HCAP patient with severe pneumonia, the presence of any of the following risks should lead to the patient being treated for MDR pathogens: antibiotic therapy or hospitalization in the past 3 months, poor functional status, and immune suppression. In the absence of these risk factors, the HCAP patient in the ICU should be treated with a severe CAP regimen.

Initial empiric therapy is either with a narrow-spectrum, generally monotherapy regimen, or with a broad-spectrum, multidrug regime (see Table 68.2). In the 2005 guidelines [2], patients with HCAP fell into the second group, but this may not be necessary for those without MDR risk factors. The timing of accurate antimicrobial therapy is an important mortality predictor, and changing antimicrobial therapy once culture results are available may not reduce the excess risk of hospital mortality associated with initial inappropriate treatment [2]. This need to get initial therapy correct has led to many patients getting a broader spectrum regimen than may be needed, and thus it is necessary to obtain cultures prior to therapy and de-escalate after 2 to 3 days, once the culture data are available.

Guidelines make a distinction between appropriate therapy and adequate therapy, with both requiring the use of an agent to which the etiologic pathogen is sensitive. However, adequate therapy also requires that the drug penetrates to the site of infection, and that it is administered in the correct dose and with multiple agents if required. The regimens listed in Table 68.9 are directed at providing appropriate therapy that is targeted to the most likely pathogens. Therapy for those who are not at risk for MDR pathogen infection can be with a second- or third-generation cephalosporin, a β-lactam/β-lactamase inhibitor combination, ertapenem, a

TABLE 68.9

INITIAL EMPIRIC ANTIBIOTIC THERAPY FOR NOSOCOMIAL PNEUMONIA

Hospital-acquired pneumonia and ventilator-associated pneumonia: early onset, no known risk factors for multidrug resistant (MDR) pathogens, any disease severity	
Potential pathogen	**Recommended antibiotic for patient type; drugs listed are meant as a group to treat all listed pathogens**
Streptococcus pneumoniae *Haemophilus influenzae* or Methicillin-sensitive *Staphylococcus aureus* Antibiotic-sensitive enteric Gram-negative bacilli *Escherichia coli* *Klebsiella pneumoniae* *Proteus* spp *Serratia marcescens* *Enterobacter* spp	Ceftriaxone OR Levofloxacin, moxifloxacin, or ciprofloxacin OR Ampicillin/sulbactam OR Ertapenem
Hospital-acquired pneumonia, ventilator-associated pneumonia, and healthcare-associated pneumonia: late onset, or with risk factors for MDR pathogens, any disease severity	
Potential pathogens	**Combination antibiotic therapy (for patient type; drugs listed are meant as a group to treat all listed pathogens)**
Pathogens listed above PLUS MDR pathogens *Pseudomonas aeruginosa* *K. pneumoniae* *Acinetobacter* spp PLUS Consider[a] *Legionella pneumophila* Methicillin-resistant *S. aureus*	 Antipseudomonal cephalosporin (cefepime, ceftazidime) or Antipseudomonal carbapenem (imipenem or meropenem) or β-Lactam/β-lactamase inhibitor (piperacillin–tazobactam) PLUS Antipseudomonal fluoroquinolone (ciprofloxacin or levofloxacin) OR Aminoglycoside (amikacin/gentamicin/tobramycin) PLUS Linezolid or vancomycin

[a]If an environmental source of Legionella is present, with a known nosocomial outbreak, use fluoroquinolone in the regimen.
Adapted from Niederman MS, Craven DE, Bonten MJ, et al: Guidelines for the management of adults with hospital-acquired, ventilator-associated, and healthcare-associated pneumonia. *Am J Respir Crit Care Med* 171:388–416, 2005, with permission.

quinolone (moxifloxacin or levofloxacin), or, for penicillin-allergic patients, the combination of clindamycin and aztreonam. Therapy for those at risk for MDR pathogens is directed at *P. aeruginosa*, *Acinetobacter* spp, ESBL producing *K. pneumonia and Enterobacter* spp, and MRSA [2]. Patients at risk for infection with these organisms should initially receive a combination an antipseudomonal β-lactam plus either an antipseudomonal quinolone (ciprofloxacin or levofloxacin) or an aminoglycoside (amikacin, gentamicin, or tobramycin). The antipseudomonal β-lactams include cefepime, doripenem, imipenem, meropenem, and piperacillin/tazobactam. Aztreonam can be used in penicillin-allergic patients. This combination regimen is generally supplemented with therapy for MRSA with either vancomycin or linezolid. In the future, telavancin may be another option for MRSA therapy.

To ensure adequate therapy, the right doses have to be used—typically, for critically ill patients with normal renal function, the correct doses of common antibiotics include cefepime 1 to 2 g every 8 to 12 hours; imipenem 500 mg every 6 hours or 1 g every 8 hours; meropenem 1 g every 8 hours; piperacillin-tazobactam 4.5 g every 6 hours; levofloxacin 750 mg daily or ciprofloxacin 400 mg every 8 hours; vancomycin 15 mg per kg every 12 hours leading to a trough level of 15 to 20 mg per L; linezolid 600 mg every 12 hours; and aminoglycosides of 7 mg per kg per day of gentamicin or tobramycin and 20 mg per kg of amikacin [2]. There is interest in optimizing dosing of antibiotics, and this means using continuous or prolonged infusions of β-lactams which are bactericidal in a time-dependent fashion, or giving once-daily high doses of aminoglycosides or quinolones, which are bactericidal in a concentration-dependent fashion. Doripenem is a new carbapenem and has been studied for the treatment of HAP and VAP, with similar efficacy to other antipseudomonal β-lactams and can be given as a 4-hour infusion to ICU patients, with some enhanced efficacy against *P. aeruginosa* when this dosing approach is used [134].

In the therapy of nosocomial pneumonia, in addition to *P. aeruginosa*, the other challenging Gram-negative organisms are *Acinetobacter* spp and ESBL-producing *Enterobacteriaceae*. For both groups of pathogens, a carbapenem is the most effective therapy, if the organisms are sensitive, but if not, then novel therapies may be needed. *Acinetobacter* can be treated with tigecycline but generally not as monotherapy, since it has not shown efficacy in clinical trials when utilized this way.

Colistin, a polymyxin, may be necessary in this setting, with some risk of nephrotoxicity. There are reports of using combinations of a carbapenem or colistin, with tigecycline, showing some efficacy against resistant *Acinetobacter* organisms [135]. Colistin has also been used to treat highly resistant ESBL-producing Gram-negatives, but if an institution has concern about these organisms, third-generation cephalosporins should not be used, since they can further induce the selection of ESBL-producing organisms and are generally not effective therapy [136].

The treatment options for suspected MRSA pneumonia have been expanded with the availability of agents such as the oxazolidinones (linezolid) and the streptogramins (quinupristin/dalfopristin). Still in development with efficacy in clinical trials is telavancin, while tigecycline, ceftobiprole, and ceftaroline are still being investigated for the therapy of MRSA pneumonia [132]. Linezolid is effective for nosocomial pneumonia, especially caused by MRSA, and is an alternative to vancomycin for the treatment of MRSA VAP. In a subset analysis of two prospective, randomized trials, linezolid had a clinical and microbiologic advantage over vancomycin for patients with documented MRSA VAP [137]. This advantage may be due to the higher penetration of linezolid into the epithelial lining fluid than with vancomycin [138]. This agent may also be preferred if patients have renal insufficiency or are receiving other nephrotoxic agents such as aminoglycosides, because of concerns of synergistic nephrotoxicity with vancomycin, but this is not conclusively proven. Linezolid is generally well tolerated, but patients must be monitored for drug-induced thrombocytopenia, especially after prolonged use (>14 days). Quinupristin/dalfopristin is an option but was less efficacious compared with vancomycin in treatment of nosocomial pneumonia caused by MRSA [139]. Teicoplanin is a glycopeptide antibiotic with antimicrobial activity similar to vancomycin and can be given once a day, but it is not available in the United States [140].

For patients at risk for infection with MDR pathogens, initial empiric therapy should involve a combination of agents, but the role of continued combination therapy is uncertain. One advantage of combination therapy is to provide synergy in the therapy of *P. aeruginosa*, which is only accomplished when an aminoglycoside is combined with a β-lactam. Synergy has only been proven to be of value in patients with neutropenia and pseudomonal bacteremia, both uncommon in the therapy of VAP [141]. Although combination therapy could theoretically prevent the emergence of resistance that is common with monotherapy, this has not been proven to be a benefit [142]. The major utility of combination therapy is to provide broader spectrum coverage than is possible with one agent alone, since most hospitals do not have a single agent that is able to cover all the likely pathogens with a high enough frequency. Adding a second agent increases the likelihood that initial empiric therapy will be appropriate, if MDR pathogens are present. In the Canadian Clinical Trials Group study of VAP, the use of combination therapy increased the likelihood of appropriate therapy for patients who had MDR pathogens from 11% to 84%, with an associated improvement in microbiologic eradication [143].

Combination therapy should include agents from different antibiotic classes to avoid antagonism of therapeutic mechanisms. For Gram-negatives, regimens usually involve the combination of a β-lactam with either a quinolone or an aminoglycoside. Although quinolones can penetrate into the lung better than aminoglycosides and have less potential for nephrotoxicity, a trend toward improved survival has been seen with aminoglycoside-containing, but not with quinolone-containing, combinations [144]. In some studies, combination therapy has been continued for less than the full course of therapy, with discontinuation of the aminoglycoside after 5 days if the patient is improving [145]. Monotherapy should be used when possible because combination therapy is often expensive and exposes patients to unnecessary antibiotics, thereby increasing the risk of drug toxicity and the selection of antibiotic resistant organisms. Once cultures are available, if the etiologic pathogen is susceptible, it is possible to change to monotherapy, using one of the agents that has proven to be effective in critically ill ventilated patients with pneumonia due to susceptible pathogens: ciprofloxacin, levofloxacin, doripenem, imipenem, meropenem, cefepime, and piperacillin/tazobactam [2]. Monotherapy with ciprofloxacin has been successful in patients with mild HAP (defined as a CPIS of 6 or less) but is less effective in severe HAP [107].

The choice of initial therapy should be based on local patterns of antimicrobial susceptibility and anticipated side effects, and should also take into account which therapies patients have recently received (within the past 2 weeks), striving not to repeat the same antimicrobial class, if possible. In addition, some studies have shown that recent therapy with quinolones promotes not only Gram-negative resistance to quinolones but also to β-lactams, and they can lead to the emergence of MRSA and MDR Gram-negatives [146]. Therefore, it may be better not to use quinolones for a first episode of hospital infection, because it may make both β-lactams and quinolones less effective if therapy is needed for a subsequent infection. Because many hospitalized patients do develop multiple infections, this strategy will preserve some therapeutic options for a second episode of infection [147]. In addition, in many hospitals, Gram-negative susceptibility to quinolones has declined and empiric coverage is improved only if an aminoglycoside is added to a β-lactam, but not if a quinolone is added [148].

For the initial antimicrobial therapy regimen to account for local bacteriologic patterns, each ICU should ideally have its own antibiogram that is updated as often as possible. Variability in the microorganisms associated with hospital-acquired infections among hospitals, as well as within the ICUs of large hospitals, has been demonstrated to occur [2]. In addition, changing temporal patterns of nosocomial pathogens and antimicrobial susceptibility have been described. Current and frequently updated knowledge of such data can increase the likelihood of prescribing appropriate initial antibiotic treatment. This is especially important for infection with MDR pathogens, as empiric therapy should be with agents that are known to be effective against these organisms. Each ICU should establish its own "go to" empiric antibiotic regimen, tailored to the antibiotic susceptibility patterns of the local flora. If patients develop HAP during or shortly after antibiotic treatment for a different infection, the empiric therapy should involve an agent from a different antibiotic class. Recent exposure to a class of antibiotics can predict subsequent resistance to a variety of agents, usually to the same class but occasionally to other classes of agents as well [149].

In the treatment of nosocomial pneumonia, the ATS/IDSA guideline emphasizes the need for a "de-escalation" strategy of usage [2]. After 2 to 3 days, the clinical course can be assessed and the culture data reviewed, and in responding patients, efforts can be made to change the initial broad-spectrum therapy. This de-escalation can involve focusing to a more narrow spectrum agent, reducing the number of antibiotics, stopping therapy altogether in patients not likely to have infection, and making efforts to reduce duration of therapy [150]. When this strategy has been used, outcomes such as the frequency of secondary infection, antimicrobial resistance, and mortality have improved [150]. De-escalation can only be accomplished if lower respiratory tract cultures are obtained prior to initiating therapy, although rates can be high with either a nonquantitative endotracheal aspirate or a quantitatively cultured bronchoscopic sample [108]. Negative lower respiratory tract cultures can be used to stop antibiotic therapy in a patient who has had cultures obtained in the absence of an antibiotic change

in the past 72 hours and who is clinically doing well. In retrospect, such a patient may not have pneumonia but rather another diagnosis such as CHF or atelectasis. Combination therapy can be de-escalated to monotherapy once culture data are available, and aminoglycosides may be used for a short duration (5 days), when used in combination with a β-lactam to treat *P. aeruginosa* pneumonia. In clinical practice, physicians do not de-escalate often enough, even though data do not show adverse outcomes when this approach is applied to patients who are responding to initial empiric therapy [151].

The recommended duration of therapy for VAP has been the subject of recent studies. In earlier reports, significant improvements were observed for all clinical parameters generally within the first 6 days of the start of antibiotics [152]. Luna et al. [153] observed that patients who survived VAP after receiving appropriate therapy tended to have a clinical improvement by days 3 to 5, especially reflected by improved PaO_2/FiO_2 ratio, whereas nonresponding patients did not have such a response during the same time period. On the other hand, prolonged antibiotic therapy simply leads to colonization with resistant bacteria, which may be a risk factor for recurrent VAP. A multicenter, randomized, controlled trial demonstrated that patients who received appropriate, initial empiric therapy of VAP for 8 days had outcomes similar to those patients who received therapy for 14 days [154]. A trend to greater rates of relapse for short-duration therapy was seen if the etiologic agent was *P. aeruginosa* or *Acinetobacter* spp. Thus, for patients who receive initially appropriate antibiotics and have a good clinical response to therapy, the duration of therapy should be as short as 7 days, provided that the etiologic pathogen is not *P. aeruginosa*. The optimal duration of therapy for VAP due to MDR organisms such as *P. aeruginosa* or *Acinetobacter* spp is not known. Two recent, randomized, multicenter studies showed that PCT can help guide therapy discontinuation for VAP and help decrease number of days on antibiotic. Stolz et al. [86] compared a PCT-guided approach with the usual guideline approach in 101 patients. The use of the biomarker impacted significantly on a shorter duration of therapy, with a reduction of 27% in the number of antibiotic days, without showing an in-hospital mortality difference or a longer duration of mechanical ventilation between the two groups. Similar results were found by Bouadma et al. [155] when they compared 307 patients where the therapy was guided by the biomarker and the use of 314 controls. The number of antibiotic-free days was approximately 2.7 days less in the PCT group, with no differences in 28- or 60-day mortality between the two groups.

Although aminoglycosides are used in VAP, there is concern about nephrotoxicity (especially in the elderly) and these drugs being less active in areas of the lung that have a low pH levels, as may occur with pneumonia. Also, these antibiotics achieve only 40% of the serum concentration in respiratory secretions, when given intravenously. Although once-daily dosing has been proposed to take advantage of the postantibiotic effect of aminoglycosides to enhance efficacy, while reducing the need for monitoring serum levels and reducing the toxicity, a meta-analysis has shown neither enhanced efficacy nor reduced toxicity with once-daily dosing [2]. Another approach used by some investigators is the direct delivery of aminoglycosides into the airway in an effort to achieve high levels of antibiotic at the site of infection, with little risk of systemic absorption and toxicity. Clinical studies of aerosolized aminoglycosides have shown this approach to be effective in cystic fibrosis and severe Gram-negative pneumonia [156]. Small and uncontrolled series have shown that when patients have VAP due to MDR *P. aeruginosa* or *Acinetobacter* spp, aerosolized aminoglycosides, polymyxin, or colistin may be helpful as adjunctive therapy to systemic antibiotics [157,158]. One side effect of aerosolized antibiotics has been bronchospasm, which can be induced by the antibiotic or the associated diluents present in certain preparations. Pending further investigation, this therapy should be used as an adjunct to systemic antibiotics, only in patients with severe Gram-negative pneumonias who are not responding to intravenous therapy, or in patients infected by a relatively resistant organism that might be eliminated only with high local drug concentrations.

STRATEGIES FOR PREVENTION OF PNEUMONIA

Community-Acquired Pneumonia

Preventive strategies can be applied in the outpatient (prehospital) setting or in the hospital and ICU. Outpatient measures proven to reduce the incidence of severe lower respiratory tract infection are immunization against pneumococcal and influenza infection in susceptible populations [4,159]. The pneumococcal polyvalent vaccine (PPV) is directed at 23 strains of pneumococcus (accounting for 85% to 90% of all infections), and it is both cost-effective and potentially cost saving among individuals older than 65 years for the prevention of bacteremia. In a study of US hospitals, prior vaccination against pneumococcus was associated with improved survival (adjusted OR, 0.50; 95% confidence interval, 0.43 to 0.59), decreased chance of respiratory failure or other complications, and decreased length of stay among hospitalized patients with CAP [159]. With documented effectiveness of 75% in this age group, the recommendation is that all immune-competent patients aged 65 years or older should be immunized [4]. If prior history of vaccination is not available, revaccination is also safe, as there was no difference in the risk of adverse events following more than three doses of PPV, compared with one or two doses [160]. This may be relevant following vaccination with 23-valent PPV, because pneumococcal antibody levels decline to prevaccination levels within 6 to 10 years. More studies are needed before routine revaccination is advised. The current PPV is not maximally immunogenic, and a more immunogenic, 7-valent conjugate, vaccine has been developed for children, but is not yet available for adults.

Annual influenza vaccination has reduced the frequency and severity of influenza in the elderly and chronically ill patient, and vaccination of medical personnel may reduce nosocomial transmission of influenza from staff to patients [161]. Antiviral chemoprophylaxis (with oseltamivir, zanamivir, amantadine, or rimantadine) may be adjunctive to immunization and is 70% to 90% effective in avoiding infections with influenza A if it is started at the earliest recognition of an outbreak and if the circulating strain is sensitive to these agents (which has not always been the case in recent epidemics). Studies of amantadine prophylaxis demonstrated substantial reduction in nosocomial attack rates [162]. The new neuraminidase inhibitors, zanamivir and oseltamivir, are active against both influenza A and B, for prophylaxis and treatment if started within 36 hours of the onset of symptoms. They reduce clinical illness [163] and viral shedding by 2 days and prevent secondary complications of influenza, such as otitis media and sinusitis [162].

Nosocomial Pneumonia

In the ICU, several general strategies may be used to reduce the incidence of pneumonia [2] (Table 68.10). In recent years, some of these measures have been combined and applied to intubated patients as a "ventilator bundle," leading to dramatic reductions in the rate of VAP.

TABLE 68.10

PREVENTATIVE STRATEGIES AVAILABLE IN INTENSIVE CARE UNIT PNEUMONIA

To prevent tracheobronchial colonization
Infection control
Handwashing
Respiratory therapy equipment: careful handling
Maintain endotracheal tube cuff pressure to avoid aspiration
Change no more than every 48 h
Isolate patients with resistant organisms
Avoid endotracheal intubation (noninvasive ventilation)
Aspiration avoidance
Reduce use of nasogastric tubes (place orally, and if possible postpyloric)
Avoid central nervous system depressants
Daily interruption of sedation
Start enteral feeding only after >24–48 h after intubation
Keep patients semierect when possible
"Ventilator bundles"
Consider using subglottic secretion drainage
Host defense fortification
Nutritional support: consider site of feeding, pH of feeding, continuous or discontinuous enteral feeding
Avoid immunosuppressants
Restricted blood transfusion policy
Glycemic control
Influenza and pneumococcal vaccine: consider hospital-based programs
Provide antiviral prophylaxis (especially for influenza A)
Consider immunostimulation: cytokine infusion or blockade
Other potentially useful measures (multiple targets)
Topical aerosolized lower respiratory antibiotics
"Selective digestive decontamination"—oropharynx and GI tract
Selective oral decontamination
Careful consideration of GI bleeding prophylaxis in the context of enteral feeding
Antibiotic rotation/cycling
Active and passive immunization against groups of potential pathogens
Secretion mobilization: lateral rotational therapy

GI, gastrointestinal.

Infection Control and Ventilator Equipment Handling

A nationwide epidemiologic survey, the Study on the Efficacy of Nosocomial Infection control (SENIC) study, suggested that effective infection control and surveillance programs could potentially reduce the rate of nosocomial pneumonia by 20% [164]. Handwashing, although simple and effective in reducing the spread of resistant organisms, is frequently neglected in the ICU. Proper disinfection of nebulization equipment should be done after each use. Heat moisture exchangers in the ventilator circuit can eliminate the need for cascade humidification but have not been shown to reduce the incidence of nosocomial pneumonia. Ventilator circuit changes should be made no more often than every 48 hours, and more frequent changes and manipulations may add to the risk of infection [2,43]. In fact, there is no increased infection risk if tubing is never changed [165].

Prophylactic Antibiotics

Numerous studies have documented the efficacy of topical antibiotics applied to the lower airway in preventing nosocomial pneumonia in an ICU setting. However, these studies, done in the early 1970s, showed that this approach was associated with the emergence of resistant bacteria that could themselves cause fatal pneumonia, and thus the strategy was deemed unsafe and was abandoned [166].

Intense interest has been focused on "selective digestive decontamination (SDD)" as a means of preventing both nosocomial pneumonia and sepsis [167]. This approach attempts to sterilize the intestine and oral cavity of all Gram-negative organisms, assuming that the gastrointestinal tract is the source of the organisms that cause pneumonia.

Several large meta-analyses and four recent prospective trials have shown a benefit for SDD in preventing VAP and in reducing mortality [167]. The full regimen is usually a combination of topical (polymyxin, tobramycin, and amphotericin or related compounds) and systemic antibiotics (nonpseudomonal third-generation cephalosporin), but the use of only topical oral antibiotics (selective oral decontamination, SOD) or oral antiseptics (such as chlorhexidine) has also reduced the incidence of infection, but with generally no influence on overall mortality [168]. However, in a recent, large randomized trial, both SDD and SOD reduced ICU mortality rates [169]. In spite of these possible benefits, widespread use of SDD in all ICU patients should not be encouraged. In many studies, the benefits have applied only to selected populations such as surgical and trauma patients, with less benefit to medical patients. In addition, those at the extremes of disease severity (mild or severely ill) may not benefit. In addition, to be fully effective, SDD needs to be used in all patients in a given ICU, and this widespread use has been shown in some studies to promote the emergency of resistant bacteria, particularly Gram-positives such as MRSA. This is likely to be an even greater problem in ICUs with a high baseline rate of resistance. SDD may also lead to an increased rate of hospital-acquired infections in patients after they leave the ICU [170].

Control of Respiratory Secretions

Stagnation of respiratory secretions can lead to both pneumonia and atelectasis, and efforts to remove these secretions could reduce the incidence of pneumonia. One way to achieve this objective is through the use of continuous lateral rotation delivered by a rotating bed that is used in place of a traditional hospital bed to improve mucociliary clearance and help mobilize secretions. Another way to control respiratory secretions is to remove oropharyngeal contents before they can be aspirated into the lung. Continuous aspiration of subglottic secretions, through the use of a specially designed endotracheal tube, has significantly reduced the incidence of early-onset VAP in several studies [2]. Other measures to reduce the aspiration of oropharyngeal bacteria include limiting the use of sedative and paralytic agents that depress cough and other host-protective mechanisms and maintaining endotracheal cuff pressure greater than 20 cm H_2O [2].

Intestinal Bleeding Prophylaxis

Several clinical studies have documented that neutralization of gastric pH with antacids or H_2 blockers can add to the risk of nosocomial pneumonia (especially late-onset infection) in mechanically ventilated patients [2,43], because an increase in gastric pH can lead to Gram-negative overgrowth of the stomach contents, which can then be aspirated into the lung [56]. Although not all studies have shown that the gastric reservoir is an important source of infection, prevention strategies should take into account its potential influence by minimizing gastric volume and preventing aspiration of gastric contents; however, ventilator bundles have been able to reduce VAP rates, even if H_2 blockers are used. This is likely because gastric acid neutralization is combined with elevation of the head of the bed, which may prevent aspiration of gastric contents. Although

some studies have suggested a benefit of performing intestinal bleeding prophylaxis with sucralfate, at least one large, double-blind, randomized trial comparing ranitidine with sucralfate, which demonstrated a trend toward lower rates of VAP with sucralfate, also reported that clinically significant gastrointestinal bleeding was 4% higher in the sucralfate group [171]. Another study of VAP in patients with ARDS showed that the use of sucralfate and the duration of exposure to sucralfate were associated with an increased risk of VAP [73].

Ventilator Bundles

Several simple prevention strategies have been incorporated into a "ventilator bundle" that can be routinely applied to all ventilated patients. The most widely used approach is to combine five measures: peptic ulcer disease prophylaxis, deep vein thrombosis prophylaxis, elevation of the head of the bed, daily interruption of sedation, and daily assessment of readiness to wean. Some centers also apply routine mouth care and oral chlorhexidine. When applied, this strategy has been reported to lead to a 44.5% reduction in the incidence of VAP in the 35 ICUs that used this approach, and the benefit was greatest when adherence to the protocol was high [172]. In the last several years, this approach has become so popular and apparently effective that many believe that it can lead to a "zero VAP" rate. However, there is concern that the benefits of ventilator bundles have been overstated, and that it is impossible to eliminate VAP in certain high-risk patients [41,173]. In addition, although studies have shown a reduction in VAP rates, secondary benefits such as reduction in mortality and antibiotic use have not generally been reported.

Other Measures

Blood Transfusions and Glucose Control

Multiple studies have identified exposure to allogeneic blood products as a risk factor for postoperative infection and postoperative pneumonia, and the length of time of blood storage as another contributing [2]. The use of leukocyte-depleted red blood cell transfusions resulted in a reduced incidence of postoperative infections and specifically a reduced incidence of pneumonia in patients undergoing colorectal surgery [174]. In another study, in less severely ill patients, mortality was improved with a restricted transfusion strategy (transfusion trigger 7 g per dL, instead of 9 g per dL), likely due to immunosuppressive effects of nonleukocyte-depleted red blood cell units, leading to an increased risk for infection [175]. Routine red blood cell transfusion should be conducted with a restricted transfusion trigger policy.

The role of hyperglycemia in ICU infections has received much attention. Hyperglycemia may directly or indirectly increase the risk of complications and poor outcomes in critically ill patients. Van den Berghe et al. [176] randomized surgical ICU patients to receive either intensive insulin therapy to maintain blood glucose levels between 80 and 110 mg per dL or to receive conventional treatment. The group receiving intensive insulin therapy had reduced mortality (4.6% vs. 8%). When compared with the control group, those treated with intensive insulin therapy had a 46% reduction of bloodstream infections, fewer antibiotic treatment days, and significantly shorter length of mechanical ventilation and ICU stay. In the medical ICU setting, the results were less promising. Intensive insulin therapy significantly reduced morbidity but not mortality in medical ICU patients, and this was seen more in patients treated for 3 or more days [177]. More recent data have suggested that very tight control of blood glucose in the ICU may not be beneficial and may lead to clinically relevant hypoglycemia [178].

Role of Noninvasive Ventilation

The role of invasive devices in breaching mucosal barriers has been discussed earlier. Noninvasive ventilation (NIV), instead of conventional mechanical ventilation in patients with acute respiratory failure due to COPD or acute cardiogenic pulmonary edema, led to a significantly lower risk of nosocomial pneumonia, less antibiotic use, shorter ICU stay, and lower mortality [2]. Improved outcomes with NIV were also shown

TABLE 68.11

RECENT ADVANCES IN PNEUMONIA MANAGEMENT BASED ON RANDOMIZED TRIALS, LARGE DATABASE ANALYSES, AND META-ANALYSIS

- Antibiotic duration in VAP should be as short as possible. In patients with a low clinical suspicion, based on serial clinical observations, therapy can be stopped after 3 days, while those with microbiologically confirmed VAP can be safely treated for 8 days, provided that initial therapy is appropriate and that a nonfermenting Gram-negative is not responsible [61,150].
- Activated protein C can reduce mortality in patients with severe CAP, especially if *Streptococcus pneumoniae* is the etiologic pathogen, and may have particular benefit if initial empiric therapy is inappropriate [4,125].
- Linezolid is associated with a lower mortality and higher bacteriologic eradication rate than vancomycin in patients with VAP that is proven to be caused by MRSA, but quinupristin/dalfopristin is not superior to vancomycin [122,137,139].
- Quinolone monotherapy should not be used for patients with severe CAP, since it has not been proven to be safe and effective for all of the types of patients admitted to the ICU [4,118].
- Mortality in CAP can be reduced by administering the first dose of antibiotics with 4 hours of a patient's arrival to the hospital [4].
- In patients with VAP, diagnosis can be made with either endotracheal aspirate culture or bronchoscopic culture, with no difference in mortality, comparing the two methods [2].
- Combination antimicrobial therapy in VAP increases the likelihood of initially effective empiric therapy for patients who are likely to have multidrug-resistant pathogen infection, but the use of combination therapy has not been definitively proven to reduce mortality [2].
- When cephalosporins are used for empiric therapy of severe CAP, and drug-resistant *S. pneumoniae* is suspected, ceftriaxone and cefotaxime are reliable choices, while cefuroxime is not [4].
- In the presence of CAP with pneumococcal bacteremia, use of dual antibiotic therapy is associated with reduced mortality, compared with monotherapy, especially for patients with severe pneumonia [115,116].

CAP, community-acquired pneumonia; ICU, intensive care unit; MRSA, methicillin-resistant *Staphylococcus aureus*; VAP, ventilator-associated pneumonia.

in immunosuppressed patients with pulmonary infiltrates and respiratory failure [179]. In addition, to reduce the duration of mechanical ventilation and the risk of VAP, specific strategies in ICU patients are needed, such as the use of protocols to facilitate and accelerate weaning and judicious use of sedation [2]. Accidental extubation and reintubation should be avoided, as they increase the risk of VAP [180].

Nutritional Support. Traditionally, early enteral feeding has been recommended in ICU patients over parenteral nutrition. However, in VAP, enteral nutrition has been considered a risk factor mainly because of an increased risk of aspiration of gastric contents [2]. In an attempt to define the timing of starting enteral nutrition, a strategy of early enteral feeding (day 1 of intubation) was associated with a higher risk for ICU-acquired VAP when compared with late administration (day 5 of intubation) [181]. In terms of site of feeding, a meta-analysis showed that postpyloric feeding compared with gastric feeding was associated with a significant reduction in ICU-acquired HAP (relative risk, 0.76; 95% confidence interval, 0.59 to 0.99) [58].

Role of Antibiotic Rotation

The concept of antibiotic rotation or cycling has also been investigated as a resistance control strategy, with potential benefits of reducing the incidence of VAP, especially due to resistant organisms. In theory, a class of antibiotics or a specific antibiotic is withdrawn from use for a defined time period and reintroduced at a later point in time in an attempt to limit bacterial resistance to the cycled antimicrobial agents [145,182]. Although there was initial enthusiasm for this approach, recent studies have been less supportive, and most ICUs focus on antimicrobial stewardship, focusing on monitoring local patterns of resistance and introducing heterogeneity into the choice of antibiotics [145,183].

Advances in managing acute infectious pneumonia, based on randomized, controlled trials or meta-analyses of such trials, are summarized in Table 68.11.

CHAPTER 69 ■ LUNG BIOPSY

SCOTT E. KOPEC AND RICHARD S. IRWIN

Lung biopsy is indicated whenever it is necessary to obtain a definitive diagnosis of a localized or diffuse pulmonary disease, usually after noninvasive diagnostic modalities have been used unsuccessfully.

Multiple lung biopsy techniques are available that have been well characterized with regard to tissue yield, diagnostic yield, complications, contraindications, and mortality rate. The relative usefulness of a particular biopsy technique depends not only on the availability of local expertise but also on the clinical situation. Each of the commonly used biopsy procedures is briefly described, and an approach to the lung biopsy procedure in the critically ill patient that focuses on the following questions is outlined: (a) When should a lung biopsy be considered in the critically ill patient? (b) Which biopsy technique should be chosen? (c) How should the specimens be handled?

BIOPSY PROCEDURES

General Considerations

Lung biopsy procedures can be grouped into two broad categories: open (i.e., surgical) and closed (i.e., nonsurgical). The major distinction between the two is that closed procedures avoid major surgical intervention and general anesthesia at the expense of a lower likelihood of obtaining a definitive

TABLE 69.1

CONTRAINDICATIONS AND RELATIVE CONTRAINDICATIONS TO LUNG BIOPSY [1–5]

Open thoracotomy biopsy
Contraindication
Too ill to undergo general anesthesia
Thorascopic lung biopsy
Contraindications
Too ill to undergo general anesthesia
Extensive pleural adhesions
Uncorrectable coagulopathy
Postpneumonectomy patient
Severe pulmonary hypertension
Relative contraindications
Inability to place a double-lumen endotracheal tube
Inability to tolerate single lung ventilation
Closed biopsy
Contraindications
Uncorrectable coagulopathy (including uremia)[a]
Unstable cardiovascular status
Severe hypoxia likely to worsen during bronchoscopy
Inadequately trained bronchoscopist
Poor patient cooperation
Relative Contraindications
Recent myocardial infarction or unstable angina
Adjacent vascular abnormalities
Positive-pressure ventilation
Cavitating lesions (especially with air-fluid levels or >10 cm diameter)
Severe pulmonary hypertension
Adjacent emphysematous lung disease
Suspected echinococcal disease
Uncontrollable cough

[a]Bronchoalveolar lavage can be performed safely in patients with severe thrombocytopenia.

diagnosis. Contraindications and relative contraindications for open and closed lung biopsy procedures are listed in Table 69.1 [1–5].

Open Biopsy Procedures

Open Thoracotomy Lung Biopsy

Because thoracotomy allows the surgeon to obtain relatively large specimens of lung tissue under direct observation, open lung biopsy is a consistently accurate lung biopsy technique. The procedure requires endotracheal intubation, general anesthesia, and pleural catheter drainage for at least 24 hours after the biopsy. A description of the technique used to perform an open lung biopsy can be found elsewhere [3,4]. The following interventions maximize diagnostic yield [4]. First, average, rather than normal or markedly abnormal, lung tissue should be preferentially sampled. Second, in cases of diffuse pulmonary disease, more than one site should be sampled, if possible. Third, areas corresponding to ground-glass appearance on high-resolution chest tomography should be biopsied, as they are more likely to reveal the inflammatory process [5]. Some authors believe that biopsies of the tip of the lingula or right middle lobe should be avoided because prior scarring, inflammation, and passive congestion of a nonspecific nature are likely to occur in these sites [6]. However, several studies refute this [4,7].

Thoracoscopic Lung Biopsy

Thoracoscopy is a percutaneous procedure that involves the endoscopic exploration and sampling of the contents of the thoracic cavity [1,8]. Unlike the other percutaneous procedures, thoracoscopic lung biopsy is considered a surgical procedure. Although there are a variety of potential uses for thoracoscopy, only lung biopsy is highlighted here. Thoracoscopic lung biopsy involves multiple small chest wall incisions and a controlled pneumothorax to collapse the lung. One incision allows the insertion of a sterile flexible endoscope to visualize the lung and pleural surfaces. A biopsy device is inserted through another incision and guided by direct endoscopic vision/video monitoring. Multiple points of entry may be necessary to determine the ideal endoscopic approach.

An advantage of thoracoscopy is that it can obtain a larger piece of lung tissue than bronchoscopy techniques, equal in size to that obtained at open lung biopsy. Where available, it is the open procedure of choice for patients in stable condition who are not requiring mechanical ventilation. Some authors caution that ventilator-dependent patients should not routinely undergo biopsy procedures by thoracoscopy because they typically cannot tolerate the change to a double-lumen endotracheal tube or the single-lung ventilation technique (see Table 69.1).

Although several studies of noncritically ill patients with interstitial lung disease demonstrated that thoracoscopy and open lung biopsy were identical in providing the diagnosis and complications [2], we are unaware of any study that compares open lung biopsy with thoracoscopic biopsy in critically ill patients. Due to the absolute and relative contraindications of thoracoscopic lung biopsy, critically ill patients on mechanical ventilation should preferentially undergo an open procedure.

Closed Biopsy Procedures

Percutaneous Transthoracic Needle Aspiration Biopsy

Percutaneous transthoracic needle aspiration biopsy involves the insertion, under guidance of fluoroscopy or computed tomography (CT), of a sterile needle through the chest wall into the area of the lung to be sampled [9]. Yields appear greatest if the procedure is performed under CT-guided fluoroscopy [10]. Needles of varying sizes (18-, 20-, 22-, and 24- to 25-gauge) can be used. In general, the thinner the needle, the fewer the complications [11]. A specimen is obtained by aspiration; it usually consists of cells (e.g., neoplastic, parenchymal, inflammatory), tissue fluids, or small tissue fragments. The major advantage of this procedure is that it can be easily performed with local anesthesia. The major disadvantages are that lung architectural integrity may not be maintained in the specimen, and the incidence of pneumothorax can be as high as 20% [12].

Bronchoscopic Procedures

A variety of techniques, including bronchial and transbronchial biopsy, bronchial brushing, transbronchial needle aspiration, and bronchoalveolar lavage (BAL), can be easily and safely performed with the flexible bronchoscope. A detailed discussion of flexible bronchoscopy is presented in Chapter 9.

Transbronchial Lung Biopsy. Transbronchial lung biopsy is performed by passing the bronchoscope to the segmental level, instilling a dilute solution of epinephrine, and then advancing flexible biopsy forceps into the radiographically abnormal area [13]. The forceps usually are advanced under fluoroscopic guidance. They are passed in the closed position until resistance is met or the patient signals that he or she has chest (pleural) pain. If pain is felt, the forceps are withdrawn in 1-cm

increments until pain is no longer perceived. If no pain is felt, the forceps are opened, pressure is gently applied, and the forceps are closed. If no chest pain is felt, the forceps are then removed. Some authors recommend wedging the bronchoscope into the airway from which the biopsy was taken to tamponade any potential bleeding and to prevent any blood from spilling out into other airways. However, a technique of applying continuous suction while moving the bronchoscope back and forth in the airway has been shown to be effective at controlling bleeding [14]. Synchronization of the biopsy to a phase of respiration has affected neither the amount of alveolar tissue obtained nor the integrity of the specimen [15]. Because specimens are small (not greater than 3.9 mm^2 on average [15]), multiple specimens should be obtained to maximize the yield of this technique.

Bronchial Brush Biopsy. Using a flexible wire brush, the operator performs a bronchial brush biopsy in a manner similar to forceps biopsy [16,17]. Usually under fluoroscopic guidance, the brush is passed into the radiographically abnormal area. The usefulness of this method is limited by the fact that only cellular material can be obtained and, in general, only endobronchial processes are sampled. A nodule not in communication with the bronchial tree cannot be entered with the brush, although the nodule can be sampled with a needle passed transthoracically.

Transbronchial Needle Aspiration. The transbronchial needle aspiration technique allows the clinician to pierce the walls of airways and aspirate cellular contents and tissue fluid or processes not in communication with the tracheobronchial tree. Specially designed catheters with attached needles are passed through the suction channel of the bronchoscope to the abnormal area [2]. As long as the vascularity of the area to be aspirated is appreciated or has been defined, transbronchial puncture with aspiration can be safely performed [18]. The use of endobronchial ultrasound to locate the exact location of lymph nodes and blood vessels improves yield while decreasing complications [19]. This procedure has a role in the diagnosis and staging of lung cancer and in the diagnosis of some benign mediastinal diseases, such as bronchogenic cysts and sarcoidosis [20]. When appropriately applied and with good cytopathologic support, this procedure can eliminate the need for surgical staging in a substantial number of patients with inoperable lung cancer [21].

Bronchoalveolar Lavage. BAL is a safe diagnostic extension of routine flexible bronchoscopy [22]. The tip of the bronchoscope is wedged into a segmental or smaller airway, and physiologic saline is instilled and withdrawn through the suction channel. Using this technique, it is possible to sample cellular and soluble components from the distal airways and alveoli. A detailed discussion of the use of BAL analysis in a variety of lung diseases can be found elsewhere [23]. The usefulness of BAL and bronchoscopy-protected brush-catheter cultures in diagnosing lung infections is reviewed in Chapters 9 and 68. Because BAL is not really a biopsy procedure and little or no associated bleeding occurs, it may be performed in patients with bleeding abnormalities and pulmonary hypertension.

EXPECTED RESULTS FROM LUNG BIOPSY

General Considerations

To determine what type of lung biopsy procedure should be performed and when, it is important to appreciate the expected results. The yield of positive diagnoses and the complications incurred depend on the procedure performed, the disease process, and the clinical stability of the patient. Table 69.2 lists the usefulness of several procedures with respect to specific disease processes [2,24].

TABLE 69.2

POTENTIALLY HIGH YIELDING BIOPSY PROCEDURES FOR A VARIETY OF UNDERLYING DISEASE PROCESSES [2,24]

Bronchoalveolar lavage
Infections (PCP, mycobacteria, endemic fungal)
Alveolar proteinosis
Alveolar hemorrhage
Acute eosinophilic pneumonia
Lung cancer
Lymphoma
Exogenous lipoid pneumonia
Transbronchial needle aspiration
Lung cancer
Lymphoma
Infections (endemic fungi, mycobacteria, Nocardia)
Bronchial brush biopsy
Lung cancer
Metastatic cancers
Transbronchial lung biopsy
Sarcoidosis
Lymphangitic carcinomatosis
Alveolar proteinosis
Lung cancer
Chronic eosinophilic pneumonia
Amyloidosis
Lymphocytic interstitial pneumonia
Cryptogenic organizing pneumonitis
Hypersensitivity pneumonitis
Invasive aspergillosis
Open lung biopsy or video-assisted thoracoscopic biopsy
Pulmonary capillaritis
Diffuse alveolar damage
Idiopathic pulmonary fibrosis
Nonspecific interstitial pneumonitis
Inorganic pneumoconiosis

Diffuse Parenchymal Disease in Clinically Stable Patients

To maximize the diagnostic yield, the ideal biopsy procedure is one that maintains the architectural lung integrity in the specimen. The procedures that best meet this requirement are (a) open lung biopsy, (b) thoracoscopic biopsy, and (c) transbronchoscopic lung biopsy. A number of reports on stable patients with diffuse lung disease have documented average rates of mortality, complications, and diagnostic yield for these procedures (Table 69.3) [1,2]. The highest tissue and diagnostic yields with low morbidity and very low mortality rates are obtained with open and thoracoscopic lung biopsies. Transbronchoscopic lung biopsy has lower diagnostic yields but carries the lowest morbidity and mortality rates of any of these biopsy procedures.

Although open and thoracoscopic lung biopsies more consistently yield adequate tissue and an increased likelihood of definitive diagnosis than transbronchoscopic forceps lung

TABLE 69.3

REPRESENTATIVE RESULTS OF LUNG BIOPSY PROCEDURES IN DIFFUSE LUNG DISEASE

Procedure	Mortality (%)	Complications (%)	Diagnostic yield (%)
Open	0–4.7	5–7[a]	94–95
Thoracoscopy	0–8	0–15[b]	96–100
Transbronchial forceps	<0.12	<10[c]	84

[a]Includes pneumothorax, empyema, and bleeding.
[b]Includes subcutaneous emphysema, infection, persistent air leak, and hemorrhage with need to convert to an open thoracotomy.
[c]Includes pneumothorax and hemorrhage.

biopsy, the latter may be preferred as an initial procedure to avoid the morbidity of general anesthesia, postoperative chest tube drainage, residual parenchymal and pleural scarring, postoperative pain, and increased length of hospital stay. The potential morbidity of empyema that may complicate an open or thoracoscopic lung biopsy procedure is also avoided with transbronchoscopic lung biopsy. This closed procedure is much less expensive and less painful and carries less mortality than open lung biopsy.

The overall complication rate for transbronchoscopic lung biopsy is less than 10%. The most common complication is pneumothorax, which may require chest tube drainage in up to 50% of cases [2]. Although the definitive diagnostic accuracy of transbronchoscopic lung biopsy is less than that of open and thoracoscopic lung biopsy (the tissue is smaller in quantity, often crushed, usually only peribronchiolar in origin, and not obtained under direct vision), its diagnostic yield is sufficiently high under certain conditions to justify its use as the initial biopsy procedure. For instance, in diffuse diseases such as carcinomatosis, sarcoidosis, and *Pneumocystis jiroveci* infection, transbronchoscopic forceps lung biopsy yields a specific diagnosis in 80% to 90% of cases [24,25].

Percutaneous needle aspiration (lung tap) also has a role in patients with diffuse parenchymal disease due to infection. The diagnostic yield in this setting varies from 40% to 82% [2]. Although percutaneous needle aspiration rarely causes mortality or air embolism, pneumothorax is common, occurring in approximately 25% of cases [2]. Hemoptysis occurs in 1% to 11% of patients [2]. Complication rates can be reduced by using an ultrathin needle (24- or 25-gauge) [2].

Lung Mass in Clinically Stable Patients

Because solid or cavitary masses are most often due to malignant or infectious causes, and because these diagnoses can often be readily confirmed by analyzing cellular material and fluid, open lung biopsy is usually not the preferred initial procedure. When open or thoracoscopic biopsy is performed, however, tissue and diagnostic yields should consistently approach 100%. Because nodules are usually resected in their entirety, surgical mortality depends on the severity of illness and extent of the resection [26]. The operative mortality associated with wedge resections by open thoracotomy of benign nodules in otherwise healthy, young patients is less than 1%, whereas it may vary from 2% to 12% in older patients with bronchogenic carcinomas who undergo pneumonectomy [27]. Complications of thoracotomy for lung masses in clinically stable patients are similar to those in such patients with diffuse lung disease. In a report of 242 solitary pulmonary nodules excised by video-assisted thoracoscopic surgery, there was a complication rate of 3.6% and no mortality [6] in patients undergoing thoracoscopy alone.

Percutaneous needle aspiration is extremely useful in evaluating lung masses. It carries a high diagnostic yield. A definite diagnosis is obtained in 80% to 97% of all masses, and adequate samples are obtained in 82% to 98% of cases [28,29]. If the lesion is less than 2 cm in diameter, the likelihood of obtaining adequate material is significantly decreased [28,30]. The diagnostic yield in solid malignant nodules can approach 96% [29]; in malignant and infectious cavitary lesions, 90% to 100% [28]; and in "benign" inflammatory disease, such as sarcoid nodules, 72% [2]. Although percutaneous needle aspiration is rarely associated with fatalities, complications such as pneumothorax, hemoptysis, and intraparenchymal hemorrhage or hemothorax are not uncommon [28–31]. The risk of pneumothorax increases with smaller size lesions and the presence of surrounding emphysema [32]. Hemorrhage and pneumothorax occur much more frequently in cavitary lesions. It has been demonstrated that aspiration biopsy using smaller, ultrathin 24- to 25-gauge needles results in a significant decrease in complications without loss of excellent diagnostic yield [33]. Although some authors feel that the risk of needle-track implantation of cancer is remote and it should not be considered a contraindication to the procedure [34], the risk of spread of malignant cells may be as high as 60% [35].

Peripheral lung nodules and masses can also be sampled using the transbronchoscopic brush and forceps techniques. Complication rates are less than those for percutaneous needle aspiration biopsy. Although the diagnostic yield is also diminished and the procedures are more difficult and time consuming than percutaneous needle biopsy, transbronchial biopsies more frequently yield tissue with architectural integrity. This may allow the pathologist a better opportunity to diagnose benign conditions. In peripheral malignant lesions, the diagnostic yield of transbronchial forceps biopsy relates directly to the number of biopsies obtained under fluoroscopic guidance. With brushing alone, the diagnostic yield is approximately 40%; with brushing plus one transbronchoscopic forceps lung biopsy, diagnostic accuracy improves to 55%; with brushing plus four transbronchoscopic forceps lung biopsies, accuracy reaches 60%; and with brushing plus five transbronchoscopic forceps lung biopsies, diagnostic accuracy improves to 75% [36].

Diffuse and Localized Disease in Clinically Unstable Patients

Lung biopsy in critically ill, clinically unstable patients is most commonly considered in those who are immunocompromised hosts or who have acute respiratory distress syndrome (ARDS).

Numerous studies have considered the merits of various lung biopsy procedures in the immunocompromised host who do not have acquired immunodeficiency syndrome (AIDS). The choice of which biopsy procedure to perform depends on a number of factors, including the severity and rate of progression of the illness, differential diagnosis, underlying medical conditions, radiographic findings, and level of experience and expertise of the physician performing the procedure. The diagnostic yields of the different biopsy procedures also depend on a number of factors, including differential diagnosis, underlying medical conditions, and radiographic findings.

For critically ill patients with rapidly progressing hypoxemia and radiographic infiltrates, open lung biopsy is the procedure of choice because it is associated with the highest yield and can be surprisingly well tolerated in critically ill patients [37]. Mortality rates are probably less than 1%, with several studies

reporting a mortality rate of 0% [37–39]. For less severely ill patients in whom progressive hypoxemia is not an immediate problem, less invasive procedures can be attempted first.

For all non-AIDS immunocompromised patients, the overall yield of BAL is around 40%, but the yield of making a specific diagnosis increases to 70% when a transbronchial biopsy is also performed [40]. However, studies have demonstrated different yields for specific groups of immunocompromised patients. For example, for solid-organ transplant patients with diffuse infiltrates, bronchoscopy with BAL can result in the correct diagnosis 59% to 85% of the time and is associated with little to no morbidity [41,42]. In neutropenic leukemic patients with diffuse infiltrates, however, BAL is of little value as it is associated with a very low yield for invasive aspergillosis, has a very high false-positive rate for bacterial pathogens, and does not aid in diagnosing drug-induced pulmonary processes [43]. In addition, in neutropenic patients, the bronchoscopic procedure itself can result in the development of pneumonia, bacteremia, and sepsis [43,44]. For patients who are immunocompromised due to a recent bone marrow transplant, BAL results in a 34% to 50% yield in determining the etiology of pulmonary infiltrates [45]. In patients with AIDS, the sensitivity of lavage alone for diagnosing *P. jiroveci* can be as high as 97% [46]. In nonneutropenic patients, BAL does not increase the already low complication rate of routine diagnostic flexible bronchoscopy (see Chapter 9).

Transbronchial biopsy in patients with diffuse pulmonary infiltrates and solid-organ transplants is associated with yields of 46% to 78% [47,48], and in patients with hematologic malignancies, a yield of 55% [47]. Transbronchial biopsy has the highest frequency in diagnosing tuberculosis, fungal pneumonia, and pulmonary involvement of hematological malignancies [47]. In non-AIDS patients, BAL in combination with transbronchial biopsy has a higher yield than BAL or transbronchial biopsy alone [40]. In this setting, the combination of BAL and transbronchial biopsy can increase yield to 70% [40]. In the bone marrow transplant population, transbronchial biopsy appears to have a low yield and adds little information while being associated with increased risks due to the frequency of thrombocytopenia [49].

Transthoracic needle aspiration biopsy has the highest yield in immunocompromised hosts with focal pulmonary processes, especially peripheral lung lesions. In these clinical settings, sensitivities of a transthoracic needle biopsy can be greater than 80% for infectious processes and greater than 90% for malignant processes [50]. Yields for fungi, tuberculosis, and *Nocardia* can be greater than 90% [50].

In critically ill patients requiring mechanical ventilation, lung biopsy may be considered to assist in diagnosis and management and to ensure that no treatable disease process is overlooked. Specific diagnosis may be made in up to 70% to 80% of the cases [38,50]. Other studies report lower yields, however, and suggest that the results of the biopsy may not alter management. While two studies demonstrated that open lung biopsy in this setting provided information that altered therapy only 47% to 60% of the time [39,51], one study demonstrated an alteration in therapy based on the biopsy results 81% of the time [38]. A second study demonstrated that altered therapy based on the open lung biopsy results lead to an improvement in survival in patients with suspected ARDS [37]. Open lung biopsy may also be helpful in the critically ill pediatric population. A study of 26 children demonstrated that open lung biopsy was diagnostic in 96% and associated with no mortalities [52]. Open lung biopsy is the recommended surgical procedure of choice in evaluating the etiology of diffuse pulmonary infiltrates in bone marrow patients with a nondiagnostic BAL [49]. Lung biopsy is particularly useful in diagnosing invasive aspergillosis in these patients [53]. However, a 20% false-negative rate for detecting fungal infections has been reported [49]. Overall, the results of open lung biopsy can change specific therapeutic interventions in 63% of bone marrow patients with diffuse pulmonary infiltrates [54].

There is no consensus about which biopsy technique is best and under which clinical circumstances in clinically unstable patients. A wide range of expected diagnostic yields exists for all procedures, and the etiology of lung disease in these patients may remain unknown in 19% to 45%, even when adequate tissue is obtained by open lung biopsy. Deciding who, when, and how to sample is further complicated by the occasionally excessive mortality rates associated with lung biopsy procedures, and by the knowledge that even with adequate biopsy material and appropriate therapy, the high mortality rates seen in this group of patients may not be altered [55]. Consequently, the clinician must adopt a practical approach to management that combines empiric therapy with available biopsy procedures.

In patients with AIDS, open lung biopsy is the most sensitive and specific procedure. However, open or thoracoscopic lung biopsy should not be the first procedure contemplated or attempted because diffuse infiltrates are most likely due to opportunistic infection, and bronchoscopic procedures accurately diagnose infection in 90% or more of the cases [46]. Open lung biopsy or thoracoscopic biopsy is appropriate when at least one bronchoscopic examination with BAL and transbronchial biopsy (unless contraindicated) has been nondiagnostic [50]. It is rarely useful in patients who worsen after treatment for a diagnosis established by bronchoscopy [46], and it should not be repeated often.

INDICATIONS FOR LUNG BIOPSY IN CRITICALLY ILL PATIENTS

General Considerations

A lung biopsy is indicated in critically ill patients when (a) the pulmonary disease process progresses and its etiology remains unknown, (b) an initial evaluation short of lung biopsy has failed to reveal the etiology and logical empiric therapy has failed to reverse the process, (c) no contraindications exist to performing the procedures, (d) the prognosis of the patient's underlying disease is good, and (e) the potential benefit from performing the procedure outweighs associated morbidity and mortality [55].

Management of Critically Ill Patients with Pulmonary Disease

The lung biopsy is part of an extensive evaluation of a pulmonary abnormality, yet in critically ill patients it is never the initial step. Any critically ill patient is, for clinical purposes, a compromised host and should be managed as such (Table 69.4).

Because of their altered defense mechanisms, critically ill patients are particularly susceptible to infection by opportunistic as well as pathogenic organisms. Nonimmunologic defenses (e.g., altered physical barriers, altered indigenous microbiologic flora) as well as immunologic defenses (e.g., altered humoral or cellular immunity) may be impaired. These impairments may be partial or transient (e.g., alcoholism, diabetes mellitus, sickle cell anemia, uremia, malnutrition) as well as prolonged or permanent (e.g., Hodgkin's disease, chronic lymphatic leukemia, acute myelogenous leukemia, multiple myeloma, inherited immune deficiency diseases, cytotoxic chemotherapy, corticosteroids, irradiation).

TABLE 69.4

MANAGEMENT OF THE COMPROMISED HOST WITH PULMONARY DISEASE

Identify the patient as a compromised host.
Construct a list of differential possibilities that remains constant from patient to patient.
Integrate the history, physical examination, and laboratory data with chest radiographic pattern to narrow the diagnostic possibilities.
Assess the urgency of the situation and the need for invasive diagnostic studies.

Four major differential diagnostic possibilities should be considered in every critically ill (compromised) patient with pulmonary disease (Table 69.5). After general diagnostic considerations, the diagnostic possibilities are narrowed by integrating the history, physical examination, and laboratory data (e.g., routine blood work; serologic studies; and smears and cultures of blood, urine, sputum, cerebrospinal fluid, ascites, and pleural effusion) with the chest radiographic pattern. A previous recent or remote chest radiograph may confirm or rule out the presence of another stable process. Although unilateral or focal infiltrates suggest bacterial infection, the presence of bilateral disease does not rule out infectious processes [52]. Unusual and opportunistic organisms such as *P. jiroveci* often present as bilateral infiltrates after administration of immunosuppressive drugs or chemotherapy [56].

The final step involves assessing clinical urgency to evaluate the need for invasive diagnostic studies such as lung biopsy. In some clinical cases, empiric therapy should be considered and invasive biopsy avoided. These cases include patients with underlying diseases that limit life expectancy, such as advanced AIDS or advanced cancer; leukemia before treatment, as the risk for opportunistic infection is low, and there is a high probability of successful treatment with antibacterial therapy; uncontrolled coagulopathies; severely impaired pulmonary function such that an invasive procedure would not be tolerated; and patient refusal to undergo an invasive procedure [50].

In other clinical settings, other less invasive treatment options should be attempted first. For example, in the thrombocytopenic, immunocompromised host who has diffuse pulmonary infiltrates and who is clinically stable with supplemental oxygen, platelet transfusions and observation may be adequate therapy. As many as 70% of infiltrates in these patients may be due to intrapulmonary bleeding [57].

Finally, in other clinical settings, lung biopsy (especially open lung biopsy) should be considered early on in the management plan. Solid-organ transplant patients and patients with other immunocompromised states (with life expectancies measured in years) who develop hypoxemia with fever and diffuse infiltrates are more likely to benefit from a biopsy [50].

DIFFERENTIAL DIAGNOSIS OF PULMONARY DISEASE IN THE COMPROMISED HOST

Manifestation of basic disease
Complication of management
Lipid embolization
Pulmonary edema
Pulmonary hemorrhage
Leukoagglutinin reaction
Radiation pneumonitis
Drug-induced pneumonitis
The presence of another, unrelated basic disease
Infection
Bacterial
Viral
Fungal
Parasitic

SELECTION OF LUNG BIOPSY PROCEDURE

Three factors should be considered in choosing a particular lung biopsy procedure: (a) local expertise, (b) the patient's condition, and (c) the potential yield of the procedure.

Local Expertise

Local expertise includes the availability of personnel skilled in performing the procedure and laboratory personnel skilled in specimen processing and analysis. If local expertise is limited (e.g., a skilled cytopathologist is not available to read bronchial brush or percutaneous needle aspiration specimens, or the microbiology laboratory is not equipped to process reliably specimens for the variety of organisms seen in immunocompromised hosts), the patient should be transferred to another institution with expanded resources.

Patient Condition

Once it has been decided that the patient's prognosis is potentially good enough to justify a lung biopsy technique, the next decision is the choice of biopsy procedure. If it is determined that the patient's condition allows time for only one diagnostic procedure (i.e., the patient is rapidly deteriorating), then an open or thoracoscopic lung biopsy should be performed. If there are no contraindications to a closed procedure and the patient's condition is such that there will be time for another diagnostic procedure if necessary, then one of the closed procedures may be preferable. Mechanical ventilation with positive pressure should not be considered an absolute contraindication to transbronchial biopsy [2]. Useful information has been obtained with transbronchial lung biopsy with acceptable morbidity (e.g., pneumothorax, hemorrhage) in a limited number of hemodynamically stable, mechanically ventilated patients.

Potential Yield of the Procedure

The usefulness of several biopsy techniques is summarized in Table 69.2. The potential yield of a particular biopsy procedure depends on local expertise and the individual clinical setting. For example, in the elderly patient with a solitary pulmonary nodule and clinically obvious disseminated carcinomatosis, percutaneous needle aspiration biopsy, which has a high diagnostic yield and relatively low complication rate, should be the initial procedure of choice to document whether the nodule is malignant. When a patient with a solitary pulmonary nodule has a clinical picture of vasculitis, however, open lung biopsy (or thoracoscopy biopsy if the lesion is peripheral) might be considered first or performed after bronchial

brushing and forceps biopsies and percutaneous needle aspirations yield nonspecific findings without evidence of malignancy or infection.

In patients with diffuse pulmonary disease, the clinical setting influences the choice of procedure. When a biopsy is performed to document the presence and type of inorganic pneumoconiosis, open lung biopsy and thoracoscopic biopsy [58] are the only procedures that yield a sufficient amount of tissue for all the requisite analyses (chemical analysis must be included). When diffuse pulmonary infiltrates suggesting sarcoidosis or carcinomatosis occur in the appropriate clinical setting, transbronchoscopic forceps lung biopsy should be initially considered because it has an extremely high yield in these situations [24,25]. In the non-AIDS immunocompromised host with diffuse pulmonary infiltrates, transbronchoscopic lung biopsy may yield a diagnosis overall up to 78% of the time [47]. In chronic interstitial pneumonias (e.g., idiopathic pulmonary fibrosis), open or thoracoscopic lung biopsy is diagnostically superior to transbronchoscopic lung biopsy [24]. If chronic eosinophilic pneumonia, desquamative interstitial pneumonitis, or bronchiolitis obliterans organizing pneumonia can be ruled in by transbronchoscopic forceps lung biopsy, however, open or thoracoscopic lung biopsy may not be necessary. If infection and malignancy can be ruled out by transbronchoscopic forceps lung biopsy and other nonbiopsy laboratory techniques, it also may be unnecessary to perform an open procedure. If the diffuse process worsens, corticosteroids can be empirically initiated, and the response to therapy can be assessed by noninvasive means (e.g., chest radiograph, gallium scan, pulmonary function studies).

HANDLING OF SPECIMENS

To maximize the diagnostic yield from any lung biopsy procedure, specimens must be rapidly transported to the appropriate laboratories by a person directly involved in the patient's management. All analyses should be planned in advance by the team involved in the case (e.g., pathologist, microbiologist, pulmonologist, infectious disease specialist).

Because large samples of tissue are obtained from open lung and thoracoscopy biopsies, multiple pieces should be processed for a variety of analyses. First, under sterile conditions, a piece of fresh tissue should be kept moist with physiologic saline and transported immediately to the microbiology laboratory to be minced, ground, and cultured for aerobic and anaerobic bacteria, fungi, and *Mycobacterium* and *Legionella* sp. A second piece should be snap frozen in liquid nitrogen and stored at −70°C to ensure that immunofluorescent studies (e.g., immunoglobulin deposition as well as T- and B-lymphocyte markers, direct fluorescent antibody staining for *Legionella* sp.), oil-red-O staining, and viral cultures can be performed if necessary. If pneumoconiosis is suspected, special studies can be performed on formalin-fixed, paraffin-embedded tissue. At this juncture, touch preparations of a freshly cut surface of the tissue can be made for cytologic analysis, and special stains can be used for rapid diagnosis of microorganisms. The pathologist should perform a frozen-section analysis to (a) advise the surgeon whether an adequate biopsy has been obtained (i.e., the tissue does or does not exhibit a pathologic lesion), (b) obtain information that could focus the workup of the specimen (e.g., order a lymphoma workup or specific viral culture), and (c) attempt to obtain a rapid definitive diagnosis. The remainder of the tissue should be placed in 10% formalin for routine histologic study and special stains.

Unlimited analysis on specimens from transbronchoscopic forceps lung biopsies cannot be performed because of the relatively small amount of tissue obtained. To maximize the diagnostic yield, four to six pieces should be obtained [36,59]. In immunocompromised patients, touch preparations of transbronchial biopsies should be obtained and stained for microorganisms. If an exogenous lipoid pneumonia, immunologic disease, or *Legionella* infection is suspected, one piece should be snap frozen for fat stains and immunofluorescent studies. One piece can be submitted to microbiology and the remaining pieces processed for routine and special pathologic stains. Once the slides have been made from bronchial brush biopsies, they can be stained in a manner similar to needle aspiration specimens.

A specimen obtained by percutaneous transthoracic needle aspiration should be sent for microbiologic as well as cytologic analyses unless infection is not even a remote possibility. For cytologic analysis, a few drops of the aspirate can first be smeared on to frosted glass slides that are immediately placed in 95% alcohol. Then, a portion can be injected into a test tube with physiologic saline so that it can be processed using the Millipore filter or cytocentrifuge, or into a vial containing a fluid preservative for use in one of the instruments capable of preparing cell monolayers [60]. Filters and slides can be stained routinely by the Papanicolaou technique and specifically by Gomori-methenamine silver (for fungi and *P. jiroveci*), periodic acid-Schiff (for fungi), and Ziehl–Neelsen stains (for acid-fast organisms). When evaluating for the possibility of *P. jiroveci*, immunofluorescent staining with monoclonal antibodies can increase the yield. Sensitivity and specificity of this test have been reported to be greater than 90% [61]. The portion for microbiology should be immediately injected into prereduced anaerobic transport medium and transported to the microbiology laboratory. In the laboratory, drops of the specimen are placed on several sterile slides and allowed to air dry for Gram's, Ziehl–Neelsen, and direct fluorescent antibody stains for *Legionella* organisms. The remaining specimen can be cultured for anaerobic and aerobic bacteria, fungi, and *Mycobacterium* and *Legionella* sp.

After submitting an aliquot of BAL fluid for microbiologic analysis, the specimen should be handled in the cytology laboratory in a manner similar to that of percutaneous aspiration specimens.

CHAPTER 70 ■ SLEEP ISSUES IN THE INTENSIVE CARE UNIT SETTING

KIM L. GORING AND NANCY A. COLLOP

OVERVIEW OF NORMAL SLEEP

Adequate quantity and quality of sleep is necessary for normal physiologic function. The average adult is recommended to obtain 7.5 to 8.5 hours of consolidated sleep within a 24-hour cycle to sustain normal neurohormonal function. The ability to achieve a normal duration and pattern of sleep rests on several factors internal and external to the subject. The important internal factors include the homeostatic and circadian drive to sleep, volitional control of the length of sleep, age, drugs, and comorbid illness. External factors include ambient temperature, noise, and light exposure, all of which influence the quantity and sleep-stage distribution throughout the night [1].

Sleep is divided between non-rapid eye movement (NREM) and rapid eye movement (REM) cycles. The normal human adult begins sleep in NREM with REM sleep occurring approximately 90 to 120 minutes later. NREM sleep is composed of stages 1 (N1), 2 (N2), and 3 (N3). Slow-wave sleep (stage 3), a deeper and more restful sleep, predominates in the first third of the night and tends to occur soon after sleep onset. As noted, REM sleep (R) occurs after 90 to 120 minutes then alternates with NREM at a periodicity of approximately 90 minutes. In a young adult, the percentage of total sleep time is broken down into N1, 2% to 5%; N2, 45% to 55%; N3 (slow-wave sleep), 13% to 24%; and REM, 20% to 25%.

Sleep is regulated through both circadian and homeostatic mechanisms. The circadian rhythm, through a 24-hour cycle of internal pacemaker activity originating in the suprachiasmatic nucleus of the hypothalamus, helps to determine the sleep–wake cycle. This cycle tends to be synchronized to the 24-hour day predominantly by environmental stimuli, specifically light exposure, and can easily be disrupted in an environment devoid of light/dark shifts. Melatonin is a hormone involved in the regulation of the sleep–wake cycle. It is synthesized in the pineal gland and its secretion underlies a strong circadian periodicity designed to promote sleep at night. Maximum secretion tends to be associated with an absence of light, almost exclusively at night between 9 PM and 3 AM, with lowest baseline values between 7 AM and 9 AM [2], thereby increasing the drive to sleep at night. Hormone secretion (e.g., cortisol) and body temperature changes throughout the day are other examples of systems exhibiting circadian activity.

Homeostatic mechanisms also influence sleep–wake cycles. Homeostatic drive is similar to thirst: the longer you are without sleep, the sleepier you become. Voluntary control of sleep onset and prior sleep deprivation enhance the homeostatic drive to sleep, regardless of environmental cues, and also affects sleep regulation.

Sleep onset is associated with a loss of wakefulness stimuli that, even in normal, healthy people is associated with an initial instability in ventilation. N1 sleep is characterized by a decrease in respiratory drive with irregular breathing, decrease in muscle activity, and an increase in upper airway compliance. As sleep progresses through N2 and N3, respirations become stable with a regular rate and tidal volume but a fall in minute ventilation of 0.5 to 1.5 L per minute (approximately 13% decrease) occurs. This is thought to be secondary to resetting of the central chemoreceptor set point that controls the ventilatory drive [3]. The result is a gradual increase in $PaCO_2$ by 4 to 6 mm Hg and a decrease in pH by 0.03 to 0.05 units across the night (Fig. 70.1). On awakening, the central chemoreceptor set point returns to normal and minute ventilation increases.

Sleep is a necessary part of life. Sleep deprivation is associated with decreased or abnormal immune function [4,5], impaired motor and cognitive function [6,7], and has been shown to influence morbidity and mortality outcomes in critically ill patients [8]. Animal data show that extremes of sleep deprivation lead to failure to thrive and eventual death [9]. Metabolic consequences of fragmented sleep in humans are increasingly being recognized. The development of insulin resistance with increased blood pressure, heart rate, cortisol level, and sympathetic activity have been recognized to occur with short-term sleep deprivation. There is an abnormality in thermal regulation and an increase in inflammatory cytokines (tumor necrosis factor-α [TNF-α], interleukin 1 [IL-1], and IL-6) and C-reactive protein, which are known to cause vascular injury and increase insulin resistance [10,11]. This serves to highlight the necessity of good-quality sleep for normal metabolic and physiologic function, especially important in a critically ill population.

ABNORMALITIES OF SLEEP IN THE INTENSIVE CARE UNIT

Abnormal Quantity and Quality of Sleep

Sleep research in the ICU is a murky pond made cloudy by the multitude of confounding variables and questionable reliability of methods used to evaluate sleep during critical illness. The sleep architecture of ICU patients has been well documented to be abnormal. However, there is a great variation in reported abnormalities in both NREM and REM sleep amongst investigators. This may in part be due to the tools used to measure sleep which range from polysomnography (PSG) (the gold standard) to actigraphy, bedside observation, and patient recall. The PSG is expensive and time consuming resulting in the utilization of the other methods to detect sleep. The significant limitations of the other methods include an inability to describe sleep architecture and the occurrence of sleep state misperception. Their strengths include the ability to study large numbers and over extended periods [12]. PSG results using Rechtschaffen and Kales methodology for sleep staging may be unreliable because of discrepancies in analyzing electroencephalographic (EEG) waveforms in part due to distortion of waveforms from medication, underlying illness (e.g., sepsis, encephalopathy), and measurement artifact due to the ICU environment [13,14]. An observational methodologic study evaluating the reproducibility

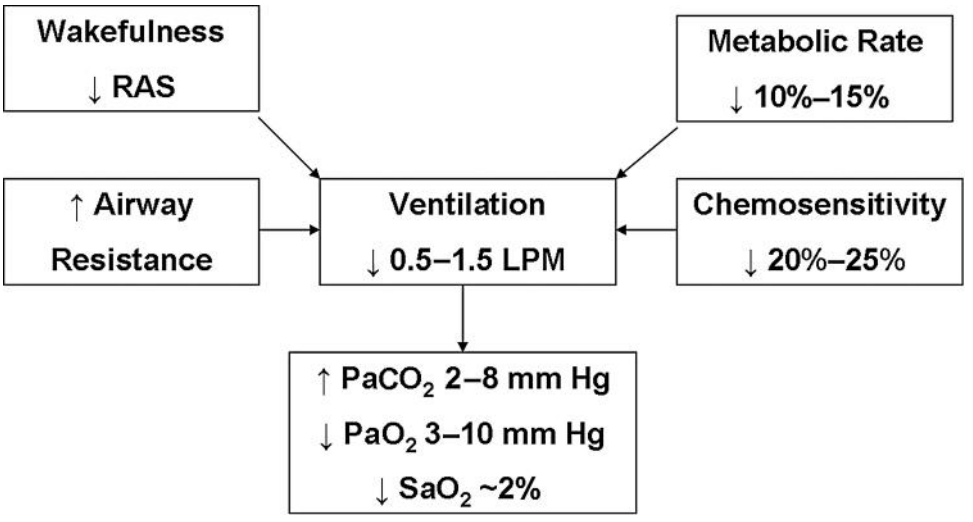

FIGURE 70.1. Changes in the respiratory system and blood gases during normal sleep. The decrease in reticular activating system (RAS), metabolic rate, and responsiveness to arterial PaO_2 and PCO_2 along with increased airway resistance would lead to decreased ventilation and arterial blood gases during sleep in normal individuals. LPM, liters per minute. [From Mohsenin V: Sleep in chronic obstructive pulmonary disease. *Semin Respir Crit Care Med* 26:110, 2005, with permission].

of manual versus computer-based sleep assessment concluded that more reproducible results of EEG analysis may be obtained with the use of computer-based spectral analysis as opposed to the manual method of scoring [15]. Notwithstanding the above discussion, sleep architecture in the ICU has generally been reported to have higher quantities of lighter N1 and N2 sleep and reduced slow wave and REM sleep. In addition, some patients have abnormal EEG characteristics of stage 2 sleep (absence of spindles and K complexes) [8]. Partial arousal states have been reported; the EEG shows slow-wave sleep but accompanied by movements typical of wakefulness [8]. Studies with 24-hour PSG recordings have found total sleep time to range between 3.6 and 6.2 hours a day in patients both with and without sedatives or hypnotics [16–18]. Other studies reveal average total sleep times of 7 to 10.4 hours per day, but with large variations in total sleep time among patients, with some sleeping for less than an hour and others for 12 to 15 hours [8,19,20]. Many studies highlight that patients spend almost equal amounts of time asleep during the day as at night [8,18]. Estimations of patient's total sleep time based on observation alone tend to overestimate the amount of sleep and have no way of detecting more subtle episodes of sleep disruption [17,21].

Critically ill patients were found to spend 6% or less of total sleep time in REM [8,20,22]. By contrast, Gabor and colleagues reported REM sleep to be as much as 14.3% of total sleep time [18]. It is unclear if this represented REM rebound from prior ICU-associated sleep deprivation or may have been a rebound from REM-suppressant medication. Patients were also found to experience frequent arousals and awakenings, with investigators reporting a range of 35 to 54 arousals per hour of total sleep time [8,23].

This highlights that not only is sleep in the ICU different from normal in terms of less time spent in deeper stages but the lighter stages of sleep have abnormal EEG patterns of uncertain clinical significance and more frequent arousals throughout total sleep time. Sleep patterns remain altered with continued ICU stay. It may take several days for sleep architecture to normalize after the patient is transferred to the general medical ward [18].

More recently, the effect of continuous versus intermittent sedation versus neuromuscular blocking agents on sleep in mechanically ventilated patients was evaluated. In all groups, there was an increase in total sleep time coupled with an increase in slow-wave sleep of low amplitude. The authors speculated that the increased delta activity may have been the result of a metabolic process or medication effect [24]. This highlights the fact that an elevated total sleep time in the ICU resulting from medication is not identical to physiologic sleep and cannot be assumed to deliver the same restorative function.

The sequelae of abnormal sleep in the ICU ranges from patient perception of excessive sleepiness while in the ICU coupled with an appreciation of poor-quality sleep as compared to home [25] to abnormalities in ventilation and even acute psychoses.

CAUSES OF SLEEP DISRUPTION

Noise and Hospital Staff

The environmental stimulus most reported in the literature as disturbing sleep is noise [25–29]. The level of noise in the ICU ranges from 50 to 85 decibels (dB) through a 24-hour period [26–29]. This level of noise is comparable with a busy office (70 dB) or a pneumatic drill heard 50 ft away (80 dB) [28–30]. These noise levels exceed that recommended by the US Environmental Protection Agency for hospital settings suggested to be 45 dB during the day and 35 dB at night [31]. The sources of noise as identified by ICU patients include equipment and conversation among staff [24]. Noise may disrupt sleep in two ways: either arouse/awaken the patient or produce a change to a lighter sleep stage. There is some debate, however, as to what degree the noise causes the arousal or whether noise may simply coincide with many of the frequent awakenings ICU patients experience.

Reports have suggested that the response to noise may vary based on the age and gender of the patient. Healthy men and women were monitored for changes in sleep stages with EEG in a controlled environment. The environmental noise in these studies included simulated sonic booms and jet aircraft flyover noise. Older individuals and women had lower sleep thresholds and were more likely to be awakened or shift to a different sleep stage [29]. However, findings in healthy subjects may not apply to critically ill patients whose sleep threshold is altered by sleep deprivation, drugs, or encephalopathic states. One study showed no difference in perceived ICU sleep quality or daytime sleepiness by way of gender nor were there significant correlations between perceived sleep quality and age or length of ICU stay. However, in this study, information was gained by way of a sleep questionnaire without EEG monitoring [25].

Freedman et al. [25], using a questionnaire distributed to ICU patients on the day of their discharge from the unit, showed perceived differences in individual environmental factors in terms of their degrees of ICU sleep disruption. Checking vital signs and phlebotomy were perceived as most disruptive. These were followed by noise, diagnostic tests, nursing interventions (e.g., bathing), ambient light, and medication

administration. In terms of environmental noise, talking and telemetry alarms were perceived as significantly more disruptive to sleep than the phone or beepers. The investigators also compared perceived sleep disruption between patients discharged from medical, surgical, and cardiac ICUs and concluded that medical ICU patients perceived their sleep to be more disrupted by environmental factors than did patients in other units. The study's design was again limited by lack of EEG verification of sleep architecture and the lack of control for severity of illness and medications used. This study highlighted that environmental noise, although an important contributor to sleep disruption, is but one of many environmental factors causing poor sleep in the ICU.

Another study using a questionnaire administered to ICU patients within the first week of their stay reported that the physical stressors patients considered the most important included pain and inability to sleep due to noise and nasogastric and endotracheal tubes. Loss of self-control, autonomy, and lack of understanding about attitudes and procedures were the main psychological stressors [32].

Does reduction in noise levels result in better sleep in the ICU? Investigators evaluated sleep outcomes in 18 female patients in an acute obstetrics/gynecologic unit and found a statistically significant improvement in subjective outcome measures in those who wore earplugs as compared with those who did not [33]. A PSG study in healthy volunteers randomly exposed to either simulated ICU noise or earplugs during sleep showed an increase in sleep disruption associated with ICU noise as compared with use of earplugs. There was also an increase in REM sleep in those using earplugs [34]. Whether it is the peak noise level or a change in the noise level that causes sleep disruption is unclear. Investigators added white noise to the background noise and reported a decrease in arousal frequency from 48 per hour to the no noise baseline of 13 per hour [35]. This supports the thought that maintenance of a certain level of unobtrusive background noise in the ICU may be helpful in reducing arousal frequency.

Sleep in the ICU is poor in terms of quality and lack of continuity. Nursing care activities, phlebotomy, noise, the presence of invasive tubes, pain, and patients' lack of understanding of their medical care all contribute to the poor sleep. Despite this, the cause of 68% of arousals could not be identified by Gabor and coworkers [18] in a PSG study assessing noise as a cause of disrupted sleep in seven mechanically ventilated patients. Other potential culprits include underlying medical illness, mechanical ventilator mode, and medications.

Medications

The effect on sleep of the vast number of medications used in the ICU setting is not well established. Many drugs improve sleep and others have adverse effects, and often patients are on a number of medications that may have polarizing effects on sleep. Table 70.1 lists medications that are often used in the ICU and characterizes their known effects on sleep.

Sedative/hypnotics are frequently used in the ICU to control symptoms of anxiety and insomnia. They are also used as muscle relaxants and anticonvulsants. The most frequently used sedative/hypnotics are of the benzodiazepine class. Benzodiazepines exert their sedative/hypnotic effect through the γ-aminobutyric acid-benzodiazepine receptor complex. Equally popular are two nonbenzodiazepine drugs, zolpidem and zaleplon. Zolpidem is an imidazopyridine compound and zaleplon is a pyrazolopyrimidine compound. Both drugs also bind selectively to the γ-aminobutyric acid-benzodiazepine receptor complex. The neuroanatomic sites at which these drugs act is less well understood, but a number of findings suggest that the basal forebrain and anterior hypothalamus are the crucial areas [36,37]. The half-life of the benzodiazepines ranges from 48 to 120 hours (flurazepam) to 2 to 6 hours (triazolam). They are lipophilic, which may result in an increase in the volume of distribution, especially in the elderly or the obese. Metabolism is through the hepatic microsomal system, therefore limiting their safe use in hepatically impaired patients. Overall, these drugs are generally well tolerated and have much less respiratory depressant effect than barbiturates.

PSG studies of benzodiazepines reveal decreased sleep latency and increased total sleep time, consistent with their clinical effects. There is increased spindle activity and mild

TABLE 70.1

DRUGS COMMONLY USED IN INTENSIVE CARE UNITS AND THEIR EFFECTS ON SLEEP PATTERN

Drug class or individual drug	Sleep disorder, induced or reported	Possible mechanism
Benzodiazepines	↓ REM, ↓ SWS	γ-Aminobutyric acid type A receptor stimulation
Opioids	↓ REM, ↓ SWS	μ-Receptor stimulation
Clonidine	↓ REM	α_2-Receptor stimulation
Nonsteroidal anti-inflammatory drugs	↓ TST, ↓ SE	Prostaglandin synthesis inhibition
Norepinephrine/epinephrine	Insomnia, ↓ REM, ↓ SWS	α_1-Receptor stimulation
Dopamine	Insomnia, ↓ REM, ↓ SWS	D_2-Receptor stimulation/α_1-receptor stimulation
Beta-blockers	Insomnia, ↓ REM, nightmares	Central nervous system beta-blockade by lipophilic agents
Amiodarone	Nightmares	Unknown mechanism
Corticosteroids	Insomnia, ↓ REM, ↓ SWS	Reduced melatonin secretion
Aminophylline	Insomnia, ↓ REM, ↓ SWS, ↓ TST, ↓ SE	Adenosine receptor antagonism
Quinolones	Insomnia	γ-Aminobutyric acid type A receptor inhibition
Tricyclic antidepressants	↓ REM	Antimuscarinic activity and α_1-receptor stimulation
Selective serotonin reuptake inhibitors	↓ REM, ↓ TST, ↓ SE	Increased serotonergic activity
Phenytoin	↑ Sleep fragmentation	Inhibition of neuronal calcium influx
Phenobarbital	↓ REM	Increased γ-aminobutyric acid type A activity
Carbamazepine	↓ REM	Adenosine receptor stimulation and/or serotonergic activity

REM, rapid eye movement; SE, sleep efficiency; SWS, slow-wave sleep; TST, total sleep time.
From Bourne R, Mills G: Sleep disruption in critically ill patients: pharmacological considerations. *Anaesthesia* 59:376, 2004, with permission.

reduction of REM sleep. More striking is the reduction in slow-wave sleep. The clinical ramification of decreased slow-wave sleep is unclear. The nonbenzodiazepines, zolpidem and zaleplon, have minimal or no effect on slow-wave or REM sleep. These drugs, however, are thought to induce more normal sleep patterns than barbiturates (a once popular sedative/hypnotic choice) that caused a severe reduction in REM sleep. Clinical efficacy studies of short-term use of both the benzodiazepines and nonbenzodiazepines in an outpatient population show that patients have better subjective ratings of sleep with minimal chance of developing tolerance.

Perception of sleep quality in ICU patients on high doses of sedatives is less predictable. A questionnaire rating sleep quality with nocturnal propofol as opposed to midazolam was administered to a group of nonintubated critically ill patients. Although there was no difference in self-perception of sleep quality between the two drugs, there was a disparity in perceived sleep quality, with some patients reporting improved sleep quality and others rating extremely poor sleep, although all infusions had been titrated to achieve deep but arousable sleep to the observer [38]. Dexmedetomidine (Dex), a sedative with analgesic properties, was compared with Propofol in a randomized clinical trial in patients post-CABG evaluating the patient reported level of satisfaction in the 24-hour postoperative period. There was no statistically significant advantage of Dex over Propofol [40].

Although use of a sedative/hypnotic is a reasonable approach to promote a sleep state in an ICU patient, the quality of the sleep may not be in direct proportion to the quantity. This medicated sleep state while mimicking normal sleep has enough abnormal architecture to lead one to question whether the patient receives the necessary restorative, physiologic boost a good night's sleep should provide.

Psychoactive medications such as *antidepressants* and *antipsychotics* are not often prescribed in the acute setting in the ICU, but many patients may come into the unit taking these medications. PSG shows tricyclic depressants generally increase total sleep time and decrease wakefulness, especially the tertiary amines such as amitriptyline and imipramine. The secondary amines (e.g., nortriptyline, desipramine) are less sedating. Serotonin-selective reuptake inhibitors generally increase sleep latency and decrease REM sleep and total sleep time.

Sedation is a common side effect of the traditional antipsychotics, but the incidence and degree of sedation varies significantly among the drugs. Haldol is less sedating than the older chlorpromazine. Clozapine is a newer agent with significant sedating effects. Sedation is reported less frequently with risperidone and olanzapine.

ICU patients may need *antiseizure medication*. It is well known that sedation occurs across the classes of antiepileptics. A few well-known examples include phenobarbital, phenytoin, and valproic acid. The sedative effect is to some extent dose dependent, but generally, there is decreased sleep latency and increased total sleep time with impaired daytime function. The newer agents (e.g., lamotrigine and topiramate) also have subjective reports of increased sedation, but PSG data are lacking.

Several drugs used in the ICU for *hemodynamic support* are also psychomotor stimulants. They include norepinephrine, dopamine, and phenylephrine infusions. They are all direct sympathomimetics and serve to raise blood pressure either through chronotropic and inotropic effects on the heart or through vasoconstriction of peripheral vessels. There is an associated increase in arousal, motor activity, and alertness that is most likely masked in the ICU by the concomitant use of sedatives. There are no PSG studies to our knowledge examining the effect of these drugs on sleep. Kong and coworkers [39] studied the efficacy of midazolam and isoflurane in reducing plasma levels of catecholamines with similar levels of sedation. Although comparable levels of sedation were achieved with both drugs, isoflurane but not midazolam lowered plasma catecholamine levels. PSG data were not simultaneously recorded, but given the central nervous system stimulant effect of catecholamines, it is a reasonable assumption that high levels may produce sleep fragmentation in the ICU. In summary, patients receiving continuous infusions of sympathomimetics or drugs with sympathomimetic effects such as β-agonists may have fragmented, disrupted sleep architecture. Despite the concomitant use of sedatives leading to an unconscious state resembling sleep, these patients may derive little physiologic benefit associated with true sleep.

Other miscellaneous drugs that are commonly used in the ICU and have known sleep effects include beta-blockers, corticosteroids, and theophylline. Beta-blockers as a class are associated with insomnia, nightmares, decreased total sleep time, and REM sleep with increased daytime fatigue. These side effects are generally worse the more lipophilic the drug. Patients often note that corticosteroids disrupt sleep, although data are mainly through subjective patient reports. The results of objective studies are inconsistent. The most consistent PSG findings in healthy subjects is decreased REM. Theophylline is being used less because of better drugs with fewer side effects, although it is still occasionally used for its respiratory stimulant and bronchodilator effects. It is chemically related to caffeine and is frequently reported to disrupt sleep. The subjective reports are consistent with PSG data, which show fragmented sleep.

Other medications frequently used in the ICU include angiotensin-converting enzyme inhibitors, calcium antagonists, vasodilators, diuretics, and histamine$_2$-antagonists. There is little information about these drugs' effect on sleep, especially in the ICU patient. H_2-blockers likely do not cause sleep disturbance because they do not easily cross the blood–brain barrier. The manufacturers admit to a 2% incidence of insomnia, but there are no PSG data.

Underlying Medical Illness

The Effect of Sleep on Cardiopulmonary Syndromes

Sleep-disordered breathing in the form of obstructive sleep apnea–hypopnea (OSAH) syndromes is commonly encountered in the ICU. Many critically ill patients are admitted with an acute exacerbation of a chronic cardiopulmonary disorder, commonly congestive heart failure (CHF), and chronic obstructive pulmonary disease (COPD). Further destabilization of gas exchange may occur with sleep onset due to the following mechanisms.

1. Loss of respiratory muscle activity occurs with sleep onset due to sleep-induced muscle relaxation. The intercostals and accessory muscles of respiration play an important role in maintaining normal minute ventilation in those with abnormal ventilation perfusion matching, for example, parenchymal lung disease, chest wall deformity. A reduction in respiratory muscle activity can result in profound deterioration in gas exchange.
2. Autonomic nervous system changes with sleep onset as characterized by an increase in parasympathetic and concomitant decrease in sympathetic nervous system activity with the onset of NREM sleep results in a decrease in heart rate, stroke volume. This can lead to undesirable hemodynamic consequences in the compromised patient [41].
3. Upper airway collapse in those with underlying OSAH leads to high negative intrathoracic pressure swings in an attempt to end the apnea or hypopnea. The large intrathoracic pressure swings coupled with hypoxemia occurring from the obstructed upper airway results in an increase in afterload, preload, and ventricular dysfunction. In the patient with

cardiac dysfunction, this sleep-induced upper airway closure has been shown to exacerbate CHF [42,43].

4. Instability of the respiratory control mechanism occurs with sleep onset in the normal individual with an alteration in the central chemoreceptor set point. There is a decrease in minute ventilation by 20% coupled with a 4% to 6% increase in PCO_2 level across the night [44]. The response of the respiratory system to upper airway collapse, hypoxemia, may be exaggerated due to sleep-induced instability of the feedback loop [45]. An increase in respiratory rate beyond that necessary to correct the hypoxemia/hypercapnia may cause a decrease in PCO_2 levels below apnea threshold (the physiologic PCO_2 level above which ventilation is triggered, and below which apnea ensues). The exaggerated loop gain has been well documented to occur during circulatory delay as occurs in CHF with a low ejection fraction. The result often is a crescendo–decrescendo pattern of breathing known as Cheyne-Stokes respiration (CSR). CSR is rarely observed during REM sleep, more so occurring during NREM sleep. CSR-CSA is associated with nocturnal arousals, awakenings. Patients with severe CSR demonstrate frequent central apneas with frequent arousals, fragmented sleep, and increased sleep state changes [46–50].
5. The supine position in a normal individual is associated with a decrease in the functional residual capacity of the lung by approximately 20%. This change in posture with sleep onset coupled with sleep-induced decrease in respiratory muscle activity can lead to worsened ventilation perfusion mismatch especially in those with massive obesity, CHF, and diaphragmatic paralysis [51].
6. Patients suffering from severe COPD (forced expiratory volume in the first second less than 1.0 L) have been found to have more fragmented sleep with more wake time as documented by overnight PSG as compared with an age-matched control group [52]. Other investigators had similar findings in a hypercapnic COPD group without obstructive sleep apnea. A significant number of arousals lasting more than 1 minute were noted, along with a decrease in total sleep time and increases in sleep state changes [52,53].

It stands to reason that if patients with stable chronic disease have such disrupted sleep as a consequence of their underlying medical illness, the acute decompensation of their cardiorespiratory system as occurs with decompensated CHF or COPD will further add to reduced nocturnal total sleep time, sleep fragmentation, and increased daytime sleep.

Many hospitalized patients may attribute some of their fragmented sleep to pain. PSG data evaluating sleep stages after burn injury showed reduced total sleep time and increased fragmented sleep, with more than 63 arousals per hour. The abnormal sleep was attributed to their burn state [19]. Similarly, sleep in nine postabdominal surgery patients was analyzed. As with other reports, there was more lighter sleep and less slow-wave sleep, but the arousal index was not reported. The authors suggested that pain may have been part of the cause of the abnormal sleep architecture [17].

In summary, chronic cardiorespiratory illness, sleep-disordered breathing, and pain as a result of the underlying illness all may contribute to poor sleep in the ICU.

Mechanical Ventilation

Mechanical ventilation is commonly used in the ICU, where roughly 40% of patients require assistance with breathing [54]. Positive pressure ventilation improves gas exchange and helps with respiratory muscle rest [55]. Mechanically ventilated patients experience fragmented sleep, averaging 20 to 63 arousals per hour from a variety of internal and externally driven factors [8,18,19]. The sleep-disrupting factors external to the patient associated with the mechanical ventilation include discomfort from the endotracheal and nasogastric tubes, suctioning, physical restraints, and alarms, including ventilator alarms [56]. A specific factor internal to the patient promoting fragmented sleep is central apneas occurring during mechanical ventilation. Meza et al. [57] showed central apneas in healthy volunteers during sleep while on pressure support ventilation (PSV). The mechanism behind the central apneas could be either through a chemically mediated loss of respiratory drive by way of a ventilator-induced reduction of the PCO_2 below the apnea threshold or via a nonchemical mechanism. Other investigative work showed an inhibition of respiratory motor output in healthy volunteers on assist-control and controlled modes of ventilation whose respiratory rates or tidal volumes were increased while maintaining normocapnia [58]. The authors concluded that continuous mandatory ventilation at increased frequency, plus moderate elevations in tidal volume, reset respiratory rhythm and inhibited respiratory motor output to a greater extent than did increased tidal volume alone. In effect, central apneas may be caused either by ventilator-induced hypocapnia or ventilator-induced reset of respiratory drive with normocapnia.

Data also suggest that the mode of ventilation can influence sleep quality. A comparison was made between pressure support and assist-control mode of ventilation on sleep quality in 11 critically ill patients [55]. There was greater sleep fragmentation (79 vs. 54 arousals and awakenings per hour) and lower sleep efficiency during pressure support than during assist control ventilation. Central apneas occurred in 6 of the 11 patients during pressure support but not during assist control ventilation due to the backup rate in the assist-control mode (Fig. 70.2). These central apneas occurred predominately in heart failure patients and were secondary to a reduction of their PCO_2 below apnea thresholds. The central apneas and overall sleep efficiency in the pressure support group were improved by addition of dead space to the ventilator circuit, which caused an increase in CO_2 levels above the apnea threshold. The number of arousals and awakenings decreased from 83 to 44 events per hour in this group (Fig. 70.2). The conclusion was that pressure support mode may lead to hypocapnia that, when combined with the lack of a backup rate and wakefulness drive, can lead to central apneas with sleep fragmentation, especially in patients with heart failure. Other investigators report conflicting data—Hardin et al. failed to find any difference in arousal frequency with different ventilator modes. Of note, the small study size and patient sedation may have contributed to their findings [24]. Other investigators compared a low level PSV (6 cm H_2O) with the assist-control mode in patients with acute or chronic respiratory failure who were near extubation. Assist-control mode was associated with improved sleep architecture with increased slow-wave sleep and REM sleep [59]. Cabello and Thille [60] compared automatically adjusted PSV with clinician-adjusted PSV and assist-control in nonsedated patients. There was no appreciable difference in sleep between the groups. Proportional assist ventilation was compared with PSV in sedated patients; proportional assist was associated with better patient–ventilator synchrony, less arousals and awakenings, and improved sleep architecture than in the PSV group [61].

Melatonin

Melatonin secretion in healthy individuals follows a stable circadian rhythm promoting consolidated nocturnal sleep. The loss of adequate melatonin secretion could lead to sleep deprivation, especially deleterious in an already physiologically compromised group such as the critically ill patient. Measurement of a urinary metabolite of melatonin in 17 septic, sedated

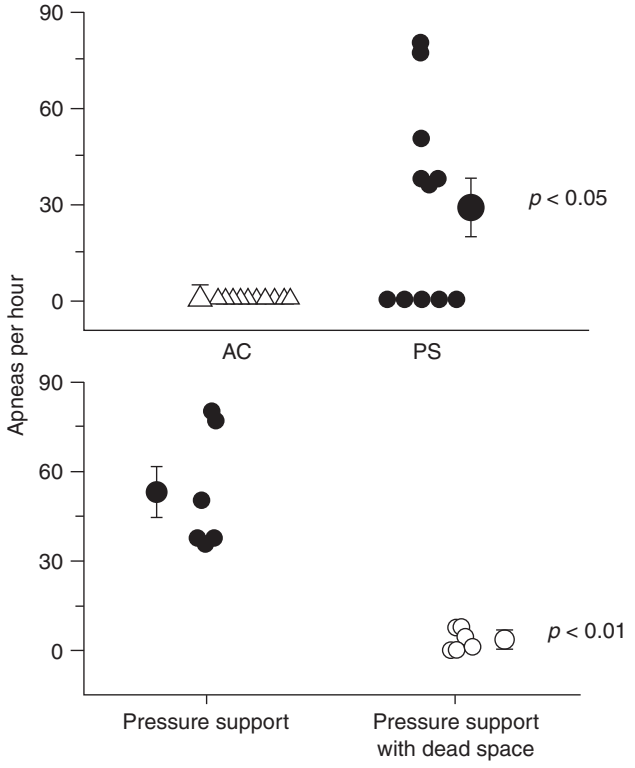

FIGURE 70.2. Number of apneas per hour during assist-control ventilation (AC; *open triangles*), pressure support (PS; *closed circles*), and pressure support with added dead space (*open circles*). Six of 11 patients developed apneas during pressure support as compared with none during assist-control ventilation (*top*). In the patients who developed apneas, the number of apneas decreased with the addition of dead space (*bottom*). Individual and group mean values are shown. Bars represent the standard error (SE). [From Parthasarathy S, Tobin M: Effect of ventilator mode on sleep quality in critically ill patients. *Am J Respir Crit Care Med* 166:1425, 2002, with permission.]

patients as compared with nonseptic patients and a normal control group suggested impaired melatonin secretion occurred in the septic group as compared with the nonseptic patients and the control group [62]. Other investigators have found a loss of circadian release of melatonin in mechanically ventilated, sedated patients with no relation of the level of sedation to the abnormality of melatonin secretion [63]. Beta-blockers are also known to impair melatonin secretion through blockade of central β-adrenoreceptors, which control secretion of melatonin from the pineal gland [64,65].

The impairment of melatonin secretion in critically ill patients, therefore, is most likely multifactorial, in which endogenous factors such as sepsis play a role, and exogenous factors including medications such as beta-blockers and the loss of the external zeitgeber (light/dark cycles) amplify the disruption.

There is one small pilot study and several anecdotal reports of melatonin use in critically ill patients that described improved sleep quality and efficiency, leading in some instances to quicker ventilator weaning [66,67]. The doses used varied from 5 to 10 mg according to clinician discretion. More recently, a larger randomized clinical trial evaluating melatonin in tracheostomized ICU patients failed to show a statistically significant difference in total sleep time or diurnal variation of sleep between the control and intervention groups despite confirmation of therapeutic serum drug levels in the intervention group [68]. At this point, the data on melatonin does not warrant its use in ICU patients as a sedative or to help reset circadian rhythm.

CONSEQUENCES OF SLEEP FRAGMENTATION AND DEPRIVATION

Sleep is essential for normal physiologic function. Animal studies showed multiorgan dysfunction leading to death in sleep-deprived rats as compared with a non–sleep-deprived control group [9]. Healthy human subjects with 24 to 48 hours of sleep deprivation and or fragmented sleep demonstrate impaired memory, labile moods, slower response times to controlled stimuli, and poor impulse control [6,7]. The lack of consolidated sleep may influence morbidity in critically ill patients.

Neurologic Consequences

Sleep deprivation has been associated with the development of mental status changes in ICU patients. These changes include delirium, agitation, and psychosis. This has been labeled the "ICU syndrome" and is typically seen after a week in the ICU. Helton and colleagues [69] were among the first to describe mental status changes in ICU patients. They studied 62 critically ill patients and found that delirium occurred in one third of patients with severe sleep deprivation (>50% sleep loss), 10% of those with moderate sleep deprivation (<50% sleep loss), and 3% of those with adequate sleep. The limitations of the study include the lack of PSG data; sleep was assessed by the staff and may have been underestimated, and a cause-and-effect relationship between sleep deprivation and delirium was inferred. Other authors have described delirium occurring in up to 60% of older hospitalized patients [70].

Wood et al. [71] reported 83% of a mechanically ventilated cohort developed delirium during an ICU stay and the delirium persisted in 10% of these patients at hospital discharge. Baseline dementia appears to be a risk factor for the development of delirium in the ICU.

The development of posttraumatic stress disorder is recognized as a significant problem occurring after a stay in the ICU. Jones and Griffiths [72] studied 45 patients discharged from the ICU and proposed that the development of posttraumatic stress disorder symptoms may have been related more to the recall of delusions as opposed to the memories of real adverse events that occurred during their ICU stay.

Cardiopulmonary Consequences

Sleep loss has been shown to impair respiratory muscle performance. A comparison of respiratory muscle strength and pulmonary function was made in healthy subjects after normal sleep and after 30 hours without sleep [73]. There was a decrease in inspiratory muscle endurance, but preservation of expiratory muscle strength. Other aspects of respiratory muscle control are compromised by sleep deprivation. Genioglossal muscle activity (important in upper-airway patency) deteriorates after sleep deprivation in healthy subjects [74–76], and other investigators have found decreased spirometric values in stable COPD patients after a period of sleep loss [74–77]. There are no data on respiratory muscle performance in sleep-deprived critically ill patients. Based on the data presented here, however, respiratory muscle response to increased mechanical loads either during or after mechanical ventilation in a sleep-deprived patient may be compromised, potentially interfering with recovery from an acute cardiorespiratory illness.

The effect of sleep deprivation on the ventilatory response to hypoxia or hypercapnia is controversial. Initial reports found

an impaired hypoxic and hypercapnic ventilatory response in healthy young men after 24 hours without sleep, but with intact resting ventilation [77]. Subsequent reports refuted this finding; after strictly controlled environmental influences, healthy subjects without sleep for 24 hours were not found to have an alteration in chemoreceptor set points (i.e., no change in hypoxic or hypercapnic ventilatory response after sleep deprivation) [78]. There are no data in critically ill patients.

"REM rebound" is a well-recognized result of sleep deprivation. Once out of the ICU or in the recovery phase of their illness, previously sleep-deprived patients experience both increased REM and slow-wave sleep for repayment of their sleep debt [19]. Moreover, REM sleep is known for the accompanying autonomic variability in the form of irregular breathing, heart rate, and more profound hypoxemia in the susceptible patient. REM rebound therefore carries the inherent risk of hemodynamic instability in those with cardiorespiratory compromise and may play a role in ICU morbidity and mortality.

Immunologic and Metabolic Consequences

Sleep deprivation alters immune function. There is a decreased production of lymphocytes and reduced leukocyte phagocytic action [4,5]. Studies in young, healthy men showed an increase in urinary nitrogen after 48 hours of no sleep, suggesting sleep deprivation leads to a catabolic state [79]. Although there have been no studies in critically ill patients, the implication remains that sleep deprivation may play a role in impaired recovery from infection and poor tissue healing.

Activity of the corticotropic axis is circadian driven. Plasma levels of adrenocorticotropin and cortisol are highest in the morning and lowest in the evening, near the point of sleep onset in normal individuals. This axis is modulated by the sleep/wake condition. Sleep onset is associated with a short-term inhibition of cortisol secretion. Sleep deprivation is associated with an increase in evening cortisol the day following sleep loss. Sleep loss appears to delay the return to decreased evening activity of the corticotropic axis [80–82].

The thyroid axis is also affected by sleep deprivation. Plasma thyroid-stimulating hormone (TSH) levels are at their lowest in the day and highest in the night around the beginning of the sleep period. During sleep, there is a progressive decline in TSH levels. Sleep overall inhibits TSH secretion, and sleep deprivation relieves this inhibition; awakenings during nocturnal sleep are associated with short-term increases in plasma TSH and triiodothyronine (T_3) levels [83,84].

METHODS TO IMPROVE SLEEP IN THE INTENSIVE CARE UNIT

It is important to ensure an adequate amount of time for patients to sleep. Before improving quality, quantity must be guaranteed. Several hospitals have now put in place protocols allowing an uninterrupted period of sleep for critically ill patients [85]. Obtaining vital signs, laboratory draws, or other bedside care is deferred during this period.

As discussed previously, a noisy environment is responsible for an estimated 30% of fragmented sleep, and the use of earplugs, in combination with background white noise, may be of some benefit to improving patients' sleep.

Enhancing the drive to sleep at night is facilitated by different methods. Realignment of the intrinsic body clock to a normal day/night schedule is helped by introducing light/dark cycles into the ICU. Exposure to sunlight or overhead lights (10,000 lux or more) in the morning helps to reduce endogenous melatonin secretion and decreases the drive to sleep during the day. In addition, sitting the patient out of bed and avoiding sedatives during the day will decrease daytime sleep episodes and consequently increase the homeostatic and circadian drive to sleep at night. Administration of a short-acting sedative/hypnotic at night with reduction of ambient lights to less than 250 lux, or complete darkness, encourages endogenous melatonin secretion that may consolidate and improve sleep quality. There may be a role for exogenous melatonin in those with impaired melatonin secretion; however, further studies are needed to determine which patients may benefit.

An awareness of the effect of underlying medical illness on the quality of sleep is important and, as is practical, should be addressed, including screening for and initiation of noninvasive positive pressure ventilation for treatment of obstructive sleep apnea (OSA) and Central sleep apnea-Cheyne-Stokes Respiration (CSA-CSR) as indicated. There needs to be adequate treatment of pain syndromes.

Application of the principles presented here may improve overall sleep quality and quantity in the ICU and ultimately lead to improved morbidity and mortality. A multidisciplinary approach involving physicians, nurses, other hospital personnel, and the administration is needed to increase awareness and improve both the environment and the approach to enhanced sleep in the hospital setting. Further studies are needed on sleep in the ICU, but the challenge of controlling for confounding influences in the ICU still remains and makes such research difficult.

PANG-YEN FAN

CHAPTER 71 ■ METABOLIC ACIDOSIS AND METABOLIC ALKALOSIS

ROBERT M. BLACK

NORMAL ACID–BASE PHYSIOLOGY

Acidemia and alkalemia denote, respectively, blood pHs below or above the normal value of 7.40. A simple (single) acid–base disturbance always causes the blood pH to change. In comparison, the coexistence of two opposing primary acid–base disturbances, such as a metabolic acidosis due to diarrhea with metabolic alkalosis due to vomiting, may result in little or no deviation of the blood pH from normal. Maintenance of blood pH at approximately 7.40 is necessary to stabilize intracellular pH at 7.20, a crucial chemical condition for optimal cell physiology.

Renal Regulation of H^+ Secretion

Maintenance of a normal plasma bicarbonate (HCO_3^-) concentration depends on reclamation of the 4,500 mEq of HCO_3^- filtered by the kidneys each day. Reabsorption of filtered HCO_3^- takes place almost entirely in the proximal tubule (Fig. 71.1). In this process, luminal HCO_3^- combines with H^+ secreted into the tubular lumen by an Na-H antiporter. The formation and subsequent dissociation of carbonic acid (H_2CO_3) to carbon dioxide (CO_2) and water (H_2O), catalyzed by carbonic anhydrase, permit CO_2 to enter the luminal membrane of the proximal tubular cell. Once inside the cell, CO_2 combines with OH^- to form HCO_3^-. An Na-3HCO_3 cotransporter then carries HCO_3^- across the peritubular membrane into the blood. As a result, filtered HCO_3^- is returned to the circulation without any net loss of H^+.

A fall in proximal tubular bicarbonate reabsorption causes urinary HCO_3^- loss and may lead to a fall in plasma HCO_3^- concentration and to metabolic acidosis. The carbonic anhydrase inhibitor acetazolamide, for example, reduces the activity of luminal carbonic anhydrase, thereby decreasing the entry of H_2O and CO_2 across the luminal membrane, which decreases HCO_3^- reabsorption by the tubular cell (Fig. 71.1).

The process of reclamation of all filtered HCO_3^- by itself is not sufficient to maintain a normal blood pH. The kidney must also excrete the 50 to 100 mEq per kg of H^+ generated each day from the metabolism of dietary proteins, particularly sulfur-containing amino acids (i.e., methionine, cystine), which are converted to sulfuric acid. This acid load is initially buffered in the body to minimize changes in blood pH, causing a clinically undetectable decrease in the plasma HCO_3^- concentration. The kidney must eventually excrete this daily acid increment to replete the HCO_3^- used in this process, however, or more severe acidemia will develop over time.

Energy requirements limit the ability of the kidney to excrete acid (H^+ ions) when the urine pH falls below 4.5. To offset this limitation, urinary buffers are present in the urine that maintain the urine pH above this critical value, permitting ongoing excretion of the daily acid load.

Two distinct urinary buffering systems enable continued H^+ secretion: titratable acids and ammonia. Titratable acids (primarily HPO_4)[1] are freely filtered through the glomerulus and can combine with H^+:

$$HPO_4^- + H^+ \rightarrow H_2PO_4$$

Approximately one-half of the daily acid load is excreted in this way.

By comparison, the most important urinary buffer is ammonia, as the abundance of this buffer can be varied according to physiologic needs. Ammonia synthesis occurs in the proximal tubule, derived principally from the breakdown of glutamine to α-ketoglutarate (Fig. 71.2) [1]. This process is stimulated by intracellular acidosis and by hypokalemia, both of which act by decreasing the intracellular pH (see following). Ammonia thus generated can combine with intracellular H^+, forming ammonium (NH_4^+). NH_4^+ is then secreted into the proximal tubule lumen by substituting for H^+ on the Na-H antiporter. Ammonia (NH_3) that forms by the dissociation of H^+ from NH_4^+ is largely reabsorbed, recycled, and then secreted into the collecting tubule. There, it is trapped in the tubular lumen as NH_4^+ by combining with secreted H^+ and excreted as ammonium chloride (NH_4Cl). For each molecule of buffered H^+ excreted in the urine, an HCO_3^- is regenerated (Fig. 71.2), thus replenishing the HCO_3^- used initially by the body to buffer daily metabolic acid load.

METABOLIC ACIDOSIS

Metabolic acidosis can be categorized by the presence or absence of an increased anion gap. The *anion gap* (AG) refers to the difference between measured cations (Na^+) and measured anions (chloride [Cl^-] and HCO_3^-):[2]

$$AG = Na^+ - (Cl^- + HCO_3^-)$$

The normal AG varies between 3 and 11 mEq per L and averages approximately 7 to 8 mEq per L [2]. These unmeasured anions consist of proteins (primarily albumin), sulfates, phosphates, and circulating organic acids. Uric acid is a large molecule and therefore does not contribute significantly to the AG even when hyperuricemia is present.

[1] *Titratable acidity is determined by adding alkali to the daily urine volume. It is equal to the number of milliequivalents of base required to return the urine pH to 7.4.*

[2] *Potassium (K^+) is usually not included in the calculation of the AG because changes large enough to alter the gap significantly are uncommon or incompatible with life.*

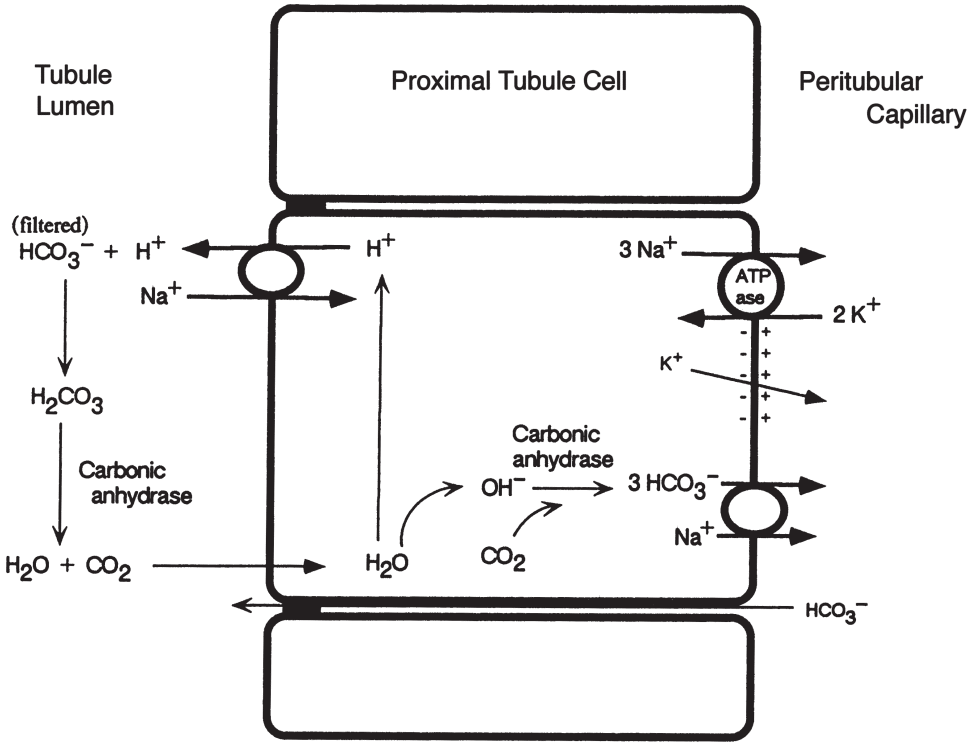

FIGURE 71.1. Proximal tubular reclamation of filtered bicarbonate (HCO_3). The first step in maintaining normal acid–base balance is the reabsorption of all filtered HCO_3. Inability to accomplish this results in metabolic acidosis (proximal, type 2, renal tubular acidosis). See text for details. ATPase, adenosine triphosphatase.

A reduction in the plasma albumin concentration can lower the baseline AG (approximately 2.5 mEq for every 1 g per dL fall in the albumin concentration) [3]. Thus, the hypoalbuminemic patient may not have a high AG even in the presence of a disorder that typically causes an elevation (e.g., lactic acidosis; see later).

Metabolic Acidosis with an Increased Anion Gap

The causes of metabolic acidosis associated with an increased AG are listed in Table 71.1. Lactic acidosis is the most frequent form in hospitalized patients, whereas chronic renal failure is the principal cause of an increased AG in ambulatory persons.

Chronic Kidney Disease (CKD)

Renal disease represents an interesting example of the potential overlap between normal and elevated AG acidosis. The high AG in patients with advanced chronic kidney disease is usually a late finding and reflects a severe reduction in glomerular filtration rate (GFR). As the GFR falls below 20 to 30 mL per minute (plasma creatinine >3 to 4 mg per dL), anions, such as sulfate and phosphate, that would normally be excreted by filtration are retained. With lesser degrees of renal dysfunction, however, metabolic acidosis appears primarily because H^+ (HCl) secretion is reduced, with little or no effect on the AG.

The metabolically generated daily acid load on a typical American diet approximates 50 to 100 mEq. This acid, mainly sulfuric, is immediately buffered by $NaHCO_3$:

$$H_2SO_4 + 2NaHCO_3 \rightarrow Na_2SO_4 + 2CO_2 + 2H_2O$$

The excess sulfate is excreted in the urine. If glomerular and tubular function decline in parallel, then the H^+ and the SO_4^{2-} are retained, producing metabolic acidosis with a high AG. If, however, there is more significant tubular dysfunction, the excretion of acid is diminished, but excretion of sulfate may be maintained due to reduced reabsorption. In the latter setting, the AG may not rise as the serum HCO_3^- concentration decreases.

Therefore, the decrease in plasma HCO_3^- (severity of acidemia) need not correlate with extent of the rise in AG in renal dysfunction. Typically, the plasma bicarbonate concentration is greater than 12 mEq per L in patients with uncomplicated CKD. A search for a second acid–base disorder is indicated when a lower HCO_3^- concentration is identified.

Lactic Acidosis

Lactic acidosis is probably the most common cause of severe metabolic acidosis encountered in the intensive care unit. The AG is always increased above baseline (normal lactate level

TABLE 71.1

CAUSES OF METABOLIC ACIDOSIS WITH AN INCREASED ANION GAP

Chronic kidney disease[a]
Lactic acidosis
Ketoacidosis (diabetic, alcoholic, starvation)[a]
Rhabdomyolysis
Ingestions
Salicylates
Methanol
Ethylene glycol
Pyroglutamic acid[b]
Toluene[c]

[a] May be associated with normal anion gap early in course or during therapy (ketoacidosis); see text for details.
[b] Usually due to acetaminophen.
[c] Toluene also may cause a non–anion gap acidosis (see Table 71.3).

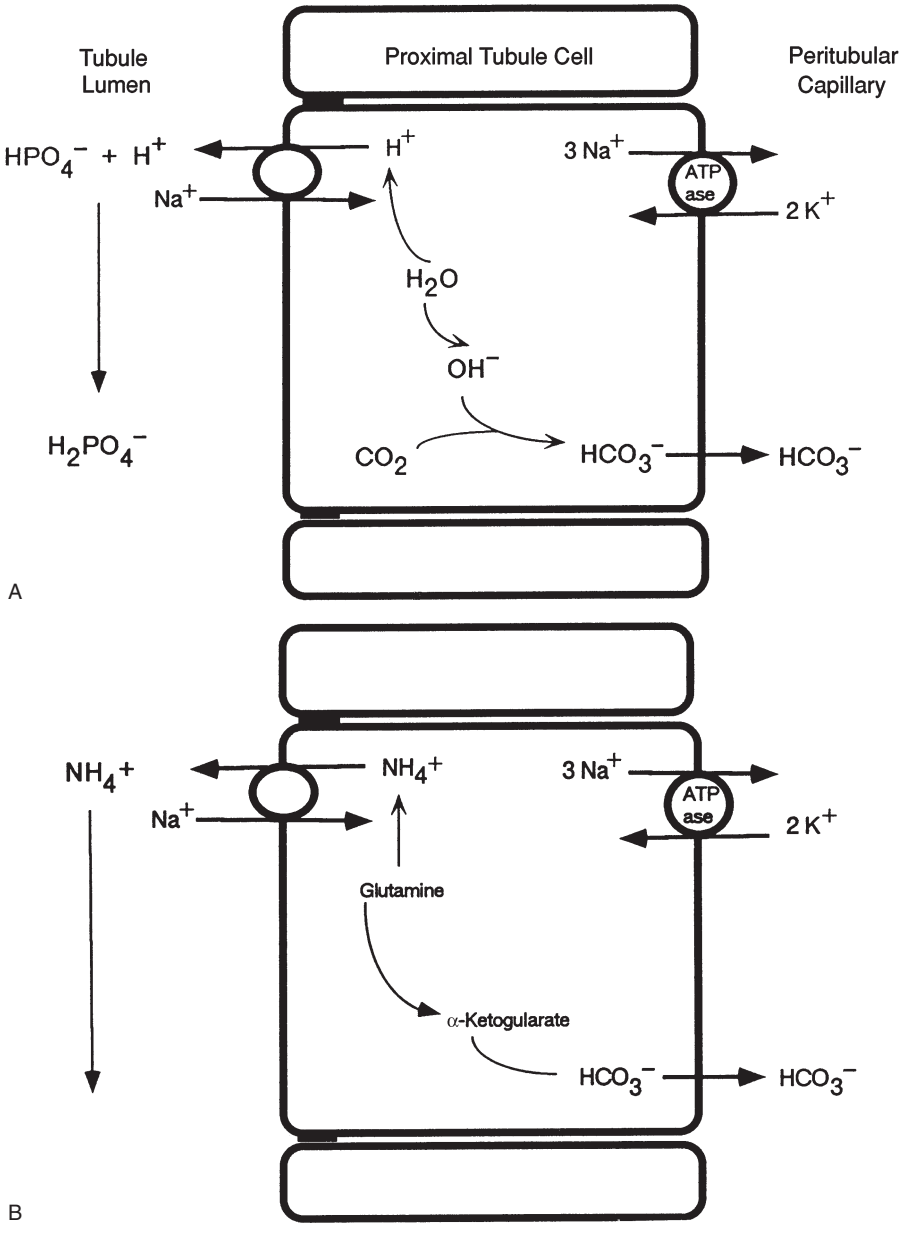

FIGURE 71.2. Excretion of the daily acid load permits the regeneration of bicarbonate (HCO_3) that was used as a buffer. Two processes are involved: the excretion of titratable acid (**A**) and the excretion of ammonium (NH_4^+) (**B**). The latter is particularly important because acidosis stimulates the breakdown of glutamine to ammonia. By comparison, hyperkalemia impairs the capacity of the proximal tubule to make ammonia, thus contributing to the metabolic acidosis observed in hyperkalemic disorders. ATPase, adenosine triphosphatase.

is <1.0 mmol per L)[3] because lactate does not appear in the urine until a higher plasma concentration (at least 6 to 8 mmol per L) is achieved. Lactate levels greater than 5 mmol per L are considered diagnostic of lactic acidosis, although levels between 2 and 5 mmol per L may be significant in the appropriate clinical circumstances [4]. Metformin, a biguanide commonly used in the treatment of type II diabetes mellitus, can cause lactic acidosis, particularly in patients who present with acute or chronic renal insufficiency. Hemodialysis has been used in the treatment of metformin-induced acidosis [5].

Most cases of lactic acidosis involve the L-isomer. By comparison, D-lactic acidosis, a disorder observed most commonly in patients with abnormal bowel anatomy, results in a rise in the AG, but the lactate level is normal [6]. D-Lactate is not detected by the usual lactate assay, which measures only L-lactate and a specific assay must be requested to diagnose this disorder.

Ketoacidosis

Ketoacidosis occurs when acetoacetic acid and β-hydroxybutyric acid are overproduced by the liver (see Chapter 101 for a complete discussion). Acetone, a breakdown product of acetoacetic acid, is not an acid; as such, it does not contribute to the acidemia or to the increased AG observed in this disorder.[4]

Although ketoacidosis is generally associated with an elevated AG, loss of ketoanions in the urine, particularly during intravenous fluid therapy, may attenuate the expansion of the

[3] *The more recently described condition of D-lactic acidosis requires a specific search for D-lactic acid, which is not routinely measured. This acid may be present in patients with short bowel syndrome or occasionally during antibiotic therapy, and is formed by intestinal bacteria [9,10]. Diagnosis requires a specific enzymatic assay because human lactate dehydrogenase metabolizes only L-lactate.*

[4] *Isopropyl alcohol is metabolized to acetone and can cause acute kidney injury. In this setting, ketonemia and ketonuria are characteristically present, whereas any increase in the AG is typically not due to ketoacidosis because acetoacetic acid and β-hydroxybutyric acid are not usually produced.*

AG. Once formed, ketones may be excreted in the urine before, under the influence of insulin, they can be metabolized back to HCO_3^-. Because the initially produced ketoacids titrate the plasma HCO_3^- concentration downward, the loss of urinary ketoanions (as sodium or potassium salts) is tantamount to the renal loss of HCO_3^-. The net effect is that a high AG metabolic acidosis is present before therapy in most individuals with ketoacidosis but may convert to a normal AG metabolic acidosis once saline repletion occurs and ketogenesis ceases [7].

Rhabdomyolysis

Massive muscle breakdown is an important cause of metabolic acidosis with an increased AG. Acute kidney injury due to myoglobinuria can cause retention of anions (e.g., phosphate) that have been released from damaged myocytes.

Ingestions

The most common acid–base abnormality observed with salicylate intoxication is a respiratory alkalosis caused by direct stimulation of the medullary respiratory center. A pure metabolic acidosis owing to aspirin toxicity is uncommon. With moderate-to-severe salicylate intoxication, the AG increases as salicylic acid, not simply due to accumulation of salicylate in the blood, promotes formation of lactic acid. The consequence is a mixed respiratory alkalosis with a high AG metabolic acidosis.

Methanol and ethylene glycol ingestions require early diagnosis because prompt treatment may be lifesaving. Inhibitors of alcohol dehydrogenase such as ethanol and fomepizole are used for this latter purpose, with fomepizole being the preferred agent, if available. Either agent can limit the conversion of the alcohols to their more toxic metabolic products. Methanol or ethylene glycol ingestion as a cause for high AG metabolic acidosis is suggested by the history and physical findings (see Chapter 119). The turnaround time for measurement of these toxins may delay treatment. The detection of an osmolal gap is a relatively quick way of supporting the suspected diagnosis.

The *osmolal gap* refers to the difference between the plasma osmolality (P_{Osm}) measured by the laboratory and that calculated using the following formula:

$$\text{Calculated } P_{Osm}(\text{mOsm/kg}) = 2 \times Na^+ + \text{glucose}/18 + \text{BUN}/2.8$$

Normally, the measured P_{Osm} is higher than the calculated value by 10 mOsm per kg. A larger osmolal gap indicates the presence of osmotically active substances not normally present. The most frequent causes of an increased osmolal gap are ethyl alcohol, isopropyl alcohol, ketones, lactate, mannitol, ethylene glycol, and methanol. If ethanol, lactate, or ketones cannot be identified in a patient with an AG metabolic acidosis with an osmolal gap, the diagnosis of ethylene glycol or methanol intoxication should be strongly suspected [8]. In the intensive care unit setting, a high osmolal gap acidosis has also been associated with the use of continuous high-dose infusions of lorazepam for more than 48 hours. Propylene glycol, which is used as a solvent for intravenous medications including lorazepam, has been implicated as the cause of the hyperosmolar metabolic acidosis in this scenario [9]. It is important to understand that the presence of an osmolal gap that results from an ingested alcohol may only be detected when P_{Osm} is measured in the laboratory by freezing-point depression [10]. Also, after the alcohol is metabolized, the osmolal gap may disappear.

Toluene (present in glue and metabolized to hippuric acid) is a rare cause of metabolic acidosis. The AG rises early and then returns toward normal, as hippurate is excreted by the kidneys, a process that is similar to the renal handling of ketones (see previous discussion) [11].

Rarely, acetaminophen administration in therapeutic doses can lead to an elevated AG metabolic acidosis in metabolically stressed individuals, including pregnant women. In this setting, reduced glutathione stores permit the generation of pyroglutamic acid (5-oxoproline) [12].

Metabolic Acidosis with a Normal Anion Gap

Metabolic acidosis with a normal AG, which may also be called a *hyperchloremic acidosis*, is associated with the conditions listed in Table 71.2. The decrement in the plasma HCO_3^- concentration is matched by a rise in the plasma Cl^- level, maintaining electroneutrality.

Acid and Chloride Administration

The infusion of amino acid solutions during hyperalimentation is an abundant source of hydrochloric acid (HCl). The development of a metabolic acidosis is more common in patients with renal insufficiency.

Oral administration of cholestyramine chloride reportedly occasionally also causes acidemia. This resin, which is sometimes used in the management of hypercholesterolemia, is nonresorbable and can act as an anion-exchange resin, exchanging its Cl^- for endogenous HCO_3^- and producing a metabolic acidosis. Sevelamer chloride, a compound used as a phosphorous binder in chronic kidney disease, has been associated with lower bicarbonate levels than in those patients treated with calcium-based binders. The mechanism of the metabolic acidosis is believed to be similar to cholestyramine [13].

Bicarbonate Losses

Loss of HCO_3^- from the gastrointestinal tract or kidneys can lead to a reduction in the plasma HCO_3^- level. Bowel contents are alkaline compared to blood because HCO_3^- is added by pancreatic and biliary secretions. HCO_3^- is later exchanged for Cl^- in the ileum and colon. The result is that most alkali secreted into the gut lumen is reclaimed by the colon. Gastrointestinal losses of HCO_3^- (or HCO_3^- precursors such as lactate and acetate) are most commonly observed in patients with diarrhea so severe that colonic transit time is too rapid for

TABLE 71.2

CAUSES OF METABOLIC ACIDOSIS WITH A NORMAL ANION GAP

- Acid administration
  - Hyperalimentation with HCl-containing amino acid solutions
- Bicarbonate losses
  - Gastrointestinal
    - Diarrhea
    - Pancreatic or biliary drainage
    - Cholestyramine and sevelamer chloride
    - Urinary diversions (ureterosigmoidostomy)
  - Renal
    - Proximal (type 2) renal tubular acidosis
    - Ketoacidosis (particularly during therapy)
    - Post–chronic hypocapnia
- Impaired renal acid excretion
  - With hypokalemia
    - Classic distal (type 1) renal tubular acidosis
  - With hyperkalemia
    - Hyperkalemic distal renal tubular acidosis
    - Hypoaldosteronism (type 4 renal tubular acidosis)
- Reduced renal perfusion

TABLE 71.3

SOME CAUSES OF TYPES 1 AND 2 RENAL TUBULAR ACIDOSIS (RTA)

Distal (type 1) RTA	Proximal (type 2) RTA
Idiopathic	Hereditary disorders
Genetic	Cystinosis
Familial	Wilson's disease[c]
Marfan's syndrome	Glycogen storage disease, type 1
Ehlers–Danlos syndrome	Acquired disorders
Disorders of calcium metabolism	Multiple myeloma[c]
Idiopathic hypercalciuria	Primary hyperparathyroidism
Hypergammaglobulinemic states	Toxins and drugs
Amyloidosis[a]	Lead
Cryoglobulinemia	Cadmium
Drugs and toxins	Mercury
Amphotericin B	Copper (Wilson's disease)[c]
Lithium carbonate	Carbonic anhydrase inhibitors
Toluene[b]	Topiramate
Autoimmune diseases	
Sjögren's syndrome[a]	
Thyroiditis	
Chronic active hepatitis	
Primary biliary cirrhosis	
Miscellaneous	
Cirrhosis	
Medullary sponge kidney	
Associated with hyperkalemia	
Urinary tract obstruction	
Sickle cell anemia	
Systemic lupus erythematosus	
Renal transplant rejection[a]	

[a] Also may cause proximal RTA.
[b] Metabolism to hippuric acid may cause the anion gap to increase.
[c] Also may cause distal RTA.

alkali reabsorption. At times, the resulting HCO_3^- losses can approach 40 mEq per L of stool. Less frequently, metabolic acidosis from HCO_3^- depletion is a result of pancreatic fistulae, biliary drainage, or a ureterosigmoidostomy. In the last circumstance, the excretion of acid (as NH_4Cl) urine directly into the colon permits the exchange of HCl for HCO_3^- because the colon is permeable to H^+ and Cl^-, unlike the urinary bladder [14]. This problem does not usually occur with an ileal bladder.

Pancreatic HCO_3^- losses are also observed in essentially all patients with a pancreatic allograft anastomosed directly to the urinary bladder. Bicarbonate secreted into the bladder cannot be reabsorbed.

Renal bicarbonate losses can cause or contribute to acidemia in type 2 (proximal) renal tubular acidosis (RTA; Table 71.2),[5] during recovery from ketoacidosis (see previous discussion), and in patients who are posthypercapnia. In patients with proximal RTA (Table 71.3), the normal reabsorptive threshold for HCO_3^- is reduced. As a result, HCO_3^- can no longer be reabsorbed at a rate adequate to maintain the normal plasma level of approximately 25 mEq per L. As a consequence, the urine pH is alkaline (>5.3), and the fractional excretion of HCO_3^- is elevated (>15% of the filtered load).[6] Normally, this value is less than 3% because more than 97% of HCO_3^- filtered through the glomerulus is reclaimed, primarily in the proximal tubule (Fig. 71.1). HCO_3^- wasting ceases, however, and the urine becomes acidic (pH <5.3) once the plasma HCO_3^- concentration has stabilized at the new (lower) level. This process explains why the urine pH may be high or low in proximal RTA.

Renal HCO_3^- losses also occur as compensation for chronic respiratory alkalosis (chronic hypocapnia). During chronic hyperventilation, the blood pH increases as the PCO_2 decreases. As can be seen in Figure 71.1, an increase in intracellular pH diminishes H^+ excretion, leading to a concomitant decrease in HCO_3^- reabsorption. These changes cause the plasma HCO_3^- concentration to fall, partially compensating for the alkalemia. If the stimulus for hyperventilation (e.g., hypoxemia) is suddenly eliminated, the PCO_2 rapidly returns to normal. Renal compensation, by comparison, continues for 1 to 2 more days, causing a persistent reduction in the plasma HCO_3^- concentration. The resulting posthypocapnic metabolic acidosis normally resolves spontaneously.

[5] *The RTAs can be classified as type 1 (distal), type 2 (proximal), and type 4 (hypoaldosteronism). Type 3 refers to what is now considered to be an infantile variant of type 1; therefore, type 3 RTA is a term not generally applied to adults.*

[6] *The fractional excretion of HCO_3^- is equal to the amount of HCO_3^- excreted divided by the filtered load:*

$$\text{Fractional excretion } (HCO_3) = \frac{\text{urine } HCO_3^- \times \text{plasma creatinine}}{\text{urine creatinine} \times \text{plasma } HCO_3^-} \times 100.$$

Reduced Renal H^+ Excretion

Reduced renal acid excretion can be observed in four conditions: chronic kidney disease, type 1 (distal) RTA (Table 71.3), type 4 RTA (hypoaldosteronism), and states of reduced renal perfusion. The acidosis of chronic kidney disease is primarily caused by a reduction in ammonia production. Patients with chronic renal insufficiency have a substantial drop in the number of functioning nephrons. Nephrons that continue to filter, however, characteristically have filtration rates and acid excretion rates per nephron that are above normal. Impaired acid excretion in these patients occurs because the number of hyperfiltering nephrons is inadequate to compensate for those that are nonfunctioning. The AG is frequently normal in mild-to-moderate kidney disease (plasma creatinine <3 mg per dL) because Cl^- replaces the HCO_3^- used to buffer the retained acid. At this time, the GFR is still high enough to permit the excretion of anions like phosphate, which contribute to the rise in AG as renal function declines further.

The classic form of type 1 (distal) RTA (Table 71.3) occurs when H^+ cannot be pumped into the tubule lumen by the intercalated cells of the collecting tubule. The result is that urine cannot be maximally acidified (urine pH is always ≥5.5). In addition to metabolic acidosis, hypokalemia is typically present. The K^+ deficit is caused in part by enhanced distal nephron Na-K exchange, a process that is necessary to maintain Na^+ balance because H^+ cannot be secreted in response to Na^+ reabsorption. Recent studies also report distal RTA resulting from a translocation of the bicarbonate–chloride exchanger from the peritubular to the luminal membrane. The net effect is secretion of bicarbonate into the collecting tubule lumen.

The most important clinical complication of distal RTA is the formation and deposition of calcium throughout the kidney (nephrocalcinosis). This process begins in the collecting tubules, where the urine is most concentrated, and is commonly accompanied by the formation of calcium phosphate calculi. The factors that may contribute to the renal stone disease in this disorder include hypercalciuria, because metabolic acidosis causes a release of bone calcium that can then be filtered and excreted; the alkaline urine pH, which predisposes to the precipitation of calcium phosphate crystals; and, most importantly, hypocitraturia. The reduction in urinary citrate is a direct result of the metabolic acidosis, which increases proximal tubular citrate reabsorption [15]. Since calcium citrate is significantly more soluble than calcium phosphate, hypocitraturia facilitates the precipitation of calcium phosphate crystals in the tubular lumen.[7] In comparison with distal RTA, stone formation is less common and less severe in patients with proximal RTA, possibly because a proportion of these patients may have the full Fanconi syndrome, in which proximal tubular reabsorption of HCO_3^- and many other substances, including citrate, is impaired [16].

In addition to the classic form of type 1 (distal) RTA, in which hypokalemia is characteristic, a hyperkalemic variety has also been described. This disorder, as well as type 4 (hypoaldosteronism) RTA, is discussed in Chapter 72.

Clinical Signs and Symptoms of Metabolic Acidosis

Kussmaul respirations on physical examination suggest the presence of metabolic acidosis. This unusual respiratory pattern reflects an increase in tidal volume rather than a rise in respiratory rate and is caused by stimulation of the respiratory center in the brainstem by the low blood pH. As acidemia becomes more severe, nausea and vomiting or mental status changes, including coma, may occur.

Secondary hypotension also may be observed in severely acidemic patients, the hypotension resulting from depressed myocardial contractility and arterial vasodilation. Although circulating catecholamines may initially counteract the adverse cardiovascular effects of acidemia, such compensation becomes insufficient as the blood pH falls below 7.20.

The plasma K^+ concentration may be altered by the degree of metabolic acidosis. Infusion of a mineral acid such as arginine HCl, for example, causes a prompt rise in the plasma K^+ concentration as K^+ moves out of cells in exchange for H^+. By comparison, a shift of K^+ is less likely to occur in those patients with metabolic acidosis caused by organic acids, such as lactic and ketoacidosis [17]. The reason for this apparent difference is uncertain, but it may relate to the release of insulin by organic substrates (e.g., lactate), which would drive K^+ into cells.

Diagnosis

The diagnosis of a simple metabolic acidosis is made relatively easy by the presence of a low blood pH and plasma bicarbonate concentration. The detection of a widened AG can then be used to identify a specific cause for the disorder. The likelihood of identifying a specific acid(s) in a patient with a high AG acidosis increases as the width of the AG increases.

In comparison with patients with a simple metabolic acidosis, many individuals have a concomitant respiratory or second metabolic acid–base disorder. Consequently, knowledge of the appropriate respiratory compensation as well as an understanding of the ratio of the increment in AG to decrement in plasma HCO_3^- concentration is useful.

Respiratory Compensation

Stimulation of the brainstem respiratory center by acidemia causes a fall in the PCO_2 that, in uncomplicated metabolic acidosis, can be estimated from the following equation:

$$\text{Expected } PCO_2 \text{ (mm Hg)} = [(1.5 \times HCO_3^-) + 8] \pm 2$$

A PCO_2 that is substantially different from the expected value indicates a superimposed respiratory acidosis or alkalosis. For example, if the plasma bicarbonate concentration were 10 mEq per L, the expected PCO_2 would be approximately 23 mm Hg $[(1.5 \times 10) + 8] = 23$. A lower PCO_2 would indicate the presence of a concomitant respiratory alkalosis (as might be seen with a salicylate overdose), whereas a higher PCO_2 would signify a simultaneous respiratory acidosis. *This calculation is useful only in the evaluation of the respiratory response to metabolic acidosis and it is inaccurate when the plasma bicarbonate concentration is more than 20 mEq per L.*

There is a more rapid method to determine the appropriateness of respiratory compensation in patients with a primary metabolic acidosis. By a quirk of mathematics, the last two digits of the pH (27 in a patient with a pH of 7.27) should equal the PCO_2 if respiratory compensation is appropriate. A lower PCO_2 indicates a superimposed respiratory alkalosis, whereas a higher value signifies a primary respiratory acidosis.

Ratio of Change in Anion Gap to Change in Bicarbonate Concentration in Metabolic Acidosis and Its Use in Identifying a Second Metabolic Acidosis or a Metabolic Alkalosis

In patients with a high AG metabolic acidosis, the identification of a second metabolic acid–base disorder (normal AG acidosis)

[7] *Most renal calculi are composed of calcium oxalate. In comparison, the presence of a persistently alkaline urine pH predisposes to calcium phosphate stone formation.*

can be made by comparing the change in the AG to the change in the plasma HCO_3^- concentration.

The elevation in AG is due to the increase in the unmeasured anions. However, there is not always a 1-to-1 relationship between the increase in AG (ΔAG) and the fall in plasma bicarbonate (ΔHCO_3^-) because some of the excess hydrogen ions are buffered by nonbicarbonate buffers (including intracellular proteins and bone).

The magnitude of the increment in AG, therefore, generally exceeds that of the decrement in plasma HCO_3^- concentration. As the plasma HCO_3^- concentration falls, there is a progressive reduction in extracellular-buffering capacity (which almost entirely consists of HCO_3^-) [18]. The result is that the Δ/Δ ratio averages approximately 1.4 to 1.6:1 in lactic acidosis. Thus, a patient with a plasma HCO_3^- concentration of 14 mEq per L (10 mEq per L below normal) should have an AG that is approximately 24 mEq per L (16 mEq per L above normal), assuming that the baseline (normal) AG is 8 mEq per L.

Although the same principles apply to ketoacidosis, the Δ/Δ ratio averages approximately 1:1. In this disorder, the loss of ketoacid anions in the urine (as the sodium and potassium salts of β-hydroxybutyrate and acetoacetate) lowers the initially elevated AG without affecting the plasma HCO_3^- concentration. In contrast, urinary anion loss is minimal in lactic acidosis because shock is typically associated with reduced urinary flow rate, and most of the lactate that is filtered can be reabsorbed by a specific sodium-L-lactate cotransporter in the luminal membrane of the proximal tubular cells.

The amount of ketoacid anions excreted in ketoacidosis depends on the degree to which glomerular filtration is maintained. Patients with impaired renal function (owing to underlying diabetic nephropathy or volume depletion) retain the ketoacid anions and have a relatively high AG in relation to the fall in the plasma HCO_3^- concentration, similar to that in lactic acidosis. In comparison, patients with relatively normal renal function can lose large quantities of ketoacids in the urine and may have a Δ/Δ below 1. In fact, the loss of ketoacid anions in the urine causes the frequent development of a hyperchloremic (normal AG) metabolic acidosis during the treatment (recovery phase) of diabetic ketoacidosis [19].

Conversely, when the ΔAG is more than double the ΔHCO_3^-, a coexisting metabolic alkalosis and metabolic acidosis is likely. An example of this situation would be severe vomiting in a patient with ketoacidosis.

Changes in the concentration of other unmeasured cations or anions in the plasma can also lead to miscalculation of the AG. As an example, hypoalbuminemia (decreased unmeasured anions) and severe hypercalcemia (increased unmeasured cations) can lower the AG. Thus, a patient with one or both of these disorders may have a baseline AG of 4 rather than 8 or 9 mEq per L. In this setting, an AG of 13 mEq per L, which is only mildly above normal, represents a true elevation in the AG of 9 mEq per L. As a result, calculation of the Δ/Δ is most accurate when the preacidosis AG is known.

Urinary Anion Gap

Another useful tool in the evaluation of a metabolic acidosis is the urinary AG (UAG). The UAG is the difference between the sum of the urinary Na^+ and K^+ and the urinary Cl^-:

$$UAG = (Na^+ + K^+) - Cl^-$$

The most frequent use of the UAG is to identify the etiology of a normal AG metabolic acidosis with hypokalemia [20,21]. The most common nonrenal cause is diarrhea, which provokes an appropriate increase in renal H^+ secretion. These additional H^+ ions are buffered in the urine by ammonia and excreted primarily as NH_4Cl. Because NH_4^+ is not measured in the calculation of the UAG, but Cl^- is, an increased rate of renal H^+ secretion causes the UAG to become a negative number. Conversely, the presence of a positive UAG in an individual with a non-AG metabolic acidosis suggests that the disorder is due to impaired renal H^+ excretion (e.g., distal RTA). In this setting, impaired H^+ secretion leads to a fall in urinary Cl^- (which would be excreted as NH_4Cl) and a positive calculated UAG. It is important to note, however, that underlying renal insufficiency may also be associated with impaired NH_4Cl excretion owing to a limitation in ammonia synthesis; in these individuals, the UAG may remain positive even in the presence of diarrhea.

Treatment of Metabolic Acidosis

Treatment of metabolic acidosis must be directed at correction of acidemia as well as the cause of the acid–base disturbance. The likelihood that alkali administration is necessary and that it will be effective depends on the blood pH, compensatory mechanisms, and the underlying cause.

The degree of acidemia and hypobicarbonatemia should be evaluated before administering alkali. As a general rule, alkali therapy generally is not needed until the arterial blood pH drops below 7.15 to 7.20 [22]. An exception may occur when the plasma HCO_3^- concentration falls to less than 10 to 12 mEq per L, despite a blood pH of more than 7.15. Alkali administration is usually unnecessary if the acidosis is likely to resolve spontaneously (e.g., lactic acidosis after a grand mal seizure).

Alkali Administration

HCO_3^- therapy should be considered in patients with moderate-to-severe metabolic acidosis. However, depending on the etiology, the use of exogenous bicarbonate remains controversial [22]. The initial goal of alkali therapy is to raise the arterial blood pH to 7.20, a typically safe level at which the patient is at less risk of cardiovascular compromise. The pH does not need to be corrected back to normal because the potential risks of HCO_3^- therapy (e.g., hypernatremia, hypercapnia, fluid overload, cerebrospinal fluid acidosis, and "overshoot" alkalosis) are likely to outweigh the benefits, as long as renal function (and therefore acid-excretory ability) is relatively intact.

The quantity of exogenous bicarbonate required to produce a change in pH is determined by estimating the total body HCO_3^- deficit. The apparent HCO_3^- space is about 50% of lean body weight in healthy subjects. In patients with more severe metabolic acidosis (plasma HCO_3^- concentration <10 mEq per L), cellular and bone buffering become more prominent owing to the marked reduction in the quantity of available extracellular buffer (primarily HCO_3^-). This preferential entry of H^+ into cells causes the HCO_3^- space to expand to approximately 70% of the lean body weight.

These are only rough guidelines and cannot replace ongoing monitoring of serum bicarbonate level and arterial pH during the correction phase. Furthermore, if there is continuing alkali loss from diarrhea, then the HCO_3^- requirements are substantially increased because the apparent volume of distribution of HCO_3^- is much greater than 70% of body weight in this setting.

Treatment of Specific Causes of Metabolic Acidosis

Renal Disease. Treatment of the metabolic acidosis of renal dysfunction depends on the clinical manifestations and the severity of the acidosis. Most individuals with acute kidney injury can be managed with dialysis or using the guidelines for alkali administration listed previously. There is some recent data suggesting that alkali therapy can slow down the rate of

decline in chronic kidney disease and reduce mortality in this setting [23].

Ketoacidosis. The plasma glucose concentration does not correlate with the degree of acidemia in ketoacidosis [24]. Moreover, the blood glucose level may normalize before ketoacid production has ceased.

The initial management of patients with diabetic ketoacidosis with very large fluid volumes has been challenged [7]. The advantages of intensive fluid administration may be limited after the intravascular volume has been restored because volume expansion then leads to the excretion of ketone anions in the urine. Moreover, excessive expansion of the plasma volume reduces proximal tubular HCO_3^- reabsorption, in part by reducing Na-H exchange. The net effect is normalization of the AG without a significant increase in the plasma HCO_3^- concentration. In this setting, spontaneous correction of the metabolic acidosis requires regeneration of new bicarbonate by the kidney (a process that may take several days), in contrast to the rapid increase in HCO_3^- that occurs when ketone anions are metabolized back to HCO_3^- in the liver as insulin is given. Consequently, fluid administration should be tempered after intravascular volume compromise has been corrected.

Alkali administration is not usually necessary for patients with ketoacidosis, There appears to be no difference in mortality between patients treated with $NaHCO_3$ versus controls [22]. Insulin therapy should raise the plasma HCO_3^- concentration as ketone anions are metabolized. Patients who may benefit from cautious alkali therapy include those with severe acidemia (in whom cardiovascular compromise is secondarily present) and those with a normal AG acidosis. As already discussed, the latter condition pertains to those who have sustained major urinary losses of ketones, rendering them depleted of potential bicarbonate substrate.

Lactic Acidosis. Correction of any predisposing disorder is the primary therapy for lactic acidosis. Reversal of circulatory failure, hypoxemia, or sepsis reduces the rate of lactate production and enhances its removal.

The benefit of $NaHCO_3$ in the treatment of lactic acidosis remains unproven [22]. The potential benefits of alkali administration principally involve the maintenance of normal cardiovascular homeostasis. This potential advantage must be weighed against possible deleterious effects such as volume overload, hypernatremia, and overshoot alkalosis after restoration of tissue perfusion. Recent data also suggest that HCO_3^- therapy may not improve the blood pH or survival in lactic acidosis. Alkali therapy may also have a direct negative effect on cardiac function by reducing coronary perfusion pressure, which could explain the fall in cardiac output observed in some patients treated with HCO_3^- in this setting [14].

As a result of these potential problems, no concrete recommendations can be made regarding alkali therapy in lactic acidosis. One approach might be to administer HCO_3^- to maintain the arterial blood pH above 7.15 to 7.20 and the plasma HCO_3^- concentration above 10 to 12 mEq per L, as suggested previously (see Alkali Administration section). However, if the lactate level increases without a significant improvement in clinical status or blood pH, the benefit of continuing alkali administration should be questioned. It appears that correction of the underlying cause of lactic acidosis is the most important goal, as measures raise the bicarbonate level without a fall in lactate have not been associated with a reduction in mortality [14]. These findings are consistent with the hypothesis that the high mortality in lactic acidosis results from the underlying disorder causing the acidosis, not from the acidemia per se.

Drug and Toxin Ingestions. The treatment of toxins and ingestions is discussed in Section 10.

Renal Tubular Acidosis. The acidemia of type 1 (distal) RTA can be corrected with HCO_3^- or a precursor such as citrate. The usual requirement is 1 to 3 mEq per kg per day, which should be sufficient to buffer that fraction of the daily acid load (50 to 100 mEq per day) that is not being excreted. In general, a potassium salt is administered (e.g., potassium citrate) because this repairs the K^+ deficit as well. Large doses of oral $NaHCO_3$ can cause gastrointestinal symptoms by generating CO_2 in the stomach. This problem can be minimized by the use of citrate, most of which is ultimately metabolized in the body to HCO_3^-. Solutions are available that contain 1 to 2 mEq per mL of sodium, potassium, or sodium and potassium citrate.

The initial step in the management of type 2 (proximal) RTA is to determine the presence of a treatable underlying disorder, such as vitamin D deficiency, multiple myeloma, or the use of a carbonic anhydrase inhibitor. Even if no specific therapy is available, correction of the acidemia may not be required in adults if the patient is asymptomatic and if there is only mild-to-moderate reduction in the plasma HCO_3^- concentration. In comparison, treatment is always indicated in young children because restoring acid–base balance can permit normal growth to resume.

The evaluation and treatment of the hyperkalemic form of distal RTA and of type 4 RTA (hypoaldosteronism), in which hyperkalemia is also present, can be found in Chapter 73.

METABOLIC ALKALOSIS

Primary metabolic alkalosis is characterized by an elevated plasma HCO_3^- concentration in the presence of an arterial pH above 7.40. When there is a concomitant metabolic acidosis, however, the blood pH may be increased, decreased, or normal. Because hyperbicarbonatemia may represent the appropriate response to chronic respiratory acidosis, by itself it is not diagnostic of metabolic alkalosis. These conditions can be easily distinguished by measurement of the arterial blood pH, which is reduced in respiratory acidosis.

Pathophysiology and Etiology

There are two steps involved in the development of metabolic alkalosis. The factors that mediate the *generation* phase may differ from those that enable its *maintenance*. For this reason, the evaluation and treatment of metabolic alkalosis are made easier by first reviewing the pathophysiology of these factors.

A primary rise in the plasma HCO_3^- concentration can be induced by one or more of three mechanisms: (a) loss of acid from the gastrointestinal tract or in the urine, (b) administration of HCO_3^- or a precursor such as citrate, or (c) loss of fluid with a Cl^--to-HCO_3^- ratio that is higher than that of plasma [25]. The third condition is sometimes referred to as *contraction alkalosis* because the total HCO_3^- content remains relatively unchanged while the extracellular fluid volume "contracts around it," thereby elevating the HCO_3^- concentration. In contrast to the first two mechanisms, contraction alkalosis is rarely responsible for more than a mild increase in the plasma HCO_3^- concentration. Loss of fluid with an electrolyte composition similar to that of plasma, as might occur with hemorrhage, does not result in a contraction alkalosis because HCO_3^- is lost proportionately to the other molecular components of plasma.

The excess in HCO_3^- generated by any of these processes should be rapidly excreted in the urine. The maintenance of a metabolic alkalosis, therefore, indicates an impairment of renal HCO_3^- excretion. The most common hindrances to renal disposal of bicarbonate are volume and potassium depletion.

Under ordinary conditions, HCO_3^- appears in the urine when the plasma level rises above the normal value of approximately 25 mEq per L. In the presence of volume depletion, however, the capacity of the proximal tubule to reabsorb HCO_3^- increases, allowing the plasma HCO_3^- level to rise without triggering bicarbonaturia. Several mechanisms account for these changes, including stimulation of luminal Na-H countertransport (Fig. 71.1) by angiotensin II, generated in response to volume contraction [26]. Most hypovolemic states are associated with Cl^- depletion. Because tubular luminal Cl^- appears to be important in distal nephron Cl^-–HCO_3^- exchange, it is not surprising that correction of the metabolic alkalosis usually requires Cl^- repletion as well [27]. In comparison, giving Cl^- may be ineffective when primary or secondary hyperaldosteronism, severe hypokalemia, or renal insufficiency is responsible for the defect in HCO_3^- excretion. The cause of a metabolic alkalosis can usually be identified by how readily it responds to administration of Cl^- (see Diagnosis section). The effect of hypokalemia in the maintenance of metabolic alkalosis is discussed later in this chapter.

Alkali Administration

Because administered HCO_3^- is normally excreted rapidly in the urine, alkali administration must be massive, or renal impairment must limit the excretion of HCO_3^- if metabolic alkalosis is to develop. Milk-alkali syndrome is an uncommon disorder characterized by hypercalcemia and metabolic alkalosis. It is now rarely seen, probably because nonabsorbable antacids, proton-pump inhibitors, and H_2-blockers have largely supplanted the use of large quantities of baking soda and milk as treatment of gastritis and peptic ulcer disease. The chronic ingestion of milk and calcium carbonate–containing antacids can lead to the development of metabolic alkalosis, however, because the increased HCO_3^- load cannot be excreted as a result of renal impairment from chronic hypercalcemia [28].

Chloride-Responsive Metabolic Alkalosis

Generation of Chloride-Responsive Metabolic Alkalosis. The two most common causes of metabolic alkalosis are diuretic therapy and loss of gastric secretions (resulting from nasogastric suction or vomiting) (Table 71.4). Thiazide and loop diuretics can generate a metabolic alkalosis, regardless of whether they are given to treat hypertension or states of volume overload such as congestive heart failure. H^+ loss results from increased distal Na^+ presentation in the presence of elevated aldosterone levels, which causes enhanced distal nephron Na-H exchange. Hydrogen secretion in this nephron segment is associated with increased HCO_3^- generation. The proximal tubule may also play an important role because stimulation of the renin–angiotensin system by volume depletion enhances the activity of the Na-H antiporter, thereby increasing H^+ secretion and HCO_3^- reabsorption. To the degree that the urinary anion losses represent primarily Cl^-, a component of contraction alkalosis may also occur.

Although volume contraction may contribute to the metabolic alkalosis caused by vomiting and nasogastric suction, and occasionally with intestinal Cl^- wasting [29], gastric H^+ losses are primarily responsible for the generation of metabolic alkalosis in this setting. Secretion of gastric acid results in the retention of 1 mEq of HCO_3^- for each milliequivalent of H^+ that is secreted because both of the ions are derived from the intracellular dissociation of carbonic acid:

$$H_2CO_3 \rightarrow HCO_3^- + H^+$$

This process does not normally lead to metabolic alkalosis because the 80 to 200 mEq of HCl secreted by the stomach each day enters the duodenum, where it stimulates an equivalent amount of HCO_3^- secretion from the pancreas. By comparison, when vomiting or nasogastric suctioning occurs, the H^+ secreted by the stomach never reaches the duodenum and therefore cannot induce pancreatic HCO_3^- secretion. Hence, there is a net retention of HCO_3^-. As in diuretic use, distal nephron Na-H exchange also contributes to the development of this disorder because aldosterone levels are stimulated by the loss of extracellular volume.

Renal H^+ and K^+ losses also contribute to the metabolic alkalosis and K^+ depletion observed in hypercalcemic states [30].

Metabolic alkalosis also may be observed after the rapid correction of chronic respiratory acidosis. This *posthypercapnic metabolic alkalosis* occurs because chronic respiratory acidosis activates compensatory renal mechanisms that induce HCl loss in the urine; the ensuing rise in the plasma HCO_3^- concentration is appropriate in that it returns the arterial pH toward normal. The plasma HCO_3^- generally increases by approximately 3.5 mEq per L for every 10 mm Hg rise in the arterial PCO_2. If hypercapnia is rapidly reversed, however (most frequently by artificial ventilation), because the excess HCO_3^- that has been generated may persist a while, alkalemia ensues.

Maintenance of Chloride-Responsive Metabolic Alkalosis. As reviewed previously, renal excretion of HCO_3^- normally begins when the plasma level exceeds 25 mEq per L. The normal kidney can excrete large quantities (>1,000 mEq per L) without a substantial increase in the plasma HCO_3^- concentration. As a result, maintenance of a Cl^--responsive alkalosis implies a reduction in renal HCO_3^- excretion. Reduced GFR and, more importantly, enhanced proximal tubular $NaHCO_3$ reabsorption limit HCO_3^- excretion, allowing the increase in plasma HCO_3^- to persist. Normally, Cl^- is the major anion reabsorbed with Na^+. In states of Cl^- depletion, as occurs in Cl^--responsive metabolic alkalosis, however, Na^+ must be reabsorbed with the next most abundant anion, HCO_3^-.

TABLE 71.4

MAJOR CAUSES OF METABOLIC ALKALOSIS

Hydrogen loss
Gastrointestinal
Loss of gastric secretions (vomiting or nasogastric suction)[a]
Chloride-losing diarrheal states
Renal
Loop or thiazide-type diuretic[a]
Mineralocorticoid excess[a]
Postchronic hypercapnia
Hypercalcemia[b]
High-dose intravenous penicillins
Bartter's and Gitelman's syndromes
Bicarbonate retention
Massive blood transfusion
Administration of large amounts of $NaHCO_3$
Milk-alkali syndrome
Contraction alkalosis
Diuretics[a]
Loss of high chloride/low bicarbonate gastrointestinal secretions[a] (vomiting and some diarrheal states)
Hydrogen movement into cells
Hypokalemia
Refeeding

[a]Most common causes.
[b]Primary hyperparathyroidism is frequently associated with a mild metabolic acidosis (see text for details).

Consequently, the need to preserve volume prevents correction of the alkalosis.

Hypokalemia also promotes renal HCO_3^- reabsorption and contributes to the maintenance of metabolic alkalosis. K^+ losses frequently occur with diuretic administration or gastric acid losses. If the plasma HCO_3^- concentration exceeds the reabsorptive capacity of the proximal renal tubule, the resultant bicarbonaturia obligates excretion of a cation (e.g., Na^+). Some of the Na^+ leaving the proximal tubule with HCO_3^- is then reabsorbed distally in exchange for K^+. These urinary K^+ losses are primarily responsible for the hypokalemia seen with vomiting; gastric K^+ losses are usually less important because these secretions have a K^+ concentration of less than 10 mEq per L. As a result of K^+ depletion, relative intracellular acidosis occurs as H^+ shifts into cells to maintain electroneutrality as K^+ moves extracellularly in response to hypokalemia.[8] Ultimately, this intracellular acidosis stimulates proximal tubular Na-H exchange, which further reduces renal HCO_3^- excretion (Fig. 71.1).

Chloride-Resistant Metabolic Alkalosis

Metabolic alkalosis in some individuals is not responsive to the administration of Cl^--containing solutions. In these disorders, a primary increase in mineralocorticoid activity, potassium depletion, or disorders of renal tubular Cl^- wasting (Bartter's and Gitelman's syndromes [31]) are usually responsible for the generation and maintenance of the alkalosis. In all of these circumstances, there is enhanced renal H^+ excretion and HCO_3^- reabsorption. Either there is no Cl^- depletion or there is an inability to reabsorb Cl^-explaining why NaCl and KCl do not correct the metabolic alkalosis in these individuals. Edematous states, such as congestive heart failure and cirrhosis, also are generally unresponsive to volume (and Cl^-) replacement, despite the reduction in effective arterial blood volume.

Mineralocorticoid Excess. Mineralocorticoids, such as aldosterone, act in the cortical collecting tubule (see Chapter 72), where they enhance Na-K exchange as well as H^+ secretion. As a result, overproduction of an endogenous mineralocorticoid (as occurs in primary aldosteronism) or with the ingestion of a substance that can increase the mineralocorticoid activity of cortisol (e.g., glycyrrhizic acid in licorice [32]) leads to hypokalemia and metabolic alkalosis. Hypertension is characteristically present in these disorders. In contrast to patients with secondary increases in mineralocorticoid activity (e.g., as in congestive heart failure), edema does not occur. This phenomenon, called *aldosterone escape*, results at least in part from the high renal interstitial pressures generated by the hypertension that limits further NaCl reabsorption; it is also possible that atrial natriuretic peptide, released in response to volume expansion, contributes to this phenomenon.

In addition to the direct effect of aldosterone on H^+ secretion, hypokalemia also appears to be necessary for the maintenance of a significant metabolic alkalosis in patients with primary mineralocorticoid excess. The mechanism of this effect involves the development of intracellular acidosis with increased H^+ secretion and HCO_3^- reabsorption by the proximal tubule and enhanced distal nephron Na-H exchange.

Severe Hypokalemia. The effect of mild-to-moderate hypokalemia on the generation and maintenance of metabolic alkalosis has been discussed. Severe hypokalemia (plasma K^+ <2 mEq per L) can additionally impair distal Cl^- reabsorption by an unknown mechanism. In this setting, some of the Na^+ that is normally reabsorbed with Cl^- must be reabsorbed in exchange for H^+.

Bartter's and Gitelman's Syndromes. Bartter's syndrome is a rare cause of metabolic alkalosis typically seen in children and young adults. The loop of Henle appears to be the site responsible for this disorder. Metabolic alkalosis is also present in patients with Gitelman's syndrome, in which the defect occurs in the thiazide-sensitive site of the distal tubule. In contrast to patients with primary aldosteronism, patients with Bartter's and Gitelman's syndromes are normotensive or slightly hypotensive. The associated volume depletion causes chronic activation of the renin–angiotensin–aldosterone system, increasing distal nephron K^+ and H^+ secretion, as in patients receiving to a loop or thiazide diuretic.

Clinical Manifestations

Most patients with metabolic alkalosis do not suffer clinically from the effects of alkalemia [33]. When symptoms are present, they are typically those associated with volume depletion (e.g., weakness, muscle cramps, postural dizziness) or hypokalemia (e.g., muscle weakness, polyuria, polydipsia). The usual symptoms of alkalemia are due to increased neuromuscular excitability and are exhibited as paresthesias, carpopedal spasm, or lightheadedness, although these findings are relatively more common in patients with acute respiratory alkalosis.

Diagnosis

The cause of metabolic alkalosis can usually be elicited from the history and physical examination. One of the most important aspects of the physical examination in identifying a cause is the determination of blood pressure. Except for the hypertensive individual taking a diuretic, hypokalemia in the presence of metabolic alkalosis and hypertension should suggest the presence of a primary mineralocorticoid-induced disease, such as hyperaldosteronism. Normotensive individuals with no obvious cause most often have surreptitious vomiting or diuretic ingestion (*pseudo-Bartter's syndrome*) as the precipitating event; Bartter's and Gitelman's syndromes are much rarer.

The urinary Cl^- concentration is important because urinary Na^+ wasting may occur in the presence of a high plasma HCO_3^- concentration even if volume depletion is present. $NaHCO_3^-$ losses develop when the plasma HCO_3^- level exceeds the renal reabsorptive threshold, a condition that obligates the excretion of HCO_3^- with a cation to maintain electroneutrality. The most abundant cation in the filtrate is Na^+, even in low perfusion states. As a result, the urine Na^+ concentration should not be used to infer the volume status of an individual with an increased plasma HCO_3^- concentration, unless it is less than 20 mEq per L. By comparison, the urinary Cl^- concentration characteristically is low in hypoperfusion states because Cl^- is not affected by bicarbonaturia.

[8] *The pathophysiology of this phenomenon is more complex and probably depends on a change in the membrane potential induced by hypokalemia. As can be seen in Figure* 71.1*, the interior of the tubular cell is electronegative compared with the outside. This potential difference is determined primarily by the difference between K^+ intracellular and K^+ extracellular. Because there is substantially more K^+ inside the cell (approximately 130 mEq per L) than in plasma (approximately 4 mEq per L), a fall in the plasma K^+ concentration causes the inside of the cell to become more electronegative as the membrane potential increases. It appears that this negative intracellular charge on the basolateral membrane is the driving force for Na-3HCO_3 reabsorption. Thus, the cell interior may become more acid in hypokalemic states because more HCO_3^- leaves the cell.*

TABLE 71.5

URINE CHLORIDE CONCENTRATION IN METABOLIC ALKALOSIS

Less than 15 mEq/L	Greater than 20 mEq/L
Vomiting	Mineralocorticoid excess
Nasogastric suction	Alkali loading
Postdiuretic administration	During diuretic administration
Posthypercapnia	Severe hypokalemia
High-dose penicillin therapy	Bartter's and Gitelman's syndromes
Alkali loading[a]	

[a]Since the maintenance of metabolic alkalosis requires impairment of renal bicarbonate excretion, the pathophysiology of the renal limitation determines the urinary chloride concentration. If, for example, there is underlying hypovolemia, the urinary chloride concentration is low (<15 mEq/L); in comparison, the urinary chloride concentration is >20 mEq/L when the cause of renal bicarbonate retention is a reduction in glomerular filtration rate, as in the milk-alkali syndrome, or in patients with acute tubular necrosis who received large alkali loads.

Measurement of the urinary Cl^- concentration is useful in differentiating these disorders (Table 71.5). The urinary Cl^- concentration is typically less than 15 mEq per L, with hypovolemia caused by vomiting or diuretic therapy (if the effect of the diuretic has worn off). Higher values are found if the diuretic is still in effect, if Bartter's or Gitelman's syndromes or severe hypokalemia are present, or if there is primary mineralocorticoid excess (e.g., primary aldosteronism). Diuretic abuse may be distinguished from Bartter's or Gitelman's syndromes in some cases by screening the urine for diuretics.

Mixed Acid–Base Disturbances with Metabolic Alkalosis

Respiratory Compensation. The increased arterial pH in metabolic alkalosis leads to a compensatory rise in the PCO_2. This decrease in respiration is due to direct suppression of the medullary respiratory center by alkalemia. In general, the PCO_2 rises approximately 0.7 mm Hg for every 1 mEq per L elevation in the plasma HCO_3^- concentration [34], a relationship that pertains up to a PCO_2 rises approximately 60 mm Hg (plasma HCO_3^- concentration = 53 mEq per L); values above this level are unusual because further hypoventilation is limited by the development of hypoxemia. The identification of a PCO_2 greater or less than predicted suggests the presence of a second primary acid–base disturbance, respiratory acidosis or respiratory alkalosis, respectively.

Metabolic Alkalosis with Metabolic Acidosis. The ratio of the increment in AG to decrement in the plasma HCO_3^- concentration (Δ/Δ) can be used to identify the presence of a metabolic alkalosis in a patient with metabolic acidosis. In such cases, the increment in the serum AG is greater in magnitude than the apparent fall in the bicarbonate level.

Treatment of Metabolic Alkalosis

Rapid correction of metabolic alkalosis is usually not necessary due to the general rarity of adverse effects directly related to the rise in pH. As a result, there is ordinarily time to identify the cause of the disorder and to institute specific therapy. Any exogenous sources of alkali (e.g., preparations containing HCO_3^-, acetate, lactate, or citrate) should be discontinued.

Because hypomagnesemia may be present in some patients with metabolic alkalosis, a serum magnesium level should be checked, particularly in patients with refractory hypokalemia, as hypomagnesemia predisposes to renal potassium wasting.

Chloride-Responsive Metabolic Alkalosis

Chloride replacement (as NaCl, KCl, or both) is appropriate for management of most individuals with a low urinary Cl^- concentration. Administration of Cl^--containing fluid with K^+ ameliorates the alkalosis by permitting renal excretion of the excess HCO_3^-. It allows more Na^+ to be reabsorbed with Cl^-, rather than in exchange for H^+; it reduces the volume stimulus for Na^+ retention, permitting HCO_3^- excretion in the urine; and it increases the plasma K^+ concentration, which raises the tubular cell pH and reduces renal H^+ secretion. Replacement of the volume deficit with non–Cl^--containing solutions of Na^+ or K^+ does not correct the alkalosis or hypokalemia because non-Cl^- anions obligate further K^+ and H^+ excretion. Patients with vomiting or nasogastric suction also may benefit from H_2-blockers or other medications that reduce gastric acid secretion. They are not, however, substitutes for Cl^- replacement, which is still necessary to correct the already present chloride deficit.

The therapy of metabolic alkalosis in edematous patients (e.g., those with congestive heart failure and advanced liver disease) is more difficult. Although renal perfusion is characteristically reduced, leading to a low urinary Cl^- concentration, Cl^- administration (e.g., as 0.9% saline) does not enhance HCO_3^- excretion because the reduced effective arterial blood volume is not corrected by this therapy. In this setting, the carbonic anhydrase inhibitor acetazolamide (at a dose of 250 to 375 mg once or twice daily orally or intravenously) may be useful because it permits fluid mobilization while decreasing HCO_3^- reabsorption in the proximal tubule. An adverse consequence of acetazolamide administration is the tendency for more K^+ wasting. Careful monitoring of the plasma K^+ concentration is necessary. When the plasma K^+ level is low, the use of a distally acting K^+-sparing diuretic (e.g., amiloride or spironolactone) can be considered.

In extremely rare instances, these maneuvers may be insufficient, or the metabolic alkalosis may be so severe that adverse neurologic symptoms of alkalemia are present. In such instances, HCl can be given intravenously to lower the plasma HCO_3^- concentration. HCl is usually given as a solution isotonic to plasma (150 mEq H^+ and 150 mEq Cl^- in each liter of distilled H_2O). The volume needed to reduce the plasma HCO_3^- concentration can be estimated from the HCO_3^- deficit. Because the volume of distribution of HCO_3^- is approximately 50% of the lean body weight, the amount of HCl needed to lower the plasma HCO_3^- concentration from 45 to 35 mEq per L in a 70-kg man can be calculated as follows (assuming there are no ongoing HCO_3^- losses):

$$HCO_3^- \text{ excess} = 0.5 \times 70 \times (45 - 35) = 350 \text{ mEq}$$

This would require administration of slightly more than 2 L of an isotonic HCl solution. Because the very low pH of this solution can injure small veins and tissues, particularly if extravasation occurs, administration should generally occur during at least 24 hours using a large (central) vein. As a result, the administration of HCl may outweigh the potential benefits.

Dialytic therapy may be helpful in the unusual patient presenting with metabolic alkalosis, volume overload, and renal failure. Peritoneal dialysis typically contains lactate as the HCO_3^- precursor at a concentration of approximately 40 mEq per L, an amount that may worsen the alkalosis. By comparison, the alkali level can be adjusted with most current

hemodialysis machines. It is important to note that citrate used for anticoagulation in some continuous dialytic therapies can lead to metabolic alkalosis as well [35].

Chloride-Resistant Metabolic Alkalosis

Individuals with a urinary chloride concentration greater than 15 mEq per L are unlikely to respond to Cl^--containing solutions such as physiologic saline, with correction of the metabolic alkalosis. Since the effective renal blood flow is already normal or Cl^- reabsorption must be impaired, the administered Cl^- is rapidly excreted in the urine. Moreover, enhanced distal Na^+ presentation increases Na-K exchange, leading to a rise in urinary K^+ excretion with more severe hypokalemia in states of primary mineralocorticoid excess.

In a hypertensive patient, primary aldosteronism should be considered. Removing the source of aldosterone (by adrenalectomy when an aldosterone-secreting adenoma is present) or blocking its action (with a K^+-sparing diuretic, such as amiloride) is usually sufficient to correct the hypokalemia and metabolic alkalosis and to control hypertension in this disorder.

The abnormality in Bartter's and Gitelman's syndromes, impaired Cl^- reabsorption, cannot be corrected with treatment. Therapy is therefore directed at improving the laboratory abnormalities, particularly hypokalemia and metabolic alkalosis. Nonsteroidal anti-inflammatory drugs (including COX-2 inhibitors) reduce renin secretion (a prostaglandin-dependent process) and may be effective in reducing the plasma HCO_3^- and K^+ levels to or near normal, although K^+ supplementation also may be required. Angiotensin-converting enzyme inhibitors or K^+-sparing diuretics may be useful alone or in combination, but they have the potential risk of causing the already slightly low blood pressure to fall. It is important to exclude surreptitious diuretic use or forced vomiting in these individuals before assigning a diagnostic or therapeutic regimen used for Bartter's or Gitelman's syndromes because the former are far more common disorders.

CHAPTER 72 ■ DISORDERS OF PLASMA SODIUM AND PLASMA POTASSIUM

ROBERT M. BLACK

DISORDERS OF PLASMA SODIUM

Hyponatremia and hypernatremia are conditions commonly observed in the intensive care unit. They are defined as plasma Na^+ concentration below 135 mEq per L and above 145 mEq per L, respectively. The correct management of patients with these disorders depends on an understanding of normal salt (NaCl) and water (H_2O) physiology.

It is important to appreciate that hyponatremia represents a disorder of water balance; the plasma sodium concentration reflects the ratio of water to sodium in the body. By itself, however, the presence of hypo- or hypernatremia cannot be used to assess the volume status of a patient. Furthermore, the plasma sodium concentration has little relationship to the urinary sodium concentration.

Hypothalamic osmoreceptors influence thirst and the release of antidiuretic hormone (ADH). The latter increases U_{Osm}, causing water retention by enhancing the permeability of the collecting tubules to water. ADH is also released in response to effective volume depletion (hypovolemia). Although water retention causes extracellular volume expansion, this is slight, as approximately two thirds of the water enters the cells. As a result, volume-mediated ADH release can occur even in states of hyponatremia (see following discussion).

Relationship Between Plasma Na^+ and Plasma Osmolality

The osmolality of plasma (P_{Osm}) is determined by the sum of the osmolar contributions of the individual osmotically active substances. In plasma, Na^+ salts, glucose, and urea (blood urea nitrogen [BUN]) are the major determinants of osmolality. Therefore, the P_{Osm} can be estimated by the following formula:

$$P_{Osm} \approx 2 \times \text{plasma } Na^+ + \text{glucose}/18.0 + \text{BUN}/2.8$$

Using this equation,[1] it is evident that the major determinant of the P_{Osm} in healthy individuals is the plasma Na^+ concentration.

The ability of a solute (such as sodium) to promote shifts of water between the intracellular and extracellular compartments depends not only on its capacity to increase the P_{Osm} but also on its exclusion from one of these compartments. Because urea can cross almost all cell membranes readily, it cannot promote the movement of water between the intracellular and extracellular spaces. As such, urea is referred to as an *ineffective osmole*. A rise in the BUN is detected as an increase in the measured (by the laboratory) and calculated P_{Osm}, but there is no change in the plasma Na^+ concentration because urea does not obligate water movement from the intracellular to the extracellular space. Because urea is an ineffective osmole and because glucose normally contributes less than 8 mOsm per kg, the effective P_{Osm} correlates best with the plasma Na^+. Thus, effective P_{Osm} can be described as follows:

$$P_{Osm}(\text{effective}) \approx 2 \times \text{plasma } Na^+ \text{concentration}$$

Sodium is confined primarily to the extracellular fluid by the Na-K antiporter present in most cells. This pump also maintains a high (approximately 130 mEq per L) intracellular K^+ concentration; thus, potassium is the principal effective osmole inside cells. The ability of water to cross almost all cell membranes indicates that the P_{Osm} must be in equilibrium with the intracellular osmolality. In fact, osmolality is equal throughout all body compartments, explaining the need for only one osmoreceptor.

Because osmotic equilibrium exists throughout body water, calculation of water deficits or excesses, when dealing with a hyponatremic or hypernatremic individual, respectively, must be based on total body water (TBW) and not merely on the extracellular fluid volume. Moreover, loss of potassium from the body, as might occur with diuretic administration, affects the plasma Na^+ concentration.

Two processes participate in the reduction in plasma Na^+ concentration induced by potassium losses. Sodium movement into cells to maintain electroneutrality lowers the plasma Na^+, and loss of potassium from the gastrointestinal tract or kidneys causes a fall in the plasma potassium with a larger fall in the intracellular potassium. The result is a reduction in the intracellular osmolality that leads to water movement from cells to the extracellular compartment.

Finally, although plasma hypoosmolality is always associated with hyponatremia, a high P_{Osm} can occur in the absence of hypernatremia. Other ineffective osmoles (in addition to urea) have the ability to raise the measured P_{Osm} without affecting water shifts. The most important of these are the alcohols: ethanol, ethylene glycol, and methanol. By contrast, severe hyperglycemia can induce hyponatremia by pulling water out of cells, but the P_{Osm} will be elevated. This phenomenon, seen most often in diabetics, is referred to as *hyperosmolar hyponatremia*.

Regulation of Plasma Osmolality

Maintenance of the plasma Na^+ concentration within narrow limits (285 to 292 mOsm per kg) depends on the ability of the kidneys to excrete water (to prevent and on a normal thirst mechanism with access to water). Under normal conditions, the quantity of water that can be excreted in the urine far exceeds the amount ingested.

Renal water excretion is determined by two factors: urinary solute excretion and the ability to generate a maximally dilute

[1] *The molecular weights of glucose and nitrogen are 180 and 14, respectively. As a result, the osmotic effect of glucose is determined by dividing by 18 (because the concentration is in 100 mL of plasma and not 1 L), whereas that of BUN is obtained by dividing by 2.8 (there are two nitrogens on each molecule of urea).*

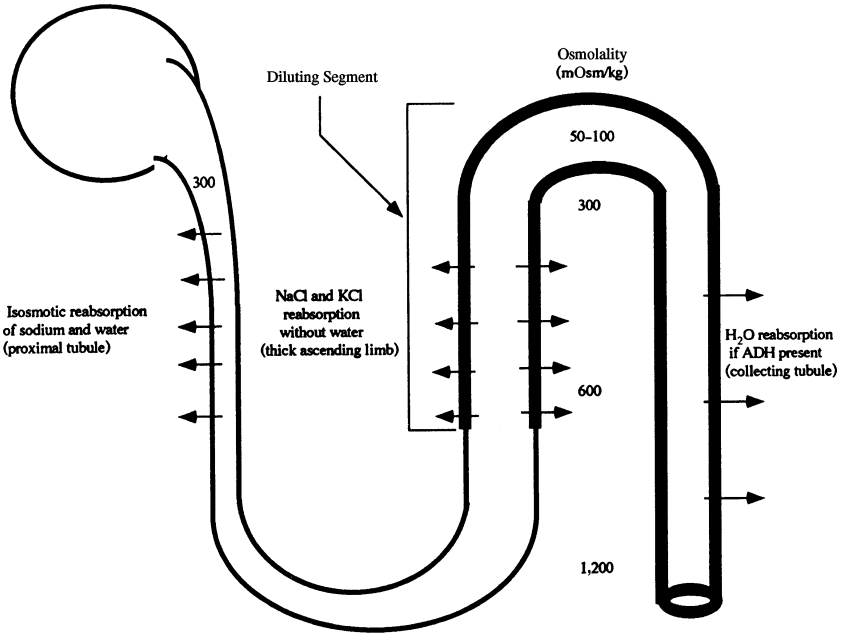

FIGURE 72.1. Excretion of a dilute urine. Solute entering the early proximal tubule has an osmolality identical to that of plasma; fluid is isotonically reabsorbed in this nephron segment. Separation of solute from water (H_2O) within the tubule begins in the thick ascending limb of Henle, which is impermeable to H_2O. Excretion of a urine with a minimum osmolality of 50 to 100 mOsm per L requires intact function of this nephron segment as well as suppression of antidiuretic hormone (ADH) release. [Adapted from Iwasaki Y, Oiso Y, Yamauchi K, et al: Osmoregulation of plasma vasopressin in myxedema. *J Clin Endocrinol Metab* 70:534, 1990.]

urine (U_{Osm} <100 mOsm per kg) [1]. The typical American diet affords a solute intake between 600 and 1,200 mOsm—average 900 mOsm—per day. Assuming an output that approximates intake, the daily urinary solute excretion of a typical adult would also average 900 mOsm. Dietary NaCl, KCl, and protein, which is broken down to urea, make up most of this solute load. The individual who excretes 900 mOsm of solute per day and who can dilute urine maximally (down to 50 mOsm per kg) has the capacity to excrete up to 18 of water in a 24-hour period:

$$900\,\text{mOsm}/50\,\text{mOsm/kg} = 18\,\text{L}$$

The capacity to dilute urine begins in the loop of Henle and continues to the collecting tubule. This portion of the nephron, which is impermeable to water, is often referred to as the *diluting segment* (Fig. 72.1). As filtrate passes through the loop of Henle, solute is removed by the Na-K-2Cl transporter located in the cells of thick ascending limb and by the NaCl carrier in the distal tubule. Filtrate leaving the diluting segment and entering the early collecting tubule characteristically is very dilute, with a urinary osmolality (U_{Osm}) of less than 100 mOsm per kg.

A maximally dilute urine cannot be excreted if the removal of salt by the pumps and carriers in the diluting segment is impaired or if the collecting tubule is rendered permeable to water by the presence of ADH (see following discussion). Inability to dilute the urine may have serious consequences. For example, for a patient unable to achieve urinary dilution below an osmolality of 300 mOsm per kg, the amount of water that can be excreted on a normal diet is reduced to 3 L:

$$900\,\text{mOsm}/300\,\text{mOsm/kg} = 3\,\text{L}$$

As discussed earlier, solute excretion is normally determined by dietary intake. A reduction in dietary sodium and protein intake, as is seen in the patient on a "tea-and-toast" diet, limits the capacity to excrete water. If solute intake falls to 150 mOsm per day, for instance, water excretion is limited to approximately 3 L even when urinary dilution is normal:

$$150\,\text{mOsm}/50\,\text{mOsm/kg} = 3\,\text{L}$$

It is easy to see that the combination of impaired diluting ability with a concomitant reduction in solute intake is more likely to impair water excretion and result in hyponatremia than either disturbance alone.

Regulation of Antidiuretic Hormone

Healthy adults are able to excrete very large or very small volumes of urine, the concentration of which varies according to the P_{Osm}. The primary hormone regulating water excretion in health is ADH. ADH (called *arginine vasopressin* in humans) is synthesized in the supraoptic and paraventricular nuclei of the hypothalamus. Hypothalamic osmoreceptors for ADH release are stimulated by hyperosmolality and inhibited by hypoosmolality. A change in osmoreceptor cell volume is probably the factor that modifies ADH secretion in response to changes in the P_{Osm}. The concentration of urea, an ineffective osmole incapable of altering cell volume, neither promotes nor inhibits ADH release.

A 1% to 2% reduction in P_{Osm} (P_{Osm} <280 mOsm per kg) maximally inhibits ADH release, leading to a U_{Osm} that is less than 100 mOsm per kg [2]. By contrast, a 1% to 2% increase in P_{Osm} above normal, or a 7% to 10% decrease in blood pressure or volume (even in the presence of plasma hypoosmolality), stimulates ADH release [1]. In the presence of ADH, the luminal membranes of the cortical and medullary collecting tubules become permeable as water channels (aquaporins) are generated. This change permits water reabsorption, increasing the final urine osmolality.

Hyponatremia

In most settings, the development of hyponatremia with hypoosmolality represents the retention of ingested or administered water. Thus, the causes of hyponatremia can be divided into those in which water excretion is abnormal and those in which water excretion is normal but water ingestion is considerably increased.

TABLE 72.1

CAUSES OF HYPONATREMIA

Impaired water excretion (U_{Osm} >100 mOsm/kg and usually >300 mOsm/kg)
Hypovolemic states
True volume depletion (by gastrointestinal, skin, or renal losses)
Edematous states with reduced effective arterial blood volume (advanced liver and heart disease)
Diuretics (particularly thiazides)
Advanced chronic kidney disease
Endocrine deficiencies (hypothyroidism and hypoadrenalism)
Syndrome of inappropriate antidiuretic hormone secretion
Cerebral salt wasting
Reduced solute intake (tea-and-toast diet, beer drinkers' hyponatremia)[a]
Normal water excretion (U_{Osm} >100 mOsm/kg)
Primary polydipsia
Psychiatric disorders (particularly with phenothiazines)
Hypothalamic disorders
Hyponatremia without hypoosmolality
Normal P_{Osm}
Pseudohyponatremia (hypertriglyceridemia, hyperproteinemia, genitourinary tract irrigation)
Increased P_{Osm}
Hyperosmolar hyponatremia (hyperglycemia, mannitol infusion in renal failure)
Azotemia (effective osmolality is reduced)

[a] U_{Osm} <100 mOsm/kg, but normal water excretion is impaired by the reduced solute load; see text for details.
P_{Osm}, osmolality of plasma; U_{Osm}, osmolality of urine.
Adapted from Iwasaki Y, Oiso Y, Yamauchi K, et al: Osmoregulation of plasma vasopressin in myxedema. *J Clin Endocrinol Metab* 70:534, 1990; and Stasior D, Kikeri D, Duel B, et al: Nephrogenic diabetes insipidus responsive to indomethacin plus dDAVP [letter]. *N Engl J Med* 324:850, 1991.

Hypoosmolar Disorders with Impaired Water Excretion

The U_{Osm} is typically greater than 100 mOsm per kg in patients with reduced water excretion (Table 72.1). An exception to this rule occurs when solute intake is markedly reduced, as in the patient subsisting on a solute-poor diet.

Hypovolemic Hyponatremia. A fall in effective perfusion pressure stimulates release of ADH [3]. Hypovolemic hyponatremia can occur in states of volume depletion or in edematous individuals with congestive heart failure (CHF) or advanced liver disease because each of these conditions is associated with a reduced effective arterial blood volume. As discussed previously, the resulting increase in the U_{Osm} (e.g., to 600 mOsm per kg) would limit renal water excretion on a 900 mOsm per day diet to 1.5 L, assuming all of the ingested solute were excreted (900 mOsm per kg 600). Solute excretion tends to be reduced in these settings, which are characterized by enhanced tubular salt reabsorption. In addition, most stimuli that activate angiotensin II release also stimulate thirst and lead to increased water ingestion, despite concurrent hypoosmolality.

Diuretic-Induced Hyponatremia. The ability to excrete a dilute urine is impaired by diuretics, whether they act in the thick ascending limb of Henle (loop diuretics) or in the distal tubule (thiazide-type diuretics) (Fig. 72.2). Each class reduces salt transport out of the diluting segment, thus raising the minimum achievable U_{Osm}. Raising the minimum U_{Osm}, however, does not usually lead to hyponatremia because a large volume of urine can still be excreted by most patients.

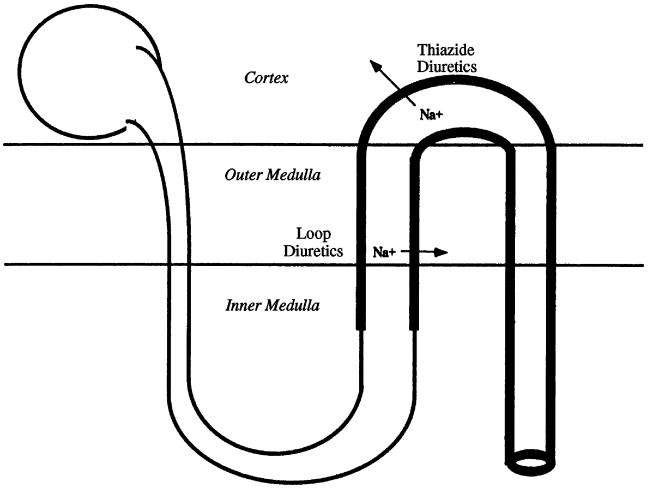

FIGURE 72.2. Site of action of loop and thiazide diuretics. Loop diuretics inhibit the Na-K-2Cl cotransporter in the medullary portion of the thick ascending limb of Henle, whereas thiazides block a simple NaCl carrier in the cortical portion of the distal tubule. These differences explain, in part, the susceptibility of individuals treated with thiazide-type diuretics to the development of hyponatremia. See text for details. [Adapted from Iwasaki Y, Oiso Y, Yamauchi K, et al: Osmoregulation of plasma vasopressin in myxedema. *J Clin Endocrinol Metab* 70:534, 1990.]

Almost all cases of diuretic-induced hyponatremia in otherwise healthy individuals have been caused by thiazide-type, rather than loop, diuretics [4]. This observation is attributable, in part, to different sites of the action within the renal tubule (Fig. 72.2). Loop diuretics, which act in the outer medulla, reduce the solute concentration in the renal medullary interstitium. Although ADH *permits* water reabsorption from the collecting tubule, medullary osmolality *drives* the process. A fall in the interstitial osmolality from 1,200 to 300 mOsm per kg, for instance, would limit the maximum U_{Osm} that can be generated from 1,200 to 300 mOsm per kg. By comparison, thiazide diuretics, which act in the cortex, impair diluting capacity but have a lesser effect on concentrating ability. Thus, the U_{Osm} may be 600 mOsm per kg in the thiazide-treated individual; if the urinary osmoles are primarily NaCl and KCl, urinary electrolyte losses can exceed those contained in an equal volume of plasma. In these patients, therefore, the plasma Na^+ may actually fall in the absence of ongoing water intake. For reasons that are not well understood, however, most individuals with thiazide-induced hyponatremia gain weight, indicating that the hyponatremia is at least in part a result of increased water intake [4]. This disorder occurs more frequently in women, typically occurs early in therapy (within 1 to 4 weeks), and is more likely to be observed in elderly individuals [5]. As discussed previously, accompanying hypokalemia also may contribute to the fall in P_{Osm}.

Advanced Chronic Kidney Disease. The normal glomerular filtration rate (GFR) is approximately 180 L per day. As renal function decreases, the ability to excrete water also decreases. The limitation in water excretion occurs for two reasons: tubular dysfunction leads to an inability to dilute the urine maximally, even in the absence of ADH, and the drop in GFR, particularly when severe, reduces daily solute excretion.

Endocrine Deficiency. Hypothyroidism and hypocortisolism can impair water excretion. Both may reduce cardiac output or

stroke volume, leading to increased ADH release. The resulting fall in GFR adversely affects free water excretion by diminishing delivery of filtrate to the diluting segments. Decreased delivery may be particularly important in patients with myxedema in whom hyponatremia may develop despite appropriate suppression of ADH release [6].

Another factor contributing to the hyponatremia of hypocortisolism is that corticotropin-releasing factor promotes the corelease of adrenocorticotropic hormone (ACTH) and ADH, although the reason for the concomitant release of these hormones is not known [7]. It is important to note that adrenocortical dysfunction (as in Addison's disease) leads to reduced cortisol and aldosterone levels, the latter predisposing to hyperkalemia. The presence of a low cortisol level alone, due to either pituitary or hypothalamic disease, or the abrupt withdrawal from prolonged exogenous corticosteroid administration may cause hyponatremia but should not alter potassium homeostasis, because aldosterone release is normal.

Syndrome of Inappropriate Antidiuretic Hormone Secretion. The syndrome of inappropriate ADH secretion (SIADH) is characterized by the following: plasma hypoosmolality; U_{Osm} more than 100 to 150 mOsm per kg (because ADH should be absent in the hypoosmolar state); urinary Na^+ concentration of more than 20 mEq per L, reflecting normal renal perfusion; normal adrenal, renal, and thyroid function; and normal potassium and acid–base balance. *The U_{Osm} does not need to exceed the P_{Osm} to make this diagnosis.* SIADH may be caused by enhanced hypothalamic ADH secretion, ectopic hormone production (usually by cancer), or administration of medications with ADH activity (Table 72.2).

In approximately one third of patients, the SIADH is associated with resetting of the hypothalamic osmostat. This disorder has been described in patients with hypovolemia, psychosis, and chronic malnutrition and in normal pregnancy (in which the plasma Na^+ concentration decreases by the second trimester from 140 to 135 mEq per L). ADH release is not suppressed until the P_{Osm} falls well below normal in this disorder. As a result, the P_{Osm} may vary between 240 and 250 mOsm per kg (plasma Na^+ approximately 120 to 125 mEq per L), compared with the normal value of approximately 285 to 292 mOsm per kg. In contrast to the classic form of the SIADH, in which nonsuppressible ADH release is seen, ADH secretion ceases when the P_{Osm} falls below this new, reset level. Because suppression of ADH prevents a further fall in the plasma Na^+ concentration, the severity of hyponatremia is limited in this condition.

An increasingly common cause of hyponatremia is symptomatic human immunodeficiency virus (HIV) infection [8]. Although hyponatremia in HIV-infected patients may result from volume deficiency or adrenal insufficiency, many patients have SIADH. Pneumonia due to *Pneumocystis jiroveci* or other organisms, central nervous system infections, and malignant disease are most often responsible in this setting.

Elevated ADH levels have been reported with the use of medications and various recreational drugs. The association of hyponatremia with the use of 3,4-methylenedioxymethamphetamine (Ecstasy) has been reported. The cause has been reported to be related to increased water drinking and the inappropriate presence of ADH [2]. Similar effects may be seen with the commonly prescribed selective serotonin reuptake inhibitors (SSRIs) used for the treatment of depression [9].

Cerebral Salt Wasting. Cerebral salt wasting is a rare disorder characterized by a low P_{Osm}, a U_{Osm} above 100 to 150 mOsm per kg, and a urine Na^+ concentration greater than 20 mEq per L [10]. Unlike SIADH, however, evidence of volume depletion (including low central filling pressures) is present. In affected individuals, therefore, the high urinary Na^+ represents inappropriate salt wasting rather than a response to normal tissue perfusion (as in SIADH patients).

The cause of this putative syndrome is unclear. It has been proposed that there may be increased release of natriuretic peptide from hormone-producing neurons in the brain that are activated by central nervous system dysfunction [11]. Both hypouricemia and renal tubular dysfunction have been reported. Mineralocorticoid replacement therapy with fludrocortisone acetate has been effective in some patients.

Reduced Solute Intake. As discussed previously, a reduction in salt and protein intake can lead to hypoosmolality if water intake exceeds output. Severely reduced solute intake, as occurs with a tea-and-toast diet, can cause hyponatremia even with normal degrees of water intake. "Beer drinkers' hyponatremia" occurs for a similar reason; the limited amount of solute in beer relative to its water content may be inadequate to permit excretion of the ingested water. In both conditions, the U_{Osm} should be maximally dilute (U_{Osm} <100 mOsm per kg). The absence of polyuria and the development of hyponatremia with normal or slightly above normal fluid intake distinguish these

TABLE 72.2

MAJOR CAUSES OF THE SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE (ADH) SECRETION

Disorders	Comments
Pulmonary diseases	Acute asthma, atelectasis, empyema, pneumothorax, acute respiratory failure, tuberculosis, carcinoma, pneumonia
Neurologic disorders	Meningitis, tumors, psychiatric disorders, subarachnoid hemorrhage, herpes zoster, Wernicke's encephalopathy
Ectopic production	Cancer (particularly oat-cell carcinoma of lung)
Drugs	Intravenous cyclophosphamide, carbamazepine, chlorpropamide, nonsteroidal anti-inflammatory drugs (because prostaglandins block ADH effect), cisplatin[a]
After major surgery	Pain afferents stimulate hypothalamic ADH release (lasts for 2–5 d), after mitral commissurotomy for mitral stenosis (acute decrease in left atrial pressure releases ADH)
Administration of exogenous ADH or oxytocin	Oxytocin can reduce plasma Na^+ concentration in mother and fetus
Symptomatic human immunodeficiency virus infection	See text for details
Idiopathic	Important to continue periodic monitoring for an underlying disorder, particularly carcinoma; vasculitis (such as temporal arteritis) should be considered in elderly patients when no other cause is apparent
Cerebral salt wasting	See text for details

[a]Hyponatremia induced by cisplatin may be due to renal salt wasting.

individuals from those with primary polydipsia (see following discussion).

Hypoosmolar Disorders with Normal Water Excretion. Psychiatric patients, particularly those with schizophrenia, often have abnormalities in water balance. Evaluation of psychotic patients has revealed that a variety of defects in water handling can occur that affect thirst, the release of ADH, and the renal response to ADH. Depending on the abnormality that is present, the patient may present with polydipsia and polyuria or hyponatremia.

Hyponatremia has been reported in as many as 13% of marathon runners and may occasionally be fatal. Although the exact mechanism has not been elucidated, risk factors for developing low serum sodium levels include weight gain during the race, female sex, racing time, and lower body mass index [12].

Primary Polydipsia. These individuals may have psychiatric disorders or may intentionally drink large volumes of water for social (dietary) or health reasons. This may be manifested clinically by exaggerated weight gain during the day associated with a transient reduction in the plasma sodium concentration [13].

In some individuals, a central defect in thirst regulation plays an important role in the pathogenesis of polydipsia. For example, the osmotic threshold for thirst may be reduced below the threshold for the release of ADH [14]. These patients continue to drink until the P_{Osm} is less than the threshold level. This implies truly prodigious water intake, as ADH secretion is suppressed by the fall in P_{Osm}, resulting in rapid excretion of the excess water and continued stimulation of thirst. The osmotic regulation of thirst differs from that of healthy subjects, in whom the thirst threshold is roughly equal to or a few milliosmoles per kilogram higher than the threshold for ADH [15]. The mechanism responsible for abnormal thirst regulation in this setting is unclear [16]. Drug therapy may contribute to the increase in water intake if the medication induces the sensation of a dry mouth.

Because people with normally functioning kidneys and regulation of ADH secretion are capable of excreting more than 10 to 15 L of urine per day, hyponatremia due to polydipsia is unusual. Despite this, there are rare patients in whom severe, and potentially fatal, hyponatremia has developed even though the U_{Osm} was appropriately dilute. More commonly, however, polydipsic patients manifesting hyponatremia have a concurrent abnormality in ADH release or response [17]. Concurrent thiazide diuretic therapy for systemic hypertension can lead to a marked and symptomatic reduction in the plasma sodium concentration in these patients.

There is no proven specific therapy for primary polydipsia with or without hyponatremia in psychotic patients. Limiting water intake rapidly raises the plasma sodium concentration because the excess water is readily excreted in a dilute urine. The risk of inducing osmotic demyelination (see later) in this setting is unclear; it has been suggested that patients with primary polydipsia and repeated episodes of acute hyponatremia are generally resistant to neurologic injury induced by rapid correction (see following discussion).

Over time, limiting the use of drugs that cause dry mouth, restricting fluid intake, and frequent weighing (to detect water retention) may be helpful. Antagonists to ADH are not likely to be useful if the urine is already maximally dilute but may help in patients with primary polydipsia and concomitant SIADH.

Hyponatremia Without Hypoosmolality

Hyponatremia may occur without plasma hypoosmolality. An increase in the plasma concentration of proteins (as immunoglobulins in multiple myeloma) or lipids (primarily triglycerides in lipemic plasma) can reduce the plasma Na^+ concentration. Lipids and proteins displace water from a given volume of plasma but do not affect the Na^+ concentration in the water phase of plasma [18]. As a result, the measured P_{Osm} is normal in this condition, which is called *pseudohyponatremia*. Because the sodium concentration in the aqueous component of plasma is normal, this form of hyponatremia is not of pathophysiologic consequence. The methods of electrolyte determination currently used in many laboratories (ion-selective electrodes) are not affected by plasma lipids or proteins.

An unusual form of hyponatremia, sometimes associated with a normal P_{Osm} but occasionally with hypoosmolality, can be observed after lithotripsy, uterine irrigation after endometrial ablation, or with transurethral prostatectomy [19–21], which often requires the use of as much as 20 to 30 L of nonconductive flushing solutions containing glycine, sorbitol, or mannitol. Some patients absorb 3 L or more of fluid through the exposed mucosal vascular plexus, leading to a dilutional reduction in the plasma sodium concentration that may fall below 100 mEq per L. In one prospective study of 100 patients, the incidence of hyponatremia after transurethral prostatectomy was 7%; there was one death [22]. Even when P_{Osm} is not notably reduced, confusion, disorientation, twitching, seizures, and hypotension may occur. Several methods have been devised to attempt to monitor the amount of fluid absorbed so that patients at risk for severe hyponatremia can be detected. Frequent determinations of the plasma sodium concentration are important.

There are instances in which patients with plasma hyperosmolality may develop hyponatremia (*hyperosmolar hyponatremia*). This most commonly occurs with severe hyperglycemia or when mannitol is given to patients with renal failure, resulting in an osmotic shift of water from cells into the extracellular fluid, diluting the plasma Na^+ concentration. In contrast to hypoosmolar hyponatremia, treatment is directed at correcting the high glucose concentration with insulin and free water repletion because cellular dehydration is present. For every 100 mg per dL rise in the blood sugar, the plasma Na^+ concentration falls by approximately 1.6 mEq per L [23], although this estimate varies with body size, falling more in a smaller individual.

Symptoms of Hypoosmolality

The neurologic manifestations of hyponatremia appear to be entirely due to the consequences of plasma hypoosmolality. A fall in P_{Osm} causes water movement from the extracellular space into cells. The resulting increase in cell water, which is of particular importance in the central nervous system, can lead to brain swelling. A variety of symptoms may be found, including lethargy, confusion, nausea, vomiting, and, in severe cases, seizures and coma. Focal neurologic symptoms are uncommon. Hyponatremic encephalopathy is generally reversible, although permanent neurologic damage or death has been reported, chiefly in premenopausal women [24]. Hyponatremic women may progress rapidly from minimal symptoms (such as headache and nausea) to respiratory arrest. Cerebral edema and herniation have been found in those women who died, suggesting a possible hormonally mediated decrease in the efficiency of the osmotic adaptation (see following discussion). The reason for the higher morbidity in this patient population is not well understood.

The likelihood that symptoms will develop is related to the level of hyponatremia and the rapidity with which it develops [25]. For example, a rapid decline in the plasma Na^+ concentration during several hours or days (e.g., from 140 to 115 mEq per L) may be associated with severe neurologic findings.

In comparison, a similar fall in plasma sodium occurring during 1 week or more may not cause any symptoms. In the latter circumstance, the degree of cerebral edema is much less [26]. This protective response, which begins on the first day and is complete within several days, occurs in two major steps:

1. The initial cerebral edema elevates the interstitial hydraulic pressure, creating a gradient for extracellular fluid movement out of the brain into the cerebrospinal fluid.
2. The brain cells lose solutes, leading to the osmotic movement of water out of the cells and less brain swelling [27]. The volume regulatory response begins with the movement of potassium and sodium salts out of the cells, followed by organic solutes, particularly the amino acids glutamine, glutamate, and taurine, and, to a lesser degree, the carbohydrate inositol. Electrolyte movement occurs quickly because it is mediated by the activation of quiescent cation channels in the cell membrane; organic solute loss occurs later because it requires synthesis of new transporters.

The organic solutes (called *osmolytes*) account for approximately one third of the cellular solute loss in chronic hyponatremia. Changes in the concentration of these solutes offer the advantage of restoring cell volume without interfering with protein function; in comparison, a potentially deleterious effect on protein function would occur if the volume adaptation were mediated *entirely* by changes in the cell cation (potassium plus sodium) concentration.

This adaptation is so efficient that it is not uncommon to see patients with heart failure or SIADH who are asymptomatic despite a plasma sodium concentration of 115 to 120 mEq per L. The occurrence of symptoms in patients with chronic hyponatremia usually signifies a profoundly low serum sodium concentration, less than 110 to 115 mEq per L.

Diagnosis of Hyponatremia

Three laboratory findings provide important information in the differential diagnosis of hyponatremia: P_{Osm}, U_{Osm}, and urinary sodium concentration.

Plasma Osmolality

Because P_{Osm} is mainly determined by the plasma sodium concentration, it is reduced in most hyponatremic patients. In some cases, however, the P_{Osm} is either normal (as in pseudohyponatremia) or elevated (as in hyperosmolar hyponatremia) [18].

Urine Osmolality

In patients with hypoosmolar hyponatremia, the U_{Osm} can be used to distinguish between patients with impaired water excretion, accounting for most cases, and primary polydipsia, in which water excretion is normal but intake is so high that it exceeds excretory capacity. Hyponatremia caused by primary polydipsia should completely suppress ADH secretion, resulting in the excretion of a maximally dilute urine with an osmolality less than 100 mOsm per kg and a specific gravity less than 1.003. A higher U_{Osm} indicates an inability to excrete free water normally, which suggests continued secretion of ADH.

Urinary Sodium Concentration

The two major causes of hyponatremia are hypovolemia and SIADH. These disorders can usually be distinguished by measuring the urinary sodium concentration. The urinary sodium concentration of patients with hypovolemia is typically less than 20 mEq per L, assuming the patient is not receiving diuretics. Because patients with SIADH have normal renal perfusion, unless they are on a very low sodium intake, the urinary sodium concentration is greater than 40 mEq per L. Patients with the SIADH can conserve urinary sodium normally and raise the urine osmolality further if intravascular volume depletion occurs.

Evaluation of acid–base and potassium balance may aid in the diagnosis in some hyponatremic patients. As examples, metabolic alkalosis and hypokalemia suggest diuretic use or vomiting, metabolic acidosis and hypokalemia suggest diarrhea or laxative abuse, and metabolic acidosis and hyperkalemia suggest adrenal insufficiency. On the contrary, plasma bicarbonate and potassium concentrations are typically normal in patients with SIADH. Although water retention tends to lower these values by dilution, as it does the plasma sodium and chloride concentrations, normal levels are restored by the factors that normally regulate acid–base and potassium balance.

The initial water retention and volume expansion in patients with SIADH are typically associated with hypouricemia (plasma uric acid concentration of $\leq$3 mg per dL) due to increased uric acid excretion in urine [28]. Also, urinary urea losses may cause a fall in the BUN to less than 5 mg per dL. These findings are the opposite of what is typically seen in volume depletion and thiazide-induced hyponatremia.

All of the findings seen in SIADH also have been described in the controversial syndrome of *cerebral salt wasting*, a disorder in which the high urinary sodium concentration occurs as a result of defective tubular reabsorption, and the elevation in ADH and subsequent development of hyponatremia are due to the associated volume depletion. Hypouricemia also may be present, which presumably is another manifestation of impaired renal tubular function (see previous discussion).

Fractional Excretion of Sodium

The fractional excretion of sodium (FE_{Na}) is a more accurate assessment of volume status than the urinary sodium concentration in patients with acute kidney injury; an FE_{Na} less than 1% suggests effective volume depletion. This observation has led many physicians to use the FE_{Na} in any situation in which the urinary sodium concentration might be helpful. However, the FE_{Na} may be misleading in patients with relatively normal renal function because the expected value to differentiate volume depletion from euvolemia varies with the GFR. A value of less than 1% is not the correct dividing line in this setting because this value may occur in euvolemic patients (such as those with SIADH) who have a urinary sodium concentration above 50 mEq per L and who excrete more than 100 mEq of sodium per day. As a result, the random urinary sodium concentration is more accurate for assessing the volume status in patients with hyponatremia with a normal plasma creatinine concentration. The FE_{Na} should generally not be used in this setting.

Treatment of Hyponatremia

Saline or Water Restriction

In general, the plasma sodium concentration can be raised by giving patients salt (either as saline or salt tablets) or by restricting their water intake to below the level of excretion. The choice of therapy is primarily governed by the cause of the hyponatremia. The more recent additions of antagonists to the ADH receptor in the collecting tubule (vaptans) will also be discussed.

Salt administration, usually as isotonic saline, is appropriate in those with true volume depletion; diuretic therapy, provided the diuretic is no longer acting; or adrenal insufficiency, in which cortisol replacement is also indicated. Water restriction is used in patients without neurologic symptoms who have

edematous states such as heart failure and hepatic cirrhosis and in those with SIADH, primary polydipsia, or advanced chronic kidney disease.

In a state of true volume depletion, isotonic saline corrects the hyponatremia by two mechanisms. Each liter of saline infused raises the plasma sodium by 1 to 2 mEq per L because saline has a higher sodium concentration (154 mEq per L) than plasma. By eventually causing volume repletion, it also removes the stimulus to ADH release, thereby allowing the water surfeit to be excreted. At this time, the plasma sodium concentration may return rapidly toward normal.

Isotonic saline should be considered in patients with mild-to-moderate or asymptomatic hyponatremia. In contrast, symptomatic patients or those with a plasma sodium less than 115 mEq per L usually require initial therapy with hypertonic saline. It must be emphasized, however, that careful monitoring is essential because overly rapid correction carries the risk of inducing iatrogenic neurologic complications (see following discussion) [3].

In primary polydipsia, the initiation of water restriction may result in a dramatic rise in the plasma sodium concentration. There is, however, some evidence suggesting that these patients may be less predisposed to osmotic demyelination because their hyponatremia often is of rapid onset, with less brain cell adaptation apt to occur [29].

The optimal rate of correction of hyponatremia varies with the clinical state of the patient. The following represents a reasonable approach, given the information currently available [3,30]. In asymptomatic patients, who are more likely to have chronic hyponatremia, the plasma sodium concentration should be raised at a maximum rate of approximately 0.5 mEq per L per hour and less than 12 mEq per L per day. A more rapid elevation can increase the risk of osmotic demyelination.

More rapid initial correction is indicated in patients with symptomatic hyponatremia, particularly those presenting with seizures or other severe neurologic manifestations, which primarily result from cerebral edema induced by acute (developing during 2 to 3 days) hyponatremia [30]. Here, the plasma sodium concentration can be raised at an initial rate of 1.5 to 2.0 mEq per L per hour for the first 3 to 4 hours (or longer, if the patient remains symptomatic) because the risk of persistent severe hyponatremia outweighs that of overly rapid correction. This appears to be particularly important in premenopausal women, who may progress from minimal symptoms (headache and nausea) to coma and respiratory arrest; furthermore, irreversible neurologic damage or death is relatively common in younger women with symptomatic hyponatremia, even if the hyponatremia is corrected at an appropriate rate. In comparison, men are at much less risk of symptomatic hyponatremia and of permanent neurologic injury. After the initial 3 to 4 hours of rapid correction, the rate should be slowed down so that the total rise in plasma sodium does not exceed approximately 12 mEq during the initial 24 hours.

The quantity of sodium required to achieve the desired elevation in the plasma sodium concentration *in patients with true volume depletion* can be estimated from the product of the plasma sodium deficit per liter and the TBW, which represents the osmotic space of distribution of the plasma sodium concentration. Normal values for the TBW are 0.5 and 0.6 times the lean body weight in women and men, respectively. If the initial aim in an asymptomatic hyponatremic 60-kg woman is to raise the plasma sodium concentration from 110 to 120 mEq per L, then

$$\text{Sodium deficit for initial therapy} = 0.5 \times 60 \times (120 - 110) = 300 \text{ mEq}$$

Thus, 600 mL of 3% hypertonic saline (which contains roughly 1 mEq of sodium per 2 mL, 500 mEq Na, and 500 mEq Cl per L) should be given during 20 hours at a rate of 30 mL per hour. This regimen should raise the plasma sodium concentration at the desired rate of 0.5 mEq per L per hour, and serial monitoring of the plasma sodium concentration (beginning at 2 to 3 hours) is still required.

The preceding formula may be less accurate in patients with SIADH [3]. In this setting, the administered salt in the hypertonic 3% saline is excreted because plasma volume expansion is present. Therefore, the rise in plasma sodium is not due to sodium retention. Because there are approximately 1,000 mEq of solute (Na and Cl) in a liter of 3% saline, the fluid in the renal collecting tubule is relatively hyperosmotic. This causes water to be retained in the urine and excreted simultaneously with the salt load. If, for example, the U_{Osm} were 500 mOsm per kg, the 1,000 mEq of salt excreted would obligate the elimination of 2 L of urine (a net loss of 1 L of free water, because 1 L of water was administered with the hypertonic saline). The result would be no change in total body sodium; the plasma sodium concentration would increase because of the loss of 1 L of water. Administration of the same hypertonic saline solution to an individual with SIADH and a U_{Osm} of 250 mOsm per kg would result in the loss of 4 L of urine (a net water loss of 3 L). The serum sodium would increase by a greater amount than it did in the person with the higher U_{Osm}. As a consequence of the excretion of the salt load and varying levels of U_{Osm} in patients with SIADH, the sodium replacement formula is frequently misleading in this setting.

Effect of Potassium

Potassium is as osmotically active as sodium, and giving potassium can raise the plasma sodium concentration and osmolality in a hyponatremic subject. As most of the excess potassium goes into the cells, electroneutrality is maintained in one of three ways, each of which raises the plasma sodium concentration: (a) intracellular sodium moves into the extracellular fluid; (b) extracellular chloride moves into the cells with potassium; the increase in cell osmolality promotes free water entry into the cells; and (c) intracellular hydrogen moves into the extracellular fluid. These hydrogen ions are buffered by extracellular bicarbonate and, to a much lesser degree, by plasma proteins. This buffering renders the hydrogen ions osmotically inactive; the ensuing fall in extracellular osmolality leads to water movement into the cells.

Thus, any administration of potassium must be taken into account when calculating the sodium deficit. This relationship becomes clinically important in the patient with severe diuretic or vomiting-induced hyponatremia who is also hypokalemic.

Risk of Osmotic Demyelination

Severe hyponatremia, especially if acute in onset, can lead to cerebral edema, potentially irreversible neurologic damage, and death [24]. This most often occurs when large volumes of hypotonic fluids are given to postoperative patients who have pain-induced ADH release that impairs the ability of the kidneys to excrete water or to patients with acute thiazide-induced hyponatremia. Within 24 hours, however, the brain begins to lose extracellular water into the cerebrospinal fluid and loses intracellular water by extruding sodium and potassium salts and osmolytes, thereby lowering the brain volume toward normal (see previous discussion).

The effect is that hyponatremia that develops slowly (i.e., during >2 to 3 days) is associated with a lesser likelihood of neurologic symptoms. In this setting, in which brain volume has fallen toward normal, rapid correction of severe hyponatremia may lead within 1 to several days to the development of a neurologic disorder called *osmotic demyelination* or *central pontine myelinolysis*. These lesions are detectable by cerebral computed tomography or magnetic resonance imaging. Results

of these diagnostic tests may not become positive for as long as 4 weeks, however [31].

It has been suggested that there are differences in individual susceptibility to osmotic demyelination. For example, observations indicate that psychiatric patients with primary polydipsia are relatively resistant to osmotic demyelination despite having repeated episodes of hyponatremia and, due to normal water excretory capacity, rapid correction of the plasma sodium concentration [29]. The reasons for this are not known, but this resistance to demyelination may not characterize the polydipsia of chronic alcoholics [32].

The mechanisms responsible for osmotic demyelination are not completely understood. Rapid elevation in the plasma sodium concentration leads to water movement out of the brain, which can lower the brain volume below normal. Such osmotically induced shrinkage in axons could sever their connections with surrounding myelin sheaths. Alternatively, the initial brain cell response to brain shrinkage may be the uptake of potassium and sodium from the extracellular fluid; this elevation in cell cation concentration could be toxic to the cells.

The manifestations of osmotic demyelination, which may be irreversible, include mental status changes, dysarthria, dysphagia, paraparesis or quadriparesis, and coma; seizures may occur but are less common. Patients in whom the plasma sodium concentration is raised to more than 20 mEq per L in the first 24 hours or is overcorrected to greater than 140 mEq per L are at greatest risk. Other putative risk factors for osmotic demyelination include chronic alcoholism, malnutrition, prolonged diuretic use, liver failure and transplantation, and burns [33]. On the contrary, late neurologic deterioration is rare if the hyponatremia is corrected at an average rate equal to or less than 0.5 mEq per L per hour [3,30].

Studies in experimental animals indicate that the total rate of correction during the first 24 hours is more important than the maximum rate in any given hour [34]. Demyelinating lesions are most common when the plasma sodium concentration in severe hyponatremia is raised to more than 20 mEq per L per day and are rare at a rate less than 10 to 12 mEq per L per day. This is similar to the safe average rate of correction of 0.5 mEq per L per hour observed in humans.

Recommendations

The preferred rate at which the plasma sodium concentration should be elevated varies with the clinical presentation. Due to the cerebral adaptation previously described, patients with chronic asymptomatic hyponatremia are generally at little risk for neurologic symptoms. In this setting, rapid correction is not indicated and may be harmful. Although the optimal rate of correction is not clearly proven, the current recommendation in asymptomatic patients is that the plasma sodium concentration be raised at a maximum rate of 12 mEq per L per day (which represents an average correction of 0.5 mEq per L per hour). Although it may be safe to increase the plasma sodium concentration at a rate of more than 12 mEq per day, there is no reason to correct it more rapidly *in the absence of symptoms*.

It is not known whether there is a potential benefit to administering water to previously hypoosmolar patients whose hyponatremia has been corrected much too rapidly. In rodents, a marked reduction in the incidence and severity of brain lesions was demonstrated if overly rapid correction (30 mEq per L or more during several hours) was partially reversed so that the net daily elevation in the plasma sodium concentration was less than 20 mEq per L [35]. This improvement was seen if therapy was begun before the onset of neurologic symptoms; benefit was much less likely in animals with symptomatic demyelination. The applicability of these findings to humans is uncertain.

More aggressive initial correction, at a rate of 1.5 to 2.0 mEq per L per hour, is indicated for the first 3 to 4 hours (or until the symptoms resolve) in patients who present with seizures or other severe neurologic abnormalities due to untreated and usually acute hyponatremia. The primary problem in these patients is cerebral edema, and the risk of delayed therapy is greater than the potential risk of too rapid correction. Even in this setting, however, the plasma sodium concentration should probably not be raised by more than 12 mEq per L in the first 24 hours because partial cerebral adaptation has already occurred. It is usually not necessary to continue hypertonic saline once the plasma sodium concentration is greater than 120 mEq per L.

Treatment of Hyponatremia in the Syndrome of Inappropriate Antidiuretic Hormone Secretion. Hyponatremia in SIADH results primarily from ADH-induced retention of ingested water. Appropriate therapy in this disorder depends on the severity of the hyponatremia and on the fact that, although water excretion is impaired, sodium handling is intact because there is no abnormality in volume-regulating mechanisms such as the renin–angiotensin–aldosterone system. Water restriction is the mainstay of therapy in asymptomatic hyponatremia of chronic SIADH. The associated negative water balance raises the plasma sodium concentration toward normal.

Severe, symptomatic, or resistant hyponatremia often requires the administration of salt. If the plasma sodium concentration is to be elevated, the osmolality of the fluid given must exceed that of the urine. This can be illustrated by a simple example (Table 72.3). Suppose a patient with SIADH and hyponatremia has a U_{Osm} that cannot be reduced below 616 mOsm per kg. If 1,000 mL of isotonic saline is given (containing 154 mEq each of Na and Cl or 308 mOsm), all of the salt is excreted (because sodium handling is intact), but in only 500 mL of water (308 mOsm in 500 mL of water equals 616 mOsm per kg). The retention of half of the administered water leads to a further reduction in the plasma sodium concentration. As a result, correction of the hyponatremia in these cases requires the administration of hypertonic 3% saline intravenously or salt tablets orally, preferably in combination with a drug that lowers the U_{Osm} and increases water excretion by impairing the renal responsiveness to ADH. A loop diuretic is most often used for this purpose.

Demeclocycline and lithium act on the collecting tubule cell to diminish its responsiveness to ADH, thereby increasing water excretion. These drugs tend to be too toxic or ineffective in most patients. Specific antagonists to the ADH-V_2 (antidiuretic) receptor in the cortical collecting tubule have shown promise and two have now been approved for clinical use. Two of these have been approved by the Food and Drug Administration (FDA) at the time of this writing.

TABLE 72.3

MECHANISM OF NORMAL SALINE-INDUCED WORSENING OF HYPONATREMIA IN THE SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION[a]

	Solute (mOsm)	Water (mL)
Input	308	1,000
Output	308	500
Net gain	0	+500

[a] This calculation assumes that the individual cannot dilute the urine below a urine osmolality of 616 mOsm/kg and that all the administered solute is excreted in the urine.

Conivaptan, an antagonist to both the V_1 (vascular) and V_2 (ADH) receptors, was the first. It must be given intravenously in the hospital and has the propensity to cause phlebitis. Recent data suggest that a single 20 mg bolus intravenously over 30 minutes results in a sustained water diuresis and may avoid vascular injury. It is not suitable for chronic use. Tolvaptan is an oral ADH antagonist which is specific for the V_2 receptor. It must also be initiated in the hospital but can be administered in the outpatient setting after that. Tolvaptan has been shown to decrease body weight in chronic heart failure patients in a single controlled study [36].

The choice of initial therapy in symptomatic patients is usually 3% saline and this is the preferred treatment with severe neuropathology (such as seizures). In less symptomatic individuals, a vaptan may be effective. However, as there are no controlled prospective studies comparing hypertonic saline with the vaptans, it is difficult to recommend the latter in the SIADH as first-line agents, particularly when cost is considered. When they are administered, it is important to relax fluid restriction during the initial titration with these agents to avoid an excessive rise in the serum sodium concentration.

Reset Osmostat. Hyponatremia due to a reset osmostat may occur in association with any of the causes of SIADH and accounts for between 25% and 30% of cases overall. Downward resetting of the osmostat can also occur in hypovolemic states in which the baroreceptor stimulus to ADH release is superimposed on osmoreceptor function; quadriplegia, in which effective volume depletion may result from venous pooling in the legs; psychosis; tuberculosis; and chronic malnutrition. The plasma sodium concentration also falls by approximately 5 mEq per L in normal pregnancy. How this occurs is incompletely understood, but human chorionic gonadotropin may play an important role [37].

The presence of a reset osmostat should be suspected in any patient with apparent SIADH who has mild hyponatremia (usually between 125 and 135 mEq per L) that is stable over many days despite variations in sodium and water intake. The diagnosis can be confirmed clinically by observing the response to a water load (10 to 15 mL per kg given orally or intravenously during 30 minutes). Healthy subjects and those with a reset osmostat should excrete more than 80% within 4 hours, whereas excretion is impaired in classic SIADH.

Identification of a reset osmostat is important because the therapeutic recommendations for SIADH discussed here do not apply in this setting. These patients generally have mild, asymptomatic hyponatremia due to downward resetting of the threshold for both ADH release and thirst. Because osmoregulatory function is normal around the new baseline, attempting to raise the plasma sodium concentration increases ADH levels and makes the patient very thirsty, a response that is similar to that seen with water restriction in healthy subjects. Thus, efforts to raise the plasma sodium concentration are both unnecessary and likely to be ineffective. Treatment should be primarily directed at the underlying disease.

Treatment of Hyponatremia in Edematous States. Raising the plasma sodium concentration in patients with edema may be more difficult than in those conditions described earlier. Most of these individuals have advanced CHF or liver disease. Consequently, sodium administration is generally contraindicated.

Congestive Heart Failure. Restricting water intake is the mainstay of therapy in hyponatremic patients with heart failure, although this is often not tolerable because of the intense stimulation of thirst. The combination of an angiotensin-converting enzyme (ACE) inhibitor (or angiotensin receptor blocker [ARB]) and a loop diuretic may induce an elevation in the plasma sodium concentration [38,39]. Tolvaptan may be useful in some patients (see above) but must be initiated in the hospital. Conivaptan is not indicated for treatment of hyponatremia in this setting.

Liver Disease. Hyponatremia in patients with hepatic cirrhosis usually develops slowly and produces no cerebral edema or symptoms. It is possible, however, that a low plasma sodium concentration can exacerbate hepatic encephalopathy. In view of the marked sodium and water retention, the mainstay of therapy in this setting is restricting water intake to a level sufficient to induce negative water balance and partial correction of the hyponatremia. Hypertonic saline or salt tablets are indicated only in patients with symptomatic hyponatremia. Diuretics can be given concurrently to prevent worsening of the edema, but overly rapid correction must be avoided to minimize the risk of central demyelinating lesions. As is the case with hyponatremic CHF patients, demeclocycline has been evaluated in this setting, but its use has been limited because of its nephrotoxicity [40].

Hypernatremia

Hypernatremia can be produced by the administration of hypertonic sodium solutions. However, in almost all cases, there is loss of free water. Persistent hypernatremia does not occur in healthy subjects because the ensuing rise in P_{Osm} stimulates both thirst and the release of ADH, which minimizes further water loss. The associated increase in water intake then lowers the plasma sodium concentration to normal. This regulatory system is so efficient that the P_{Osm} is maintained within a range of 1% to 2% despite wide variations in sodium and water intake. Even patients with diabetes insipidus, who often have marked polyuria due to diminished ADH effect, maintain a near-normal plasma sodium concentration by appropriately increasing water intake.

The result is that hypernatremia occurs primarily in those patients who cannot express thirst normally; most often, these patients are infants and adults with impaired mental status, and the elderly, who also appear to have diminished osmotic stimulation of thirst via an unknown mechanism [41]. A patient with a plasma sodium concentration of 150 mEq per L or more who is alert but not thirsty has, by definition, a *hypothalamic lesion* (either structural or functional) affecting the thirst center.

Etiology of Hypernatremia

The major causes of hypernatremia are listed in Table 72.4.

TABLE 72.4

MAJOR CAUSES OF HYPERNATREMIA

Unreplaced water loss
Insensible and sweat losses
Gastrointestinal losses
Central or nephrogenic diabetes insipidus
Hypothalamic lesions affecting thirst or osmoreceptor function
Primary hypodipsia
Essential hypernatremia
Reset osmostat in mineralocorticoid excess
Water loss into cells
Severe exercise or seizures
Sodium overload
Intake of hypertonic sodium solutions

Free Water Loss. The unreplaced loss of solute-free water leads to an elevation in the plasma sodium concentration. Because the plasma sodium concentration and P_{Osm} are determined by the ratio of total body solutes (i.e., *effective osmoles*, chiefly sodium and potassium salts) to TBW, the amounts of sodium and potassium in a fluid determine how loss of that fluid affects body osmolality [3]. The composition of diarrheal fluid can be used to illustrate this point. Many viral and osmotic diarrheas are associated with an isosmotic diarrheal fluid that has a sodium-plus-potassium concentration between 40 and 100 mEq per L; organic solutes, which do not affect the plasma sodium concentration, make up the remaining osmoles. Loss of this fluid tends to induce hypernatremia because water is being lost in excess of sodium plus potassium. Similar considerations apply to urinary losses during an osmotic diuresis induced by glucose, mannitol, or urea (see following discussion). Patients with secretory diarrheas such as cholera excrete a diarrheal fluid with a sodium–potassium concentration similar to that of plasma. Loss of this fluid causes volume and potassium depletion but does not directly affect the plasma sodium concentration.

With these considerations in mind, the sources of free water loss that can lead to hypernatremia if intake is not increased include the following:

- *Insensible and sweat losses.* Insensible water losses from the skin by evaporation and sweat are relatively dilute. The loss of this fluid is increased by fever, exercise, and exposure to high temperatures.
- *Gastrointestinal losses.* As mentioned previously, most gastrointestinal losses promote the development of hypernatremia because the sodium-plus-potassium concentration is less than that in the plasma. An elevation in the plasma sodium concentration with a diarrheal illness is particularly common in infants.
- *Central or nephrogenic diabetes insipidus.* Decreased release of ADH or renal resistance to its effect causes the excretion of a relatively dilute urine (see following discussion). Most affected patients have a normal thirst mechanism and, therefore, typically present with polyuria and polydipsia and, at most, a high-normal plasma sodium concentration. However, marked and symptomatic hypernatremia occurs if there is inadequate replacement (either oral or intravenous) of the urinary water losses.
- *Osmotic diuresis.* An osmotic diuresis due to glucose, mannitol, or urea causes an increase in urine output in which the sodium-plus-potassium concentration is well below that in the plasma because of the presence of the excreted organic solute. Patients with diabetic ketoacidosis or nonketotic hyperglycemia typically present with hyperosmolality, although the plasma sodium concentration may be kept normal or low by the hyperglycemia-induced water movement out of cells.
- *Hypothalamic lesions affecting thirst or osmoreceptor function.* Hypernatremia can occur in the absence of increased water losses if there is a primary hypothalamic disease impairing thirst (called *hypodipsia*). In patients with this problem, forced water intake is usually sufficient to maintain a normal plasma sodium concentration, although central diabetes insipidus (CDI), if present, should be treated.

Other hypodipsic patients do not respond to water loading, as the excess water is excreted in the urine with little change in the plasma sodium concentration. These patients have selective injury to the hypothalamic osmoreceptors, with ADH secretion being primarily governed by changes in blood volume (volume receptors remain intact). Thus, the suppression of ADH release by water loading in such patients is due to the associated mild volume expansion rather than to a fall in P_{Osm}. This disorder is termed *essential hypernatremia* [42]. Correction is difficult, since ADH release and suppression is driven by volume and not by the serum osmolality.

True upward resetting of the osmostat has been described only in patients with primary mineralocorticoid excess (such as in primary hyperaldosteronism). Presumably, the suppressive effect of chronic mild volume expansion on ADH release is responsible for this phenomenon. The plasma sodium concentration in these patients is frequently between 141 and 145 mEq per L and may be a clue to the diagnosis.

Water Loss into Cells. Transient hypernatremia, in which the plasma sodium concentration can rise by 10 to 15 mEq per L within a few minutes, can be induced by intense exercise or seizures, activities that are also associated with lactic acidosis. In this setting, the intracellular breakdown of glycogen into smaller, more osmotically active molecules, such as lactate, can increase water uptake into cells. The plasma sodium concentration returns to normal within 5 to 15 minutes after the cessation of exertion.

Sodium Overload. Acute and often marked hypernatremia, with plasma sodium concentrations even higher than 175 mEq per L, can be induced by administration of hypertonic sodium-containing solutions. Examples include salt poisoning in infants and young children, infusion of hypertonic sodium bicarbonate to treat metabolic acidosis, and massive salt ingestion, such as can occur when a highly concentrated saline emetic or gargle is swallowed [43].

This type of hypernatremia corrects spontaneously if renal function is normal because the excess sodium is rapidly excreted in the urine. Even with optimal therapy, however, the mortality rate is extremely high in adults with a plasma sodium concentration that has suddenly risen to more than 180 mEq per L [44]; for reasons that are poorly understood, severe hypernatremia is often better tolerated in young children.

Symptoms of Hypernatremia

Hypernatremia is basically a mirror image of hyponatremia. The rise in the plasma sodium concentration and osmolality causes rapid water movement out of the brain; this decrease in brain volume can cause tension leading to rupture of the cerebral veins with focal intracerebral and subarachnoid hemorrhages and possible irreversible neurologic damage. The clinical manifestations of this disorder begin with lethargy, weakness, and irritability and can progress to twitching, seizures, and coma. Severe symptoms usually require an acute elevation in the plasma sodium concentration to more than 158 mEq per L.

Despite the generalized reduction in cell volume with hypernatremia, brain volume is gradually restored due to both water movement from the cerebrospinal fluid into the brain (thereby increasing the interstitial volume) and to the uptake of solutes by the brain cells (thereby pulling water into the cells). The latter response involves an initial uptake of sodium and potassium salts, followed by the later accumulation of osmolytes such as inositol and the amino acids glutamine and glutamate [45]. The effect is that these osmolytes, which do not interfere with cell function, account for approximately 35% of the new cell solute.

As in hyponatremia, the cerebral adaptation in hypernatremia has two important clinical consequences:

1. Chronic hypernatremia is much less likely to induce neurologic symptoms. Assessment of symptoms attributable to hypernatremia is often difficult because most affected adults have underlying neurologic disease, which diminishes the protective thirst mechanism that normally prevents the

development of hypernatremia, even in patients with diabetes insipidus.
2. Correction of chronic hypernatremia must occur slowly to prevent rapid fluid movement into the brain leading to cerebral edema, which can cause seizures and coma. Although the brain cells can rapidly lose potassium and sodium in response to this cell swelling, the loss of accumulated osmolytes occurs more slowly, a phenomenon that acts to hold water within the cells. The loss of inositol, for example, requires both a reduction in synthesis of new sodium–inositol cotransporters and the activation of a specific inositol efflux mechanism in the cell membrane. The delayed clearance of osmolytes from the cell can predispose to cerebral edema if the plasma sodium concentration is corrected too rapidly.

Diagnosis of Hypernatremia and Polyuric Disorders

The cause of the hypernatremia is usually evident from the history. When the cause is unclear, the correct diagnosis can usually be established by evaluation of the integrity of the ADH-renal axis via measurement of the U_{Osm}. A rise in the plasma sodium concentration is a potent stimulus to ADH release as well as to thirst; furthermore, a P_{Osm} of more than 295 mOsm per kg (representing a plasma sodium concentration of approximately 145 to 147 mEq per L) generally leads to sufficient ADH secretion to maximally stimulate urinary concentration.

Thus, if both hypothalamic and renal functions are intact, the U_{Osm} of a person with hypernatremia should exceed 700 to 800 mOsm per kg. In this setting, unreplaced insensible or gastrointestinal losses, sodium overload, or, rarely, a primary defect in thirst is likely to be responsible for the hypernatremia. Exogenous ADH does not produce a further rise in the U_{Osm}.

The chemical composition of the urine is diagnostically useful. The urinary sodium concentration should be less than 20 mEq per L when water loss and volume depletion are the primary problems, but it is typically well above 100 mEq per L in a salt-overload state [43]. If the U_{Osm} is significantly lower than that of the hyperosmolar plasma, then either central (ADH-deficient) or nephrogenic (ADH-resistant) diabetes insipidus is present.

Diagnosis of Polyuric States and Diabetes Insipidus. *Polyuria* can be arbitrarily defined as urine output exceeding 3 L per day. It must be differentiated from the more common complaints of frequency and nocturia, which are usually not associated with an increase in the total urine output. Not counting the glucose-induced osmotic diuresis of uncontrolled diabetes mellitus, there are three major causes of polyuria in the outpatient setting. Each of these causes is due to dysregulation of water balance, leading to excessive excretion of dilute urine (U_{Osm} usually <250 mOsm per kg).

Primary Polydipsia. Primary polydipsia (also called *psychogenic polydipsia*) is characterized by a primary increase in water intake (see Hyponatremia section). This disorder is most often seen in anxious, middle-aged women and in patients with psychiatric illnesses, including those taking medications that can lead to the sensation of dry mouth. Primary polydipsia can also be induced by hypothalamic lesions that directly affect the thirst center, as may occur with an infiltrative disease such as sarcoidosis. As expected, polyuria resulting from primary polydipsia is not associated with hypernatremia.

Central Diabetes Insipidus. CDI is associated with deficient secretion of ADH. This condition is most often idiopathic (possibly due to autoimmune injury to the ADH-producing cells) or induced by trauma, pituitary surgery or infiltration, or hypoxic or ischemic encephalopathy. When CDI develops following trauma or surgery, a triphasic response may be observed [46]. In this condition, initial inhibition of ADH results in polyuria; this is followed by uncontrolled release of ADH from injured cells and, subsequently, by permanent CDI.

Nephrogenic Diabetes Insipidus. Nephrogenic diabetes insipidus (NDI) is characterized by normal ADH secretion but varying degrees of renal resistance to its water-retaining effect. In its mild form, NDI is relatively common because most patients who are elderly or who have underlying renal disease have a reduction in maximum concentrating ability. This defect, however, is not severe enough to produce a symptomatic increase in urine output. True polyuria due to ADH resistance occurs primarily in four settings: X-linked hereditary NDI in children, in which there is an abnormality in the renal V_2 receptors for ADH or in the ADH-sensitive water channel (*aquaporin 2*) [47]; chronic lithium use, which can lead to polyuria in approximately 20% of patients; hypercalcemia; and severe hypokalemia.

Each of these conditions is associated with an increase in water output and the excretion of a relatively dilute urine. With primary polydipsia, the polyuria is an appropriate response to excessive water intake. In comparison, the water loss is inappropriate with either form of diabetes insipidus. Thus, a low plasma sodium concentration at presentation (<137 mEq per L) due to water overload is usually indicative of primary polydipsia, whereas a high-normal plasma sodium concentration (>142 mEq per L) points toward diabetes insipidus. Marked hypernatremia is uncommon in diabetes insipidus because the initial loss of water stimulates the thirst mechanism, resulting in an increase in intake to match the urinary losses. An exception to this general rule is the patient with a central lesion impairing both ADH release and thirst whose plasma sodium concentration can exceed 160 mEq per L.

The correct diagnosis is often inferred from the plasma sodium concentration and from the history. The patient should be questioned about the causes of CDI or NDI and about the rate of onset of the polyuria; the polyuria is usually abrupt in CDI ("I suddenly began urinating excessively 2 days ago") but gradual in NDI or primary polydipsia.

Even if the diagnosis seems straightforward based on the history or plasma sodium concentration, it should be confirmed. This is accomplished by challenging the kidneys' ability to concentrate the urine in response to a high P_{Osm}. The P_{Osm} can be raised either by water restriction or, less commonly, by the administration of hypertonic saline (0.05 mL per kg per minute for no more than 2 hours). These maneuvers are unnecessary if the patient's P_{Osm} is already at or above 295 mOsm per kg. At this point, exogenous ADH is administered.

The water restriction test for the evaluation of polyuria involves measurement of the urine volume and osmolality every hour and plasma sodium concentration and P_{Osm} every 2 hours. The patient should stop drinking 2 to 3 hours before beginning the test; overnight fluid restriction should be avoided because potentially severe volume depletion and hypernatremia can be induced in patients with marked polyuria.

Interpretation of the water restriction test is based on the following observations: (a) raising the P_{Osm} leads to a progressive elevation in ADH release and, therefore, an increase in the U_{Osm} in normal individuals; and (b) once the P_{Osm} reaches 295 to 300 mOsm per kg (normal, 280 to 290 mOsm per kg), endogenous ADH effect on the kidney is maximal. At this point, administering ADH does not elevate the U_{Osm} unless endogenous ADH release is impaired (i.e., unless the patient has CDI).

The water restriction test is continued until the U_{Osm} reaches a clearly appropriate level of concentration (approximately 600 mOsm per kg, indicating that both ADH release and effect are intact), the U_{Osm} is stable on two or three successive

measurements despite a rising P_{Osm}, more than 3% to 5% of body weight is lost, or the P_{Osm} exceeds 295 to 300 mOsm per kg. In the last two cases, exogenous ADH is then given, usually in the form of 10 μg of deamino-8-D-arginine vasopressin [DDAVP; also called desmopressin] by nasal insufflation, and the U_{Osm} and volume are monitored over every 30 minutes for 90 minutes. Measuring the serum ADH level at the start of the test and immediately before DDAVP is administered may be useful.

Each of the causes of polyuria produces a distinct pattern:

1. CDI is usually partial and, therefore, associated with a rise in the U_{Osm} as the P_{Osm} increases. The degree of urinary concentration is clearly submaximal, however, and because ADH release is inadequate, exogenous ADH leads to a rise in the U_{Osm} of 15% to 50% and a corresponding fall in urine output.
2. NDI also is associated with a submaximal rise in U_{Osm}, but there is no urinary response to exogenous ADH. It must be emphasized that NDI is a rare cause of true polyuria in adults in the absence of lithium use, hypercalcemia, hypokalemia, or, rarely, renal tubular disease.
3. Primary polydipsia is associated with a rise in U_{Osm}, usually to more than 500 mOsm per kg, and no response to exogenous ADH because endogenous release is intact. The chronic polyuria in this disorder can partially wash out the medullary interstitial solute gradient; as a result, maximal concentrating ability is impaired and the U_{Osm} may only reach 500 to 600 mOsm per kg, as compared with 800 mOsm per kg or more in healthy subjects.

A properly performed test in which ADH is not given until the P_{Osm} exceeds 295 mOsm per kg usually establishes the correct diagnosis. The different patterns of response are depicted in Figure 72.3. There is, however, one major potential source of error. Patients with partial CDI may be hyperresponsive to the submaximal rise in ADH induced by water restriction, perhaps because of receptor upregulation. As a result, they may be polyuric at the normal P_{Osm} of 285 to 290 mOsm per kg when ADH levels are very low, but they may have a maximally concentrated urine at a P_{Osm} of more than 295 mOsm per kg when ADH levels are somewhat higher. In such patients, exogenous ADH is without effect, resulting in a pattern suggestive of primary polydipsia or NDI. Therefore, measurement of plasma ADH levels may be useful. In this condition, the serum sodium concentration is normal or elevated, in contrast to primary polydipsia, where it is typically below 140 mEq per L.

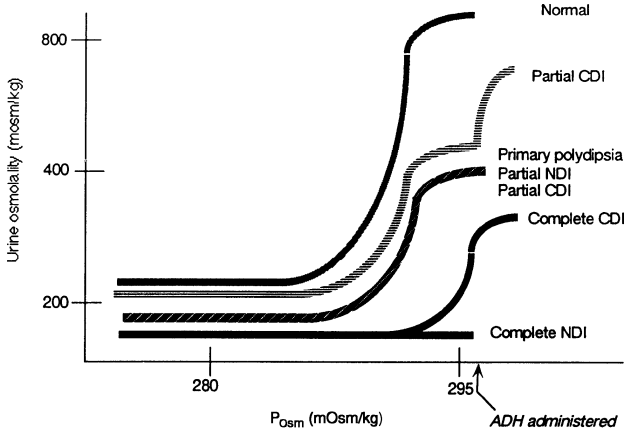

FIGURE 72.3. Response to antidiuretic hormone (ADH) after a water restriction test. ADH is given when the osmolality of plasma (P_{osm}) reaches 295 mOsm per kg, the level at which maximal ADH release and response should be present. This test identifies the cause of polyuria in approximately 80% of patients. Confusion may arise, however, with partial central diabetes insipidus (CDI). In this disorder, some individuals have lower than normal ADH levels at a normal P_{osm}, but the increase in ADH (although still subnormal) generates a maximum urine response, presumably due to increased sensitivity. Consequently, these patients exhibit polyuria at a normal P_{osm}, but the curve during the water restriction test may mimic partial nephrogenic diabetes insipidus (NDI) or primary polydipsia. Measurement of plasma ADH levels may be needed to distinguish these possibilities. [From Zerbe R, Robertson G: A comparison of plasma vasopressin measurements with a standard indirect test in the differential diagnosis of polyuria. *N Engl J Med* 305:1539, 1981, with permission.]

The previous discussion has emphasized the diagnostic approach to a water diuresis. In some polyuric patients, however, the increase in urine output is due to a solute or to osmotic diuresis in which decreased solute reabsorption is the primary abnormality. Although glucosuria is the most common cause of osmotic diuresis in outpatients, other conditions may account for inpatient cases. These include high-protein feedings (in which urea acts as the osmotic agent) and volume expansion due to saline loading or the administration of mannitol. The U_{Osm} in these disorders is usually greater than 300 mOsm per kg, in contrast to the dilute urine typically found with a water diuresis. Total solute excretion, which is calculated from the product of the U_{Osm} and volume of a 24-hour urine sample, is normal with a water diuresis (600 to 900 mOsm per day) but markedly increased with an osmotic diuresis.

Although renal disease can impair sodium conservation in the presence of volume depletion, it rarely causes sufficient sodium wasting to induce true polyuria. The polyuria of postobstructive diuresis is often misunderstood. Physicians observing a urine output that may initially exceed 1,000 mL per hour may feel compelled to replace the urine output with intravenous fluids. This merely prolongs the polyuria by protracting the volume expansion. Optimal therapy of a postobstructive diuresis consists of fluid infusion at a maintenance level, such as 75 mL of one-half isotonic saline per hour. The development of volume depletion, as evidenced by hypotension or a rise in the BUN, is unusual with this regimen.

Treatment of Hypernatremia

The water deficit of a hypernatremic patient can be estimated from the following calculation. The quantity of osmoles in the body is equal to the osmolal space (the TBW) times the osmolality of the body fluids:

$$\text{Total body osmoles} = \text{TBW} \times P_{Osm}$$

$$\text{Water deficit} = \text{current body water (plasma } Na^+/140 - 1)$$

where current (observed) body water = 60% body mass.

This formula estimates the amount of positive water balance required to return the plasma sodium concentration to 140 mEq per L. It does not account for electrolyte losses that may occur conjointly with water losses in such settings as osmotic diuresis or diarrhea. In addition, hypernatremia itself may cause mild urinary sodium wasting in hypovolemic subjects, largely as a result of reduced aldosterone release. Both hypernatremia and concurrent hypokalemia (due to gastrointestinal or renal losses) may act directly on reducing aldosterone production by adrenal glands.

Rate of Correction. As in hyponatremia, overly rapid correction is potentially dangerous in hypernatremia [45]. Rapidly lowering the plasma sodium concentration once osmotic adaptation has occurred may cause cerebral edema and lead to seizures, permanent neurologic damage, or death. This adverse sequence has been described in children in whom

hypernatremia was corrected at a rate exceeding 0.7 mEq per L per hour. In comparison, no neurologic sequelae were induced when the plasma sodium concentration was lowered at 0.5 mEq per L per hour [48].

The water deficit represents the existing amount of water loss that must be offset; ongoing free water losses, including insensible losses (approximately 40 mL per hour), must also be replaced. The replacement fluid can be administered orally or intravenously as dextrose in water. Sodium or potassium can be added if there are concurrent losses of these cations, but the addition of these solutes decreases the amount of free water that is being given. It should be emphasized that an isotonic saline solution should be used as initial therapy in the volume-depleted, hypotensive patient because restoration of tissue perfusion is of primary importance.

Treatment of Diabetes Insipidus. The major symptoms of both forms of diabetes insipidus are polyuria and polydipsia, related to the urinary concentrating defect (see previous discussion). Treatment for these disorders is aimed at decreasing the urine output.

Central Diabetes Insipidus. Because the primary problem is deficient secretion of ADH, control of the polyuria can be achieved by hormone replacement using DDAVP (desmopressin), a two–amino acid synthetic analogue of ADH. DDAVP is administered by nasal spray in a usual dose starting at 5 μg once a day. Since nocturia is often the most troubling symptom, the initial dose is usually given at night. Tablets of desmopressin are also available although their absorption may vary in different patients. Therefore, switching from one of the intranasal form to a tablet may require retitration and close monitoring. The starting dose of the tablet is 0.05 mg per day. The size and necessity for a daytime dose can be determined by the effectiveness of the evening dose. If, for example, polyuria does not recur until noon, then one-half of the evening doses may be sufficient at that time.

One important potential risk inherent in treating CDI with DDAVP is that of water retention leading to the development of hyponatremia. There are several reasons why this may occur. Patients are no longer polyuric once on therapy. Because they are on a fixed dose of DDAVP, their ADH activity is constant and not regulated. V_2 receptors may be upregulated as a result of prolonged deprivation of vasopressin. Finally, some patients may retain their habitually large consumption of water even after their polyuria ceases. Hyponatremia in this context can be avoided by giving the minimum dose that is required to control the polyuria.

Nephrogenic Diabetes Insipidus. NDI results from partial or complete resistance of the kidney to the effects of ADH. As a result, patients with this disorder are not likely to respond to either hormone administration (such as DDAVP) or to drugs such as chlorpropamide and carbamazepine that increase either the renal response to ADH or ADH secretion.

In adults, a concentrating defect severe enough to produce polyuria due to NDI is most often due to chronic lithium use or hypercalcemia. Less frequently, it is caused by other conditions that impair tubular function, such as Sjögren's syndrome (see previous discussion). Therapy targets correction of the underlying disorder or discontinuing a causative drug. In hypercalcemic patients, for example, normalization of the plasma calcium concentration usually leads to amelioration of polyuria. In contrast, lithium-induced NDI may be irreversible if the patient already has severe tubular injury and a marked concentrating defect.

Thiazide diuretics can diminish the degree of polyuria in patients with persistent and symptomatic NDI. The potassium-sparing diuretic amiloride may be helpful because of its additive effect with a thiazide diuretic and, in cases of reversible lithium-induced disease, may allow lithium to be continued (see following discussion) [49].

The combination of a low-sodium diet with a thiazide diuretic (such as hydrochlorothiazide, 25 mg once or twice daily) acts by inducing mild volume depletion. As little as a 1.0- to 1.5-kg weight loss reduced the urine output by more than 50%, from 10.0 L per day to less than 3.5 L per day, in one study of patients with NDI. This effect is presumably mediated by a hypovolemia-induced increase in proximal sodium and water reabsorption, thereby diminishing water delivery to the ADH-sensitive sites in the collecting tubules and reducing the urine output. The initial natriuresis and, therefore, the antipolyuric response can be enhanced by combination therapy with amiloride (or another potassium-sparing diuretic) [49]. This regimen has an additional benefit in that amiloride partially blocks the potassium wasting induced by the thiazide.

Thiazide diuretics also limit the ability to dilute the urine. As a result, the concentration of urine in a thiazide-treated individual with NDI typically increases, even in the absence of ADH. This contributes to the decrease in urine volume. As an example, in a patient with a normal solute excretion rate of 900 mOsm per kg per day and a maximum U_{Osm} of 150 mOsm per kg due to NDI, a urine output of at least 6 L per day is expected (900 ÷ 150). In contrast, if a thiazide diuretic limits the minimum U_{Osm} to 300 mOsm per day, daily urine output decreases to approximately 3 L each day (900 ÷ 300).

The efficacy of amiloride in patients with reversible lithium nephrotoxicity is directly related to its site and mechanism of action. This drug closes the sodium channels in the luminal membrane of the collecting tubule cells. These channels constitute the mechanism by which filtered lithium normally enters these cells and then interferes with their response to ADH. In contrast to amiloride, thiazide diuretics should be used cautiously, if at all, in patients with lithium-induced NDI *who are still taking lithium* because volume depletion can lead to increased proximal lithium reabsorption and potentially toxic plasma lithium levels.

Nonsteroidal anti-inflammatory drugs (NSAIDs) cause inhibition of renal prostaglandin synthesis. This has the effect of increasing concentrating ability because prostaglandins normally antagonize the urinary concentrating action of ADH. If, for example, healthy subjects are given a submaximal dose of ADH, the ensuing rise in U_{Osm} can be increased by more than 200 mOsm per kg if the patient has been pretreated with an NSAID. The result in patients with NDI may be a 25% to 50% reduction in urine output, a response that is partially additive to that of a thiazide diuretic. Not all NSAIDs are equally effective in a given patient. For example, some patients may have a good response to indomethacin but derive little, if any, benefit from ibuprofen. How this applies to cyclooxygenase-2 inhibitors remains to be determined. However, case reports have shown that cyclooxygenase-2 inhibitors can exacerbate CHF and have been associated with fluid overload, in a manner similar to that of traditional nonselective NSAIDS [50].

Dietary modification via the use of a low-sodium, low-protein diet can diminish the urine output in patients with NDI. The resultant decrease in net solute excretion (as sodium salts and urea) at any given U_{Osm} reduces the urine output.

Most patients with NDI have partial, rather than complete, resistance to ADH. It is therefore possible that administering exogenous ADH in doses sufficient to achieve supraphysiologic hormone levels can increase the renal effect of ADH. Although one case report of a patient with lithium-induced NDI suggested that this benefit is more likely to be achieved if DDAVP is combined with an NSAID, this has not been our experience, particularly in patients with more severe NDI.

DISORDERS OF PLASMA POTASSIUM

Potassium is the major intracellular cation. Only approximately 2% of body potassium is located in the extracellular space, where the concentration (3.5 to 5.0 mEq per L) is much lower than inside cells (125 to 140 mEq per L). This concentration difference is preserved by the Na^+/K^+–ATPase pump that actively transports sodium out of, and potassium into, most cells. Because such a small proportion of K^+ is extracellular, even a slight change in plasma potassium concentration can engender dramatic effects on myoneural cell physiology.

Normal Potassium Homeostasis

Daily potassium intake in the United States varies between 40 and 120 mEq. Most of this (approximately 90%) is eliminated by the kidney; the rest is excreted in stool. In chronic kidney disease, gastrointestinal potassium excretion increases, a process that depends, in part, on aldosterone.

Only approximately 50% of potassium ingested in the diet or administered parenterally appears in the urine during the first 4 hours. Consequently, more than half of an acute potassium load must be rapidly translocated into cells if life-threatening hyperkalemia to be averted.

Transcellular Potassium Shifts

The most important factors involved in transporting K^+ intracellularly are insulin and β-adrenergic stimulation. Insulin stimulates the Na^+/K^+–ATPase pump present in most cell membranes, accelerating the transfer process.

Activation of β-adrenergic receptors (specifically the β_2-receptor) also stimulates K^+ movement from the plasma into cells. The pathophysiology is due in part to direct stimulation of the Na^+/K^+–ATPase pump. The observation that the hypokalemic effect of terbutaline (a β-adrenergic agonist) can be blunted by somatostatin suggests that insulin may have a mediatory role in the hypokalemic response to β-adrenergic stimulation.

Aldosterone is the principal hormone stimulating K^+ secretion by the renal tubule (see following discussion). This effect is important in all epithelial cell surfaces, although its contribution to translocation of K^+ into nonepithelial cells is more controversial [51].

Renal Regulation of Potassium Excretion

Potassium is freely filtered at the glomerulus so that the concentration of K^+ entering the early proximal tubule is approximately 4 mEq per L. Ninety percent of the filtered potassium load has been reabsorbed by the time the glomerular filtrate reaches the distal tubule. Most renal K^+ excretion normally occurs as a result of secretion by the distal nephron. Potassium secretion occurs in the principal cells of the cortical collecting tubule (Fig. 72.4). Movement of potassium from the tubular cell into the lumen is controlled by the existing state of potassium balance, the rate of sodium reabsorption (a process driven by aldosterone) that generates a lumen-negative electrical gradient down which K^+ can move, and the rate of distal urine flow that maintains a high tubular cell–to–lumen potassium gradient by washing away secreted K^+.

Aldosterone enters the principal cell from the basolateral (antiluminal) side. Once inside, it binds to receptors, which increase the number of open luminal sodium channels and increase the number and activity of the Na^+/K^+–ATPase pumps

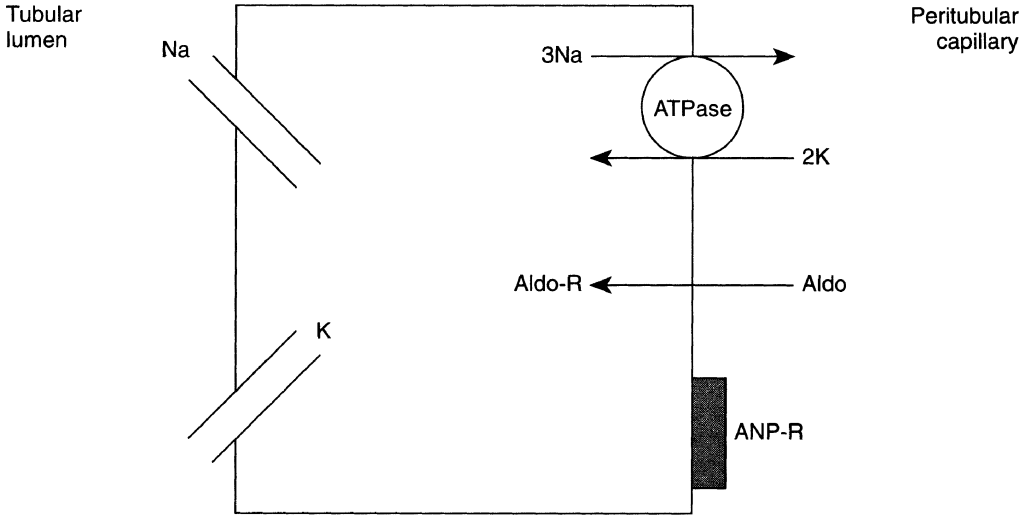

FIGURE 72.4. Schematic representation of sodium and potassium transport mechanisms in the sodium-reabsorbing cells in the collecting tubules. The entry of filtered sodium into the cells is mediated by selective sodium channels in the apical (luminal) membrane; the energy for this process is provided by the favorable electrochemical gradient for sodium (cell interior electronegative and low cell sodium concentration). Reabsorbed sodium is pumped out of the cell by the Na^+/K^+–adenosine triphosphatase (ATPase) pump in the basolateral (peritubular) membrane. The reabsorption of cationic sodium makes the lumen electronegative, thereby creating a favorable gradient for the secretion of potassium into the lumen via potassium channels in the apical membrane. Aldosterone (Aldo), after combining with the cytosolic mineralocorticoid receptor (Aldo-R), leads to enhanced sodium reabsorption and potassium secretion in the cortical collecting tubule by increasing both the number of open sodium channels and the number of Na^+/K^+–ATPase pumps. Atrial natriuretic peptide (ANP), on the contrary, acts primarily in the inner medullary collecting duct by combining with its basolateral membrane receptor (ANP-R) and activating guanylate cyclase. ANP inhibits sodium reabsorption by closing the sodium channels. The potassium-sparing diuretics amiloride and triamterene act by closing the sodium channels directly, and spironolactone acts by competing with aldosterone for binding to the mineralocorticoid receptor.

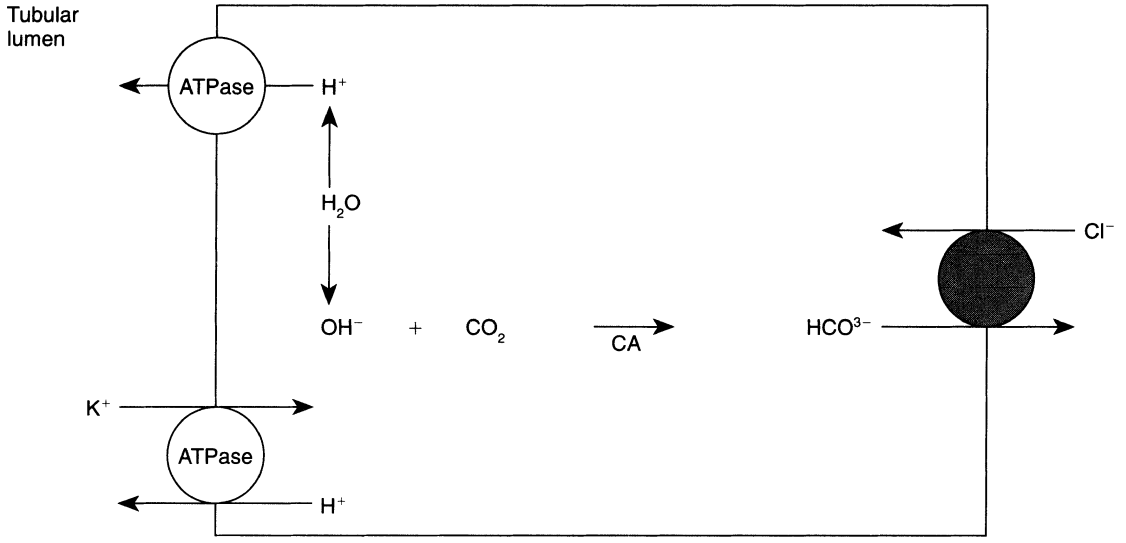

FIGURE 72.5. Transport mechanisms involved in hydrogen secretion and bicarbonate and potassium reabsorption in type-A intercalated cells in the cortical collecting tubule and in the outer medullary collecting tubule cells. Water (H_2O) within the cell dissociates into hydrogen and hydroxyl anions. The former are secreted into the lumen by H–adenosine triphosphatase (ATPase) pumps in the luminal membrane; chloride may be cosecreted with hydrogen to maintain electroneutrality. The hydroxyl anions in the cell combine with carbon dioxide to form bicarbonate in a reaction catalyzed by carbonic anhydrase (CA). Bicarbonate is then returned to the systemic circulation via chloride–bicarbonate exchangers in the basolateral membrane. The favorable inward concentration gradient for chloride (plasma and interstitial concentration greater than that in the cell) provides the energy for bicarbonate reabsorption. H-K–ATPase pumps, which lead to both hydrogen secretion and potassium reabsorption, may also be present in the luminal membrane. The number of these pumps increases with potassium depletion, suggesting that their main function is to promote potassium conservation.

in the basolateral membrane. The ensuing increase in cell potassium favors the secretion of K^+ into the lumen, down the electrochemical gradient provided by Na^+ reabsorption.

In states of potassium depletion, potassium secretion in the cortical collecting tubule is reduced, and potassium reabsorption stimulated. Reabsorption takes place in the intercalated (acid-secreting) cells of this nephron segment (Fig. 72.5).

Hypokalemia

Potassium entering the body is largely stored in the cells and then excreted in the urine. Thus, a reduction in the plasma potassium concentration can result from decreased intake, increased cellular uptake, or increased losses. These losses, which are the most common contributors to hypokalemia, can occur via the urine, the gastrointestinal tract, or, less commonly, through the skin (Table 72.5).

Causes of Hypokalemia

Decreased Potassium Intake. Because the kidney can lower potassium excretion to less than 25 mEq per day in response to potassium depletion [52], decreased intake alone rarely causes hypokalemia, but it can enhance the severity of other causes of potassium depletion such as diuretic therapy.

Increased Entry Into Cells. The markedly inequitable distribution of potassium between the cells and the extracellular fluid is maintained by the Na^+/K^+–ATPase pump in the cell membrane. Occasionally, increased potassium entry into cells may result in transient hypokalemia. Barium sulfide, used in pesticides, radiologic imaging, and depilatory agents, has been reported to cause severe transient hypokalemia when ingested [53].

Elevation in Extracellular pH. The transcellular hydrogen-ion shifts accompanying metabolic and respiratory alkalosis obligate increased sequestration of potassium in cells. In general, this direct effect is relatively small because the plasma potassium concentration falls to less than 0.4 mEq per L for every 0.1-unit rise in pH [54]. This phenomenon provides the

TABLE 72.5

MAJOR CAUSES OF HYPOKALEMIA

Decreased potassium intake
Increased entry into cells
Elevation in extracellular pH
Increased availability of insulin
Elevated β-adrenergic activity
Hypokalemic periodic paralysis
Marked increase in blood cell production
Increased gastrointestinal losses
Increased urinary losses
Diuretics
Primary mineralocorticoid excess
Loss of gastric secretions
Nonreabsorbable anions
Renal tubular acidosis
Hypomagnesemia
Amphotericin B
Aminoglycosides
Salt-wasting nephropathies, including Bartter's syndrome
Polyuria
Increased sweat losses
Dialysis

rationale for the administration of sodium bicarbonate to treat the hyperkalemia of metabolic acidosis.

Despite the fact that the direct effect of alkalemia is relatively small, hypokalemia is common in metabolic alkalosis. The major reason for this association is that the underlying cause (diuretics, vomiting, or hyperaldosteronism) leads to losses of both hydrogen and potassium ions (see following discussion).

Increased Availability of Insulin. Insulin promotes the entry of potassium into skeletal muscle and hepatic cells by increasing the activity of the Na^+/K^+–ATPase pump in the cell membrane. This effect is most prominent after the administration of insulin to patients with diabetic ketoacidosis or severe nonketotic hyperglycemia.

The plasma potassium concentration can also be reduced in nondiabetic patients by a carbohydrate load. Thus, intravenous administration of potassium chloride in a dextrose-containing solution in an effort to correct hypokalemia can transiently further reduce the plasma potassium concentration and, possibly, lead to cardiac arrhythmias [55].

Elevated β-Adrenergic Activity. Catecholamines, acting via β_2-adrenergic receptors, promote potassium entry into the cells by increasing Na^+/K^+–ATPase activity. As a result, transient hypokalemia can occur with stress-induced release of epinephrine, as in acute illness, coronary ischemia, theophylline intoxication, or alcohol withdrawal. A similar effect, in which the plasma potassium concentration can fall acutely by more than 0.5 to 1.0 mEq per L, can be achieved by the administration of a β-adrenergic agonist (such as albuterol, terbutaline, or epinephrine) [56]. This effect must be considered when diuretic therapy is used for the treatment of hypertension in patients receiving β-agonists for asthma or chronic lung disease. The hypokalemic response to epinephrine can be blocked by a nonselective beta-blocker (such as propranolol), but a β_1-selective agent (such as atenolol) offers no protection, at least at lower doses (<100 mg per day).

Hypokalemic Periodic Paralysis. Hypokalemic periodic paralysis is a rare disorder of uncertain cause characterized by potentially fatal episodes of muscle weakness or paralysis that can affect the respiratory muscles. Acute attacks—in which the sudden movement of potassium into the cells can lower the plasma potassium concentration to as low as 1.5 to 2.5 mEq per L—are often precipitated by rest after exercise, stress, or a carbohydrate meal, events that are often associated with increased release of epinephrine or insulin.

Hypokalemic periodic paralysis may be familial with autosomal dominant inheritance, or it may be acquired in patients (often, but not exclusively, Asian men) with thyrotoxicosis [57]. Recent studies indicate that the abnormal gene in patients with the inherited form of this disorder appears to code for part of the dihydropyridine calcium channel in skeletal muscle [58]. How this predisposes to hypokalemia is unclear. A recent article reported location of the gene to a locus on chromosome one [59].

Oral administration of 60 to 120 mEq of potassium chloride usually aborts acute attacks within 15 to 20 minutes. Another 60 mEq can be given if no improvement is noted. The presence of hypokalemia must be confirmed before therapy because potassium can worsen episodes caused by the normokalemic or hyperkalemic forms of periodic paralysis. Furthermore, excess potassium administration during an acute episode may lead to posttreatment hyperkalemia as potassium moves back out of the cells.

Marked Increase in Blood Cell Production. An acute increase in hematopoietic cell production is associated with potassium uptake by the new cells and possible hypokalemia. This most often occurs after the administration of vitamin B_{12} or folic acid to treat a megaloblastic anemia or of granulocyte-macrophage colony-stimulating factor to treat neutropenia.

Metabolically active blood cells may continue to absorb potassium after blood has been drawn. This phenomenon has been described in patients with acute myeloid leukemia and a high white blood cell count. In these patients, the measured plasma potassium concentration may be less than 1 mEq per L (without symptoms) if the blood is allowed to stand at room temperature for a prolonged period before separation of the plasma from the cells.

Hypothermia. Accidental or induced hypothermia (as occurs during cardiac bypass) can accelerate potassium movement into the cells and lower the plasma potassium concentration to less than 3.0 mEq per L. In contrast, hyperkalemia in an individual with severe hypothermia usually signifies irreversible tissue necrosis (including rhabdomyolysis) and is associated with a high mortality rate [60].

Acute Chloroquine Intoxication. Hypokalemia is a complication of severe chloroquine overdose [61].

Increased Gastrointestinal Losses. Loss of gastric or intestinal secretions from any cause (vomiting, diarrhea, laxatives, or tube drainage) is associated with potassium wasting and, possibly, hypokalemia. However, it should be emphasized that the concentration of potassium in gastric secretions is relatively low (5 to 10 mEq per L) and that the potassium depletion is primarily due to increased urinary losses [62]. The metabolic alkalosis that results from loss of gastric secretions raises the plasma bicarbonate concentration and, therefore, the filtered bicarbonate load above its proximal tubular reabsorptive threshold. More sodium bicarbonate and water are thus delivered to the distal potassium secretory site in the presence of hypovolemia-induced aldosterone release. Secreted potassium combines with the negatively charged bicarbonate and is excreted in the final urine, leading to hypokalemia.

The urinary potassium wasting seen with loss of gastric secretions is typically most prominent in the first few days; thereafter, proximal bicarbonate reabsorptive capacity increases, leading to a marked reduction in urinary sodium, bicarbonate, and potassium excretion. At this time, the urine pH falls from more than 7.0 to less than 5.5.

Increased Urinary Losses. Urinary potassium excretion is mostly derived from potassium secretion in the distal nephron, particularly by the principal cells in the cortical collecting tubule. This process is primarily influenced by two factors: aldosterone and the distal delivery of sodium and water. Urinary potassium wasting generally requires increases in aldosterone or in distal flow. Aldosterone acts partly by stimulating sodium reabsorption. The removal of cationic sodium makes the lumen relatively electronegative, thereby promoting passive potassium secretion from the tubular cell into the lumen through specific potassium channels in the luminal membrane.

Diuretics. Any diuretic that acts proximal to the potassium secretory site, including carbonic anhydrase inhibitors and loop and thiazide diuretics, increases distal delivery and, via the induction of volume depletion, activates the renin–angiotensin–aldosterone system. As a result, urinary potassium excretion increases, potentially leading to hypokalemia.

Primary Mineralocorticoid Excess. Urinary potassium wasting is characteristic of any condition associated with primary hypersecretion of a mineralocorticoid, as occurs with an aldosterone-producing adrenal adenoma. Affected patients are usually hypertensive, and the differential diagnosis includes diuretic therapy (which may be surreptitious) in a patient with underlying hypertension and renovascular disease, in which increased secretion of renin leads to enhanced aldosterone release. By comparison, plasma renin activity is suppressed in primary states of mineralocorticoid excess.

Nonreabsorbable Anions. The presence of nonreabsorbable anions in the filtrate draws increased amounts of sodium to the distal nephron where it is reabsorbed at the expense of potassium. Examples of nonreabsorbable anions include bicarbonate in vomiting-induced metabolic alkalosis, β-hydroxybutyrate in diabetic ketoacidosis, hippurate in toluene exposure (glue sniffing) [63], and penicillin in patients receiving high-dose penicillin therapy. The effect of nonreabsorbable anions is augmented when there is concurrent volume depletion. Both the resulting decrease in distal chloride delivery (limiting the ability of chloride reabsorption to dissipate the lumen-negative gradient) and the enhanced secretion of aldosterone promote potassium secretion [64].

Metabolic Acidosis. Increased urinary potassium losses can occur in several forms of metabolic acidosis by mechanisms similar to those already described. In diabetic ketoacidosis, for example, increased distal sodium and water delivery (due to the glucose-induced osmotic diuresis), hypovolemia-induced hyperaldosteronism, and β-hydroxybutyrate acting as a nonreabsorbable anion all can contribute to potassium wasting. Potassium wasting can also occur in both type-1 (distal) and type-2 (proximal) renal tubular acidosis (RTA) (see Chapter 73).

Hypomagnesemia. Hypomagnesemia is present in up to 40% of patients with hypokalemia [65]. In many cases, as with diuretic therapy, vomiting, or diarrhea, there are concurrent potassium and magnesium losses. Hypomagnesemia of any cause can lead to increased urinary potassium losses. Speculation surrounds the mechanism by which hypomagnesemia promotes kaliuresis; a direct effect of magnesium on tubular potassium transport is likely [66]. Moreover, in the cells of the thick ascending limb of Henle's loop, magnesium acts as a calcium channel blocker, limiting K losses from the cell into the tubule lumen. Magnesium deficiency enhances K losses from these cells. Documenting the presence of hypomagnesemia is particularly important because the hypokalemia often cannot be corrected until the magnesium deficit is repaired [65].

Salt-Wasting Nephropathies. Occasionally, renal diseases associated with decreased proximal, loop, or distal sodium reabsorption can lead to hypokalemia via a mechanism similar to that induced by diuretics. This problem may arise in patients with Bartter's or Gitelman's syndromes, tubulointerstitial diseases, such as interstitial nephritis due to Sjögren's syndrome or lupus, hypercalcemia, and tubular injury that may be induced by lysozyme in patients with acute monocytic or myelomonocytic leukemia [67]. Increased potassium uptake by the leukemic cells may also contribute to the fall in the plasma potassium concentration.

Polyuria. In the presence of potassium depletion, healthy subjects can lower their urinary potassium concentration to 5 to 10 mEq per L. If, however, the urine output is greater than 5 to 10 L per day, obligatory potassium losses can exceed to 50 to 100 mEq in this period. This problem is most likely to occur in primary polydipsia, in which the urine output may be elevated during a prolonged period [68]. An equivalent degree of polyuria can also occur in CDI, but patients with this disorder typically seek medical care soon after the polyuria has begun.

Transcutaneous Losses. Daily potassium loss through the skin is normally negligible because the volume of perspiration is low and the potassium concentration is only 5 to 10 mEq per L. However, subjects exercising in a hot climate can produce 10 L or more of sweat per day, leading to potassium depletion if these losses are not replaced. Urinary potassium excretion also may contribute because aldosterone release is enhanced by both exercise (via catecholamine-induced renin secretion) and volume loss.

Extensive burns are another situation in which potassium losses through the skin may cause hypokalemia. Although the concentration of potassium in sweat is low, the potassium concentration of fluid lost through the skin after burns may greatly exceed the plasma level because of local tissue breakdown, which leads to the release of potassium from cells.

Dialysis. Although patients with end-stage renal disease typically retain potassium and tend to be mildly hyperkalemic, hypokalemia can be induced in some patients by maintenance dialysis. This is more likely to occur in patients on chronic peritoneal dialysis, in whom dialysis is performed every day. By comparison, hemodialysis treatments are typically administered only three times per week. Nevertheless, transient hypokalemia often follows a hemodialysis treatment.

Clinical Manifestations

Most individuals with mild hypokalemia exhibit no symptoms referable to the low plasma K^+ concentration. The major disturbances seen with more severe K^+ deficiency are changes in cardiovascular, neuromuscular, and renal function. Cardiac toxicity may be manifested by serious arrhythmias due to hyperpolarization of the myocardial cell membrane, leading to a prolonged refractory period and increased susceptibility to reentrant arrhythmias. Earlier electrocardiographic changes of hypokalemia include T-wave depression with prominent U waves (Fig. 72.6).

Hyperpolarization also slows down nerve conduction and muscle contractions, which may contribute to symptoms such as muscle weakness, cramps, and paresthesias, although these are usually not observed until the plasma K^+ concentration is less than 2.5 mEq per L. Severe hypokalemia may promote rhabdomyolysis. Profound hypokalemia can also impair respiratory muscle function, leading to hypoventilation.

Polyuria due to stimulation of thirst and resistance to the action of ADH are the primary renal manifestations of hypokalemia. Increased thirst results from direct stimulation of the hypothalamic thirst center as well as from an appropriate response to polyuria. The mechanism of resistance to ADH appears to be due to reduced expression of the water channel (aquaporin-2) that fuses with the luminal membrane under the influence of ADH [69]. With potassium depletion, the fall in

FIGURE 72.6. Both hypokalemia and hyperkalemia can cause changes in the patient's electrocardiogram. The electrocardiogram from a patient with moderate hypokalemia shows prominent U waves.

concentrating ability may occur before hypokalemia is present [70].

Diagnosis

The cause of hypokalemia can usually be determined from the history. In some cases, the diagnosis is not readily apparent. The surreptitious vomiting of bulimia or the diarrhea of laxative abuse may not be omitted from the patient's history. Measurement of blood pressure and urinary potassium excretion and assessment of acid–base balance are often helpful in such cases.

Urinary Response. In the presence of potassium depletion, a healthy subject should lower urinary potassium excretion to less than 30 mEq per day; values above this level reflect at least a contribution from urinary potassium wasting. Random measurement of the urine potassium concentration can be used but is less accurate than a 24-hour collection. Extrarenal losses probably are present if the urine potassium concentration is less than 15 mEq per L unless the patient is markedly polyuric. Higher values do not necessarily indicate potassium wasting if the urine volume is reduced. The response to potassium depletion is twofold: decreased potassium secretion by the collecting tubule principal cells and increased active potassium reabsorption by H/K–ATPase pumps in the luminal membrane of the adjacent type-A intercalated cells (Fig. 72.5) [71,72]. These pumps, which are activated by hypokalemia, reabsorb potassium and secrete hydrogen.

Once urinary potassium excretion is measured, the following diagnostic possibilities should be considered in the patient with hypokalemia of uncertain origin:

- Metabolic acidosis with a low rate of renal potassium excretion is suggestive of lower gastrointestinal losses due to diarrhea, laxative abuse, or a villous adenoma.
- Metabolic acidosis with renal potassium wasting is most often caused by diabetic ketoacidosis or by type-1 (distal) or type-2 (proximal) RTA. A salt-wasting nephropathy can produce similar findings, with the associated renal insufficiency responsible for the acidemia.
- Metabolic alkalosis with a low rate of urinary potassium excretion may be due to surreptitious vomiting or diuretic use if the urinary collection is obtained several days after the vomiting or diuretic use has been halted.
- Metabolic alkalosis with renal potassium wasting and a normal blood pressure most often results from ongoing vomiting, diuretic use, or, far less commonly, from Bartter's or Gitelman's syndromes. A low urine chloride concentration helps to distinguish the hypokalemia of vomiting from that of diuretics or Bartter's and Gitelman's syndromes.
- Metabolic alkalosis with potassium wasting and hypertension suggests surreptitious diuretic therapy in patients with underlying hypertension, renovascular disease, or one of the causes of primary mineralocorticoid excess.

The possible presence of primary mineralocorticoid excess (with aldosterone and, to a lesser degree, deoxycorticosterone being the major endogenous mineralocorticoids) should be suspected in any patient with hypertension and unexplained hypokalemia and metabolic alkalosis.

The ingestion of licorice can produce a similar clinical and metabolic picture. The active compound in licorice, glycyrrhizic acid, inhibits renal 11β-hydroxysteroid dehydrogenase activity. This enzyme normally inactivates cortisol. The result is cortisol-induced stimulation of the mineralocorticoid receptor, leading to renal sodium retention and potassium loss.

The other major cause of hypertension and hypokalemia is renovascular disease, in which the hypersecretion of renin leads sequentially to increased secretion of angiotensin II and then aldosterone. It is important to be aware that hypokalemia is characteristic of malignant hypertension, which is a high-renin, high-aldosterone state, regardless of the underlying cause.

Treatment

Although hypokalemia can be transiently induced by the entry of potassium into the cells, most cases are caused by unreplaced gastrointestinal or urinary losses. Optimal therapy depends on the severity of the potassium deficit; somewhat different considerations are required to minimize continued urinary losses due to diuretic therapy or, less often, to one of the causes of primary hyperaldosteronism.

Potassium Deficit. The total potassium deficit can only be approximated because there is no strict correlation between the plasma potassium concentration and total body potassium stores. In general, the loss of 200 to 400 mEq of potassium is required to lower the plasma potassium concentration from 4 to 3 mEq per L; the loss of an additional 200 to 400 mEq lowers the plasma potassium concentration to approximately 2 mEq per L [73]. Continued potassium losses do not as readily worsen the degree of hypokalemia because of the release of potassium from the intracellular pool.

These estimates assume a normal distribution of potassium between the cells and the extracellular fluid. The most common setting in which this does not apply is diabetic ketoacidosis, a disorder in which hyperosmolality and insulin deficiency favor the movement of potassium out of the cells. As a result, patients with this disorder may have a normal or even elevated plasma potassium concentration at presentation, despite having incurred a marked potassium deficit due to urinary or gastrointestinal losses, or both. Potassium supplementation for these patients should begin once the plasma potassium concentration is 4.5 mEq per L or less, provided that the patient is producing urine, because the administration of insulin and fluids may cause a precipitous drop in the plasma potassium concentration.

Potassium Preparations. Intravenous or oral potassium chloride generally is the preferred treatment for hypokalemia. Use of the chloride salt has two important advantages. First, potassium chloride more rapidly raises the plasma potassium concentration than does potassium bicarbonate or potassium citrate, the citrate being rapidly metabolized to bicarbonate. Bicarbonate enters cells more readily than does chloride. The retention of chloride in the extracellular fluid, obligated by the need to maintain electroneutrality, limits the initial entry of potassium into the cells, thereby maximizing the rise in the plasma potassium concentration. Second, most patients with hypokalemia also have metabolic alkalosis. For example, with diuretic therapy, vomiting, and hyperaldosteronism, hydrogen loss accompanies that of potassium. Potassium must be given with chloride to such patients if both the hypokalemia and the alkalosis are to be corrected optimally (see Chapter 71). In comparison, potassium bicarbonate or potassium citrate can be given to patients with hypokalemia and metabolic acidosis, such as occurs in RTA and chronic diarrheal states.

Oral potassium chloride can be given in crystalline form (salt substitutes), as a liquid, or in a slow-release tablet or capsule. Salt substitutes contain 50 to 65 mEq per level teaspoon; they may be the ideal form of oral therapy, as they are safe, well tolerated, and much cheaper than the other preparations. Potassium chloride solutions, on the other hand, are often unpalatable, and the slow-release preparations can, in rare cases, cause ulcerative or stenotic lesions in the gastrointestinal tract as a result of the local accumulation of high concentrations of potassium.

Merely increasing the intake of potassium-rich foods such as oranges and bananas is generally less effective in the absence of

renal insufficiency. These foods contain phosphate and citrate rather than chloride and are, therefore, less likely to correct the hypokalemia and metabolic alkalosis.

Potassium chloride can be given intravenously to patients who are unable to eat or who have severe hypokalemia (see following discussion). It is usually added to a solution in which the concentration should generally not exceed 40 mEq of potassium per liter because higher concentrations can lead to pain and sclerosis of a peripheral vein. A saline solution is preferred to a dextrose solution for initial therapy because the administration of dextrose can lead to a transient 0.2 to 1.4 mEq per L reduction in the plasma potassium concentration because of glucose-induced insulin release [55].

Mild-to-Moderate Potassium Depletion. The majority of patients have a plasma potassium concentration between 3.0 and 3.5 mEq per L; this degree of potassium depletion usually produces no symptoms, except in patients with advanced liver disease or in patients with heart disease, particularly if they are taking digoxin. Treatment in this setting is directed toward replacing the lost potassium, usually beginning with 40 to 80 mEq of potassium chloride per day, and toward treating the disorder responsible for the loss of potassium.

Potassium replacement alone may be insufficient to treat patients with ongoing urinary losses due to chronic diuretic therapy, tubular dysfunction, or primary hyperaldosteronism. Potassium-sparing diuretics such as amiloride, triamterene, the aldosterone antagonists, spironolactone, and eplerenone are generally more effective than other agents, as they limit further urinary losses of both potassium and magnesium. It is frequently underappreciated, however, that, in the presence of high levels of aldosterone, greater than usual doses (up to 20 to 40 mg of amiloride and 150 to 300 mg of spironolactone) may be required to block potassium secretion. The combination of a potassium-sparing diuretic with potassium supplements should be used only with careful monitoring to prevent possible overcorrection with development of hyperkalemia and should be avoided in most patients with renal insufficiency.

Severe Hypokalemia. Potassium repletion is more urgent for patients with profound or symptomatic hypokalemia (i.e., arrhythmias, marked muscle weakness). This is most easily done orally. The plasma potassium concentration transiently rises by as much as 1.0 to 1.5 mEq per L after 40 to 60 mEq and by 2.5 to 3.5 mEq per L after 135 to 160 mEq and falls, as most of the exogenous potassium is taken up by the cells. In light of these fluxes, careful monitoring is required, and more potassium should be given as necessary. A patient with a plasma potassium concentration of 2.0 mEq per L, for example, *may* have a 400 to 800 mEq potassium deficit.

Some patients with severe hypokalemia must be treated intravenously because of medical instability or an inability to take medication orally. There are two potential limitations to intravenous therapy: A *maximum* concentration of 50 to 60 mEq per L can be administered via a peripheral vein without irritation, and, because saline solutions are preferable, volume overload is a potential risk in susceptible subjects.

The necessity for aggressive intravenous therapy occurs primarily in patients with diabetic ketoacidosis or nonketotic hyperglycemia with hypokalemia due to marked urinary potassium losses. As described previously, treatment with insulin and fluids exacerbates the hypokalemia. Because these patients are also quite volume depleted, the addition of 40 to 60 mEq of potassium chloride to each liter of half-isotonic saline can supply large quantities of potassium with less risk of pulmonary congestion.

In general, the maximum rate of intravenous potassium administration is 10 to 20 mEq per hour, although as much as 40 to 100 mEq per hour has been given to selected patients with paralysis or life-threatening arrhythmias [74]. In these cases, solutions containing as much as 200 mEq of potassium per L (20 mEq in 100 mL of isotonic saline) have been used. They should be infused into a large vein, such as the femoral vein; a central venous line has also been used, but a local increase in the potassium concentration could have a deleterious effect on cardiac conduction.

It must be emphasized that rapid intravenous administration of potassium is potentially dangerous, even in potassium-depleted patients. Thus, careful monitoring of the physiologic effects of hypokalemia (electrocardiogram [ECG] abnormalities, muscle weakness, or paralysis) is essential. Once these problems are no longer severe, the rate of potassium repletion should be slowed down to 10 to 20 mEq per hour, even though there may be persistent hypokalemia.

Hyperkalemia

Hyperkalemia is a relatively common laboratory abnormality in critically ill patients, particularly in those with oliguric acute or chronic kidney disease.

Etiology

Hyperkalemia is rare in healthy subjects because the transcellular and renal disposal adaptations prevent significant potassium accumulation in the extracellular fluid. Furthermore, the efficiency of potassium handling is increased if potassium intake is slowly enhanced, thereby allowing what might otherwise be a fatal potassium load to be tolerated. This phenomenon, called *potassium adaptation*, is mostly due to more rapid potassium excretion in the urine.

Therefore, increasing potassium intake is not commonly a cause of hyperkalemia, unless the patient has an impaired capacity for potassium excretion or the potassium loading occurs too rapidly for such adaptation to occur. As examples, acute hyperkalemia can be induced (primarily in infants because of their small size) by the administration of intravenous potassium penicillin as an intravenous bolus or by the ingestion of a potassium-containing salt substitute.

The net release of potassium from the cells, either due to enhanced release or decreased entry, can also cause hyperkalemia. As with exogenous potassium loading, the elevation is typically transient because the excess potassium is excreted in the urine. Because persistent hyperkalemia requires impairment in urinary potassium excretion, it may be inferred that this problem is generally associated with a reduction in either aldosterone effect or in the delivery of sodium and water to the distal secretory site. The causes of hyperkalemia are listed in Table 72.6.

Increased Potassium Release from Cells

Pseudohyperkalemia. *Pseudohyperkalemia* refers to conditions in which the elevation in the measured plasma potassium concentration is due to potassium movement out of the cells during or after the blood specimen has been drawn. The major cause of this problem is mechanical trauma during venipuncture, resulting in hemolysis. Because this is an in vitro phenomenon, the patient demonstrates no clinical signs and symptoms of hyperkalemia (see following discussion).

Potassium also moves out of white cells and platelets after clotting has occurred. Thus, the serum potassium concentration normally exceeds the true value in the plasma by as much as 0.5 mEq per L. This difference in normal levels is not clinically important. In contrast, a patient with marked leukocytosis or thrombocytosis (white cell or platelet count >100,000 per μL or 1,000,000 per μL, respectively) may have a measured serum potassium concentration as high as 9 mEq per L. This phenomenon is most often observed in patients with

TABLE 72.6

MAJOR CAUSES OF HYPERKALEMIA

- Increased potassium release from cells
  - Pseudohyperkalemia
  - Metabolic acidosis
  - Insulin deficiency
  - Hyperglycemia and hyperosmolal states
  - Increased tissue catabolism
  - β-Adrenergic blockade
  - Exercise
  - Other
    - Digitalis overdose
    - Hyperkalemic periodic paralysis
    - Succinylcholine
    - Arginine hydrochloride
- Reduced urinary potassium excretion
  - Hypoaldosteronism
  - Renal disease
  - Reduced effective circulatory volume
  - Selective impairment of potassium excretion
  - Medications
    - Dapsone
    - Trimethoprim
    - Nonsteroidal anti-inflammatory drugs
    - Angiotensin-converting enzyme inhibitors
    - Angiotensin receptor blockers
    - Heparin
    - Potassium-sparing diuretics

myeloproliferative diseases. With essential thrombocytosis, for example, the measured serum potassium concentration rises by approximately 0.15 mEq per L for every 100,000 per μL elevation in the platelet count.

Pseudohyperkalemia should be suspected whenever there is no apparent cause for an elevated plasma potassium concentration in an asymptomatic patient and particularly in patients with persistent hyperkalemia despite normal renal function. Comparing the serum potassium concentration with that in plasma (collected using a heparinized specimen tube) often establishes the diagnosis. Comparing the serum potassium levels drawn with and without a tourniquet also may be useful diagnostically if a significant difference is observed.

Metabolic Acidosis. The buffering of excess hydrogen ions in the cells can lead to potassium movement into the extracellular fluid; this transcellular shift is necessitated, in part, by the need to maintain electroneutrality. This phenomenon is less likely to occur in the organic acidoses, ketoacidosis, and lactic acidosis. Although the potassium level may be elevated in both of these conditions, hyperkalemia appears to result from insulin deficiency and tissue breakdown, with potassium leakage from cells rather than from the acidosis itself.

Insulin Deficiency, Hyperglycemia, and Hyperosmolality. Insulin promotes potassium entry into cells; thus, the ingestion of glucose (which stimulates endogenous insulin secretion) minimizes the rise in the plasma potassium concentration induced by concurrent potassium intake. On the contrary, in patients with uncontrolled diabetes mellitus, the combination of insulin deficiency and the hyperosmolality induced by hyperglycemia frequently leads to hyperkalemia, even though a patient may be markedly potassium depleted from previously incurred urinary potassium losses.

An elevation in P_{Osm} results in osmotic water movement from cells into the extracellular fluid. This is accompanied by potassium movement out of the cells. A similar rise in plasma potassium can occur with any solute that increases the effective P_{Osm}, such as mannitol, particularly in patients with renal failure [75].

Somatostatin, by inhibiting insulin release, can raise the plasma potassium concentration by an average of 0.6 mEq per L in healthy subjects but by more than 1.5 mEq per L to potentially dangerous levels in selected patients with end-stage renal disease [76].

Increased Tissue Breakdown. Any cause of increased tissue breakdown can result in the release of potassium into the extracellular fluid. Hyperkalemia is particularly likely to develop in this setting if renal impairment is also present. Clinical examples include breakdown of a large hematoma, as might occur in the wake of a gastrointestinal hemorrhage; rhabdomyolysis from any cause; cell breakdown in patients receiving cytotoxic or radiation therapy for lymphoma or leukemia (the tumor-lysis syndrome); and in patients with severe hypothermia. Although hypothermia characteristically results in a fall in plasma potassium concentration, hyperkalemia occurs when the insult has been sufficient to cause tissue breakdown, and it carries an extremely high mortality rate [60].

β-Adrenergic Blockade. β-Adrenergic blockers interfere with the β_2-adrenergic facilitation of potassium uptake by the cells (Fig. 72.4). This effect is associated with only a minor elevation in the plasma potassium concentration in healthy subjects (<0.5 mEq per L) because the excess potassium can be easily excreted in the urine. True hyperkalemia is rare, except in conjunction with an additional defect in potassium handling, such as a large potassium load, marked exercise, hypoaldosteronism, or renal failure [77].

Exercise. Potassium is normally released from muscle cells during exercise. The release of potassium may have a physiologic function, because the local increase in the plasma potassium concentration has a vasodilatory effect, increasing blood flow and energy delivery to the exercising muscle [78].

The increment in the systemic plasma potassium concentration is less pronounced and is related to the degree of exercise: 0.3 to 0.4 mEq per L with slow walking; 0.7 to 1.2 mEq per L with moderate exertion (including prolonged aerobic exercise with marathon running); and as much as 2.0 mEq per L after exercise to exhaustion [79].

The rise in the plasma potassium concentration is reversed after several minutes of rest and is typically associated with mild-rebound hypokalemia (averaging 0.4 to 0.5 mEq per L below the baseline level) that may be arrhythmogenic in susceptible individuals. The degree of potassium release is attenuated by prior physical conditioning (perhaps due to increased Na^+/K^+–ATPase activity) but may be exacerbated by the administration of beta-blockers.

Exercise can interfere with accurate measurement of the plasma potassium concentration. Repeated fist clenching during blood drawing can acutely raise the plasma potassium concentration by more than 1 mEq per L in that forearm, thereby representing another form of pseudohyperkalemia. Careful drawing of the blood and comparison of the plasma to the serum potassium value should identify most cases [80].

Other. Rarer causes of hyperkalemia due to translocation of potassium from the cells into the extracellular fluid include (a) digitalis overdose from dose-dependent inhibition of membrane Na^+/K^+–ATPase and (b) the hyperkalemic form of periodic paralysis, an autosomal dominant disorder in which episodes of weakness or paralysis are usually precipitated by cold exposure, rest after exercise, or the ingestion of small amounts of potassium.

The primary abnormality in at least some families with hyperkalemic periodic paralysis appears to be a point mutation in the gene for the α-subunit of the skeletal muscle cell sodium channel [81]. How this abnormality accounts for episodic muscle weakness is not clear. One possibility is that the activity of the sodium channel is inappropriately increased by a slight elevation in the plasma potassium concentration. The consequent entry of sodium to the cell down a very favorable concentration gradient depolarizes the cell membrane. This favors potassium diffusion out of the cells (because the cell potassium concentration is so much higher than that in the extracellular fluid) and the development of hyperkalemia.

Administration of succinylcholine to patients with burns, extensive trauma, or neuromuscular disease can also cause hyperkalemia.

Reduced Urinary Potassium Excretion

Impaired urinary potassium excretion generally requires an abnormality in one or both of the two major factors required for adequate renal potassium handling: aldosterone and distal nephron sodium and water delivery.

Hypoaldosteronism. Any cause of decreased aldosterone release or effect diminishes the efficiency of potassium secretion and can lead to hyperkalemia (Table 72.7). The resulting rise in the plasma potassium concentration directly stimulates potassium secretion, partially overcoming the relative absence of aldosterone. As a consequence, the rise in the plasma potassium concentration is small in patients with normal renal function, but it can be clinically important in the presence of underlying renal insufficiency or a high potassium intake.

Hyperkalemia in hypoaldosteronism is usually associated with a mild metabolic acidosis. This condition has been called *type-4 RTA* and appears to be primarily due to decreased urinary ammonium excretion.

Although aldosterone also promotes sodium retention, decreased availability of aldosterone is not typically associated with prominent sodium wasting with type-4 RTA in adults because of the ability of other antinatriuretic factors such as angiotensin II and norepinephrine to compensate. Hyponatremia is also uncommon because there is no hypovolemic stimulation for ADH release. If hyponatremia is present, primary adrenal insufficiency should be suspected. In this disorder, the concurrent lack of cortisol is a potent stimulus to ADH secretion, leading to water retention and a fall in the plasma sodium concentration.

The causes of hypoaldosteronism include disorders that affect adrenal aldosterone synthesis, the renal response to aldosterone, or renal (and perhaps adrenal) renin release (Table 72.7).

TABLE 72.7

MAJOR CAUSES OF HYPOALDOSTERONISM

Hyporeninemic hypoaldosteronism
Renal disease, most often diabetic nephropathy
Nonsteroidal anti-inflammatory drugs
Angiotensin-converting enzyme inhibitors
Cyclosporine
Human immunodeficiency virus infection, including trimethoprim administration
Primary adrenal insufficiency
Potassium-sparing diuretics (trimethoprim may act similarly)
Heparin
Congenital adrenal hyperplasia, with 21-hydroxylase deficiency being most common
Isolated impairment in aldosterone synthesis
Pseudohypoaldosteronism (end-organ resistance)
Severe illness

Hyporeninemic Hypoaldosteronism. The syndrome of hyporeninemic hypoaldosteronism, a form of type-4 RTA, is characterized by coexisting defects in the release of renin by the kidney and aldosterone by the adrenal cortex. The adrenal dysfunction may involve a local renin–angiotensin system because there is evidence that angiotensin II produced within the adrenal gland may stimulate the release of aldosterone [82].

This relatively common disorder most often occurs in patients with mild-to-moderate renal insufficiency due to diabetic nephropathy or chronic interstitial nephritis. Low plasma renin levels are common in diabetic patients, partly due to a defect in the conversion of the precursor prorenin into active renin [83]. Volume expansion induced by diabetes and other chronic kidney diseases may play a contributory role; the increase in atrial natriuretic peptide release in this setting can suppress both the release of renin and the hyperkalemia-induced secretion of aldosterone [84].

Similar hemodynamic and humoral changes occur in the acute nephritic syndrome of postinfectious glomerulonephritis: volume expansion, leading to appropriate suppression of renin release and enhanced secretion of atrial natriuretic peptide [85]. In some patients, these changes can lead to hyperkalemia that responds to mineralocorticoid replacement [86]. Recovery of renal function within 1 to 2 weeks is associated with restoration of normal potassium balance.

Low renin and aldosterone levels may also occur in several other settings:

- *NSAIDs.* NSAIDs lower renal renin secretion, which is normally partially mediated by locally produced prostaglandins. The result is that the plasma potassium concentration rises approximately 0.2 mEq per L in subjects with normal renal function but can rise by more than 1.0 mEq per L when renal insufficiency is superimposed. This can occur with specific cyclooxygenase-2 inhibitors as well as nonselective NSAIDs.
- *ACE inhibitors, ARBs, and direct renin inhibitors.* Similar considerations apply to agents that block the production or action of angiotensin II, since angiotensin II is necessary for normal aldosterone release in response to volume depletion or hyperkalemia.
- *Other.* Other causes of hyporeninemic hypoaldosteronism include the use of cyclosporine, which can lead to hyperkalemia in 15% to 25% of renal transplant recipients [87], likely from diminished secretion of and responsiveness to aldosterone, and HIV infection. Adrenalitis is frequently present in HIV. The administrations of the antibiotics trimethoprim and pentamidine are other causes of hyperkalemia. Both agents appear to close sodium channels in the distal nephron in a manner similar to that of the potassium-sparing diuretic amiloride [88,89].

Primary Adrenal Insufficiency. Primary adrenal cortical failure (also called *Addison's disease*) is associated with lack of cortisol and aldosterone. Pituitary disease, in comparison, does not lead to hypoaldosteronism because ACTH does not have a major role in the regulation of aldosterone release. Primary adrenal insufficiency is frequently due to autoimmune destruction of the steroid-producing cells in the adrenal cortex.

Potassium-Sparing Diuretics. Potassium-sparing diuretics are probably the most common cause of hyperkalemia due to impairment of aldosterone function. These drugs antagonize the

action of aldosterone on the collecting tubule cells: spironolactone and eplerenone by competing for the aldosterone receptor, and amiloride and triamterene by closing the sodium channels in the luminal membrane.

Heparin. Commercial heparin preparations exert a direct toxic effect on the zona glomerulosa cells of the adrenal cortex [90]. Even low-dose heparin can lead to a 75% reduction in plasma aldosterone levels. The mechanism appears to involve a reduction in the number and affinity of adrenal angiotensin II receptors involved in aldosterone synthesis and release. There are some reports of heparin causing hyponatremia by similar mechanisms of diminished aldosterone release [91].

Adrenal Enzyme Deficiency. In children, hypoaldosteronism can result from a deficiency of enzymes required for aldosterone synthesis, which may be associated with concurrent abnormalities in cortisol and androgen production.

Pseudohypoaldosteronism. Decreased aldosterone activity also occurs in the syndrome of pseudohypoaldosteronism. This disorder is associated with generalized resistance to the actions of aldosterone due to a marked reduction in the number of mineralocorticoid receptors in the kidney and in other target organs such as the colon and sweat glands [92].

Severe Illness. Hypoaldosteronism due to decreased adrenal production is common in critically ill patients. The stress-induced hypersecretion of ACTH in these patients may be responsible for this defect by inducing activity of 17α-hydroxylase in the zona glomerulosa. This enzyme enhances the synthesis of cortisol at the expense of aldosterone.

Chronic Kidney Disease. The ability to maintain potassium excretion at near-normal levels is generally maintained in patients with renal disease as long as both aldosterone secretion and distal tubular urine flow are maintained [93]. Patients who are oliguric or who have an additional problem such as a high-potassium intake, increased tissue breakdown, or hypoaldosteronism are more predisposed to hyperkalemia.

Effective Circulating Volume Depletion. Decreased distal tubular urine flow due to marked effective volume depletion, as might occur in heart failure or hepatic cirrhosis, can lead to hyperkalemia. In this setting, there is also a fall in the quantity of sodium presented to the potassium-secretory site in the collecting tubule. Hyperkalemia may occur even though aldosterone activity is high.

Hyperkalemic Type-1 Renal Tubular Acidosis. In some patients with type-1 (distal) RTA, the primary defect is impaired sodium reabsorption in the cortical collecting tubule. The movement of sodium from the lumen into the cell at this site makes the lumen electronegative, thereby promoting both hydrogen and potassium secretion. Inhibiting the transport of sodium, therefore, reduces both hydrogen and potassium secretion, leading to metabolic acidosis and hyperkalemia. This form of type-1 RTA is most often seen in patients with urinary tract obstruction or sickle cell disease. Patients with type-1 RTA have normal or even high aldosterone levels and are unable to acidify the urine normally (urine pH $\leq$5.0), in contrast to individuals with hypoaldosteronism and other forms of type-4 RTA who frequently exhibit a urine pH of less than 5.3.

Clinical Manifestations

The symptoms induced by hyperkalemia are related to impaired neuromuscular transmission. The ease of generating an action potential, called *membrane excitability*, is related both to the magnitude of the resting membrane potential and to the activation state of membrane sodium channels. Opening of these sodium channels, leading to the passive diffusion of extracellular sodium into the cells, is the primary step in this process. According to the Nernst equation, the resting membrane potential is related to the ratio of the intracellular to the extracellular potassium concentration. An elevation in the extracellular potassium concentration decreases this ratio and, therefore, partially depolarizes the cell membrane, making the resting potential less electronegative. This change initially increases membrane excitability because less of a depolarizing stimulus is required to generate an action potential. The later effect seen in patients is different. Persistent depolarization inactivates sodium channels in the cell membrane, thereby producing a net decrease in membrane excitability that may be manifested clinically by impaired cardiac conduction or muscle weakness, or both, or by paralysis.

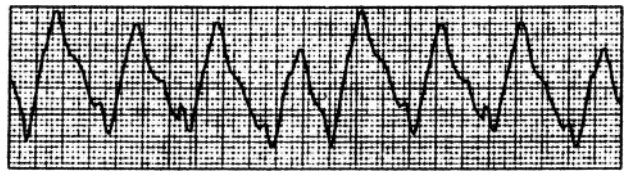

FIGURE 72.7. Marked hyperkalemia results in peaked T waves and widened QRS complexes in this electrocardiogram.

In general, severe symptoms of hyperkalemia do not occur until the plasma potassium concentration is more than 7.5 mEq per L. There is, however, substantial interpatient variability because factors such as hypocalcemia and metabolic acidosis can increase the toxicity of excess potassium. Thus, careful monitoring of the ECG and muscle strength is indicated to assess the functional consequences of the hyperkalemia. A plasma potassium concentration of more than 7.5 to 8.0 mEq per L, severe muscle weakness, or marked electrocardiographic changes are potentially life threatening and require immediate treatment using the modalities described here [94].

The earliest ECG abnormality is symmetric peaking of T waves, followed by reduced P-wave voltage and widening of QRS complexes (Fig. 72.7). If untreated, severe hyperkalemia can cause the normal QRS morphology to be lost altogether so that the ECG pattern deteriorates into a sinusoidal ECG form, with one oscillation representing a wide QRS complex and the complementary oscillation representing an abnormal T wave. ECG changes usually do not appear until the plasma K^+ concentration exceeds 6.5 mEq per L, and are more likely to develop when the rise in K^+ occurs rapidly. There is, however, no consistent relationship between the severity of the electrolyte disturbance and the ECG; in rare cases, the ECG can remain unchanged even with a plasma potassium concentration of more than 9 mEq per L [95].

The neuromuscular manifestations of hyperkalemia are nonspecific. The earliest findings are paresthesias and weakness, which can progress to paralysis affecting the respiratory muscles. These symptoms are similar to those seen with hypokalemia; cranial nerve function remains unaffected.

Diagnosis

Pseudohyperkalemia should be considered when there is evidence of hemolysis in the sample or when the platelet or white blood cell counts are markedly increased.

An asymptomatic patient with a plasma potassium concentration of 6.5 mEq per L and no ECG changes can be treated with a cation exchange resin (Kayexalate) alone, and patients with a level below 6.0 mEq per L can often be treated just with a low-potassium diet and diuretics. Any extra source of potassium intake (salt substitutes, potassium supplements, and foods with a high potassium content) should be eliminated, and any potentiating drugs (e.g., NSAIDs or ACE inhibitors) should be discontinued.

Treatment

Specific treatment of severe or symptomatic hyperkalemia is directed at antagonizing the membrane effects of potassium, driving extracellular potassium into the cells, or removing excess potassium from the body [96]. Although this can often be done in the outpatient setting, some patients should be hospitalized [97]. The following modalities, which are listed according to their rapidity of action, all may be beneficial.

Calcium. Calcium directly antagonizes the membrane actions of hyperkalemia. As mentioned previously, hyperkalemia-induced depolarization of the resting membrane potential leads to inactivation of sodium channels and decreased membrane excitability. Calcium antagonizes this membrane effect of hyperkalemia, although how this is achieved is not well understood.

The protective effect of calcium begins within minutes but is relatively short lived. As a result, calcium infusions are indicated only for severe hyperkalemia, when it is potentially dangerous to wait the 30 to 60 minutes required for insulin and glucose or sodium bicarbonate to act. The usual dose is 10 mL (1 ampule) of a 10% calcium gluconate solution infused slowly during 2 to 3 minutes with constant cardiac monitoring. This dose can be repeated after 5 minutes if the ECG changes persist.

Calcium should not be given in bicarbonate-containing solutions because this can lead to its precipitation as calcium carbonate. Because hypercalcemia can induce digitalis toxicity, calcium should be administered only when absolutely necessary to patients taking digoxin.

Insulin and Glucose. Increasing the availability of insulin lowers the plasma potassium concentration by driving potassium into the cells, apparently by enhancing the activity of the Na^+/K^+–ATPase pump in skeletal muscle. Hyperinsulinemia can be induced either by giving insulin with glucose to prevent hypoglycemia or by the intravenous administration of glucose (50 mL of a 50% glucose solution), which rapidly enhances endogenous insulin secretion in a nondiabetic patient. Glucose alone may produce a smaller rise in the plasma insulin concentration and a lesser reduction in plasma potassium concentration than does the insulin-plus-glucose regimen. Effective therapy usually produces a 0.5 to 1.5 mEq per L fall in the plasma potassium concentration. This effect begins in 15 minutes, peaks at 60 minutes, and lasts for several hours [98]. Although patients with chronic kidney disease are relatively resistant to the glycemic effect of insulin, they are not resistant to the hypokalemic effect because Na^+/K^+–ATPase activity is still enhanced.

Exogenous insulin can induce symptomatic hypoglycemia unless adequate glucose is given concurrently. If, for example, 10 units of regular insulin are given with 25 g of glucose, the plasma glucose concentration may fall to less than 55 mg per dL in as many as 75% of initially normoglycemic patients [98]. Increasing the initial glucose dose to 40 g, followed by a continuous dextrose infusion, generally prevents this problem.

Proper therapy in diabetic patients varies with the plasma glucose concentration. Both insulin and glucose should be given when the plasma glucose concentration is normal or mildly elevated because endogenous insulin release is impaired. Insulin in this case reduces the plasma potassium concentration directly by preventing a rise in the plasma glucose concentration that can exacerbate the hyperkalemia. The osmotic force generated by the high extracellular glucose concentration pulls water and, secondarily, potassium out of the cells. In comparison, insulin alone is sufficient if the patient is already hyperglycemic.

Sodium Bicarbonate. Raising the systemic pH with sodium bicarbonate promotes hydrogen ion release from the cells and a reciprocal movement of potassium into the cells. The elevation in the plasma bicarbonate concentration appears to have another direct, albeit not delineated, effect on lowering the plasma potassium concentration that is independent of pH [99].

The potassium-lowering action of sodium bicarbonate is most prominent in patients with metabolic acidosis, beginning within 30 to 60 minutes and persisting for several hours. Sodium bicarbonate appears to be less effective in correcting hyperkalemia in patients with renal failure. Insulin plus glucose or a β_2-agonist is more predictably effective in this setting.

The usual dose is 45 mEq (1 ampule of a 7.5% sodium bicarbonate solution) infused slowly during 5 minutes; this dose can be repeated in 30 minutes if necessary. Alternatively, sodium bicarbonate can be added to a glucose and saline solution. This regimen may have an additional advantage in hyponatremic patients because raising the plasma sodium concentration with this hypertonic solution can also reverse the electrocardiographic effects of hyperkalemia. Both an increase in the rate of membrane depolarization and a fall in the plasma potassium concentration by dilution may contribute to this effect. These sodium-containing solutions should be used with extreme caution in edematous patients with advanced heart failure or renal failure. Despite the physiologic rationale, bicarbonate administration appears to be less effective in lowering the serum potassium concentration in patients with end-stage renal disease who are receiving dialysis.

β_2-Adrenergic Agonists. Like insulin, β_2-adrenergic agonists drive potassium into the cells by increasing Na^+/K^+–ATPase activity. Albuterol (20.0 mg in 4 mL of saline by nasal inhalation for 10 minutes or 0.5 mg by intravenous infusion) can lower the plasma potassium concentration by 0.5 to 1.5 mEq per L within 30 to 60 minutes. Furthermore, the effect of these agents is additive to that of insulin plus glucose. The only common side effects of the β_2-agonists are mild tachycardia and the possible induction of angina in susceptible individuals. Thus, these agents should probably be avoided in patients with known active coronary disease.

Loop or Thiazide Diuretics. Loop and thiazide diuretics can be used when hyperkalemia is present in an individual with hypertension or volume overload. However, the effectiveness of diuretic therapy is frequently limited by moderate-to-severe renal insufficiency.

Cation Exchange Resin. The most readily available cation exchange resin is sodium polystyrene sulfonate (SPS). In the gut, this resin takes up potassium, and calcium and magnesium to lesser degrees, and releases sodium. Each gram of resin may bind as much as 1 mEq of potassium and release 1 to 2 mEq of sodium. Thus, a potential side effect is exacerbation of any preexisting degree of sodium overload.

The resin can be given either orally or as a retention enema. The oral dose is usually 20 g given with 100 mL of a 20% sorbitol solution to prevent constipation. However, preliminary data suggest that alternative vehicles may be safer and more effective than sorbitol [100,101]. This can be repeated every 4 to 6 hours as necessary. Lower doses (5 to 10 g with meals) are generally well tolerated (no nausea or constipation) and can be used to control chronic mild hyperkalemia in patients with renal insufficiency.

When given as an enema, 50 g of resin is mixed with 50 mL of 70% sorbitol plus 100 to 150 mL of tap water. This solution should be kept in the colon for at least 30 to 60 minutes, preferably for 2 to 3 hours. Each enema can lower the plasma potassium concentration by as much as 0.5 to 1.0 mEq per L and can be repeated every 2 to 4 hours.

Intestinal necrosis is an occasional occurrence, particularly when SPS is given orally with sorbitol within the first week after surgery [101]. Why this occurs is not clear; it is possible

that a postoperative ileus plays an important role by increasing the duration of drug contact with the intestinal mucosa.

Recently, there have been reports questioning the effectiveness of SPS. This issue remains unresolved at this time, but anecdotal experience supports its effectiveness in lowering the serum potassium level in many patients. Still, with the possible, although uncommon, risk of bowel injury, other measure should be tried first.

Dialysis. Dialysis can be used if the conservative measures listed in the preceding sections are ineffective, if the hyperkalemia is severe, if the patient has marked tissue breakdown and is releasing large amounts of potassium from the injured cells, or, of course, if the patient has hyperkalemia in the setting of renal failure. The rate of potassium removal with hemodialysis is preferred in the last two settings because it is many times faster than with peritoneal dialysis.

CHAPTER 73 ■ ACUTE KIDNEY INJURY IN THE INTENSIVE CARE UNIT

JAHAN MONTAGUE AND KONSTANTIN ABRAMOV

OVERVIEW OF ACUTE KIDNEY INJURY

Sudden disruption of previously normal or stable kidney function, usually occurring over hours or days, is termed *acute kidney injury (AKI)*, formerly referred to as *acute renal failure*. The new term underscores the diverse clinical context in which patients with many forms and causes of AKI may present, while the term failure implies an end stage of this clinical spectrum. The pathogenesis of AKI differs from that of chronic kidney disease (CKD), in which nephron loss is more gradual. However, AKI can occur in the setting of antecedent CKD.

AKI is often diagnosed when a patient is noted to have azotemia. This elevation in the blood urea nitrogen (BUN) and serum creatinine typically represents a decline in glomerular filtration rate (GFR), but in certain cases may reflect increased production without any reduction in GFR (Table 73.1).

TABLE 73.1

CAUSES OF BLOOD UREA NITROGEN OR SERUM CREATININE ELEVATION WITHOUT REDUCTION OF GLOMERULAR FILTRATION RATE

- Increased biosynthesis of urea
  - Gastrointestinal bleeding
  - Drug administration
    - Corticosteroids
    - Tetracycline
  - Increased protein intake
  - Amino acid administration
  - Hypercatabolism and febrile illness
- Increased biosynthesis of creatinine
  - Increased release of creatine from muscle (rhabdomyolysis)
- Drug interference with tubular creatinine secretion
  - Cimetidine
  - Trimethoprim
- Spuriously elevated creatinine colorimetric assay
  - Ketoacids (diabetic ketoacidosis)
  - Cephalosporins

TABLE 73.3

CAUSES OF ACUTE KIDNEY INJURY

- Prerenal azotemia
  - Hypovolemia
  - Reduced effective circulating volume
  - Autoregulatory failure
- Intrinsic renal disease
  - Glomerular diseases
  - Vascular diseases (main renal artery and microcirculation)
  - Tubulointerstitial disease
  - Acute tubular necrosis
  - Acute cortical necrosis
- Postrenal failure
  - Ureteric obstruction (bilateral or solitary kidney)
  - Lower tract obstruction (bladder neck or urethra)

Oliguria, a reduction in urine output to less than 20 mL per hour, may be present, although many forms of AKI are nonoliguric. When tubular reabsorption of glomerular filtrate is reduced as a result of either tubular dysfunction or diuretic administration, patients may be polyuric even though GFR is markedly reduced.

AKI can occur prior to a significant increase in creatinine. Several recent studies reported that even a small rise in serum creatinine correlated with increased mortality [1,2]. Therefore, the Acute Dialysis Quality Initiative Group has proposed a new classification of AKI based not only on serum creatinine but also on the degree of urinary output reduction and the requirement for renal replacement therapy [3]. This classification is reflected in the RIFLE criteria (Table 73.2), which have been shown to predict renal outcome and mortality in a variety of critically ill and hospitalized patients [4,5].

AKI may stem from any of three general conditions: impaired renal perfusion without parenchymal injury, damage to the renal parenchyma, or obstruction of the urinary tract. These etiologies are referred to as *prerenal, renal,* or *postrenal* causes of AKI, respectively, and are summarized in Table 73.3. Although it is helpful to consider the complete array of renal diseases when evaluating AKI, in the inpatient setting two thirds of cases will be due to either acute tubular necrosis (ATN) or prerenal azotemia. Hence, an extensive search for other forms of renal disease is indicated in the intensive care unit (ICU) setting only when suggested by clinical signs or laboratory findings such as urinary abnormalities indicative of glomerular disease.

Prerenal Azotemia and Autoregulatory Failure

When renal perfusion pressure decreases to a point at which GFR falls, prerenal azotemia is said to be present. This is a functional condition that does not represent intrinsic renal disease as such, although it may be superimposed on preexisting renal disease. The causes of prerenal azotemia are listed in Table 73.4. Normalization of renal blood flow, if possible, promptly restores renal function.

Hypovolemia serious enough to cause prerenal azotemia may result from gastrointestinal losses, hemorrhage, venous pooling, sequestering of fluid in "third spaces," or excessive urinary or skin losses of sodium and water. Patients will usually exhibit signs of hypovolemia, including thirst, diminished skin turgor and mucous membrane moistness, and postural hypotension. Patients whose vascular volume is functionally reduced by the hemodynamic alterations of congestive heart failure, cirrhosis, or hypoalbuminemia may develop prerenal azotemia despite having a normal or even expanded extracellular fluid (ECF) volume. Because the *effective circulatory volume* is reduced, renal perfusion is impaired just as in true hypovolemia.

When glomerular perfusion is threatened, autoregulatory mechanisms help maintain glomerular capillary pressure. If autoregulatory mechanisms are inoperative, a given reduction

TABLE 73.2

RIFLE CRITERIA

	Serum creatinine (Cr)/glomerular filtration rate (GFR) criteria	Urinary output criteria
Risk	Cr increase ×1.5 above baseline or GFR decline >25%	<0.5 mL/kg/h × 6 h
Injury	Cr increase ×2 above baseline or GFR decline >50%	<0.3 mL/kg/h × 24 h
Failure	Cr increase ×3 above baseline or Cr ≥4 mg/dL or GFR decline >75%	<0.3 mL/kg/h 24 h or anuria × 12 h
Loss	Persistent AKI >4 wk	
End stage	End-stage renal disease (AKI >3 mo)	

Summary of RIFLE criteria of AKI. Sensitivity for AKI increases toward the top of the chart, while specificity increases toward the bottom of the chart. [Bellomo R, Ronco C, Kellum JA, et al; Acute Dialysis Quality Initiative Workgroup: Acute renal failure—definition, outcome measures, animal models, fluid therapy and information technology needs: the Second International Consensus Conference of the Acute Dialysis Quality Initiative (ADQI) Group. *Crit Care* 8:R204–R210, 2004.]

TABLE 73.4

CAUSES OF PRERENAL AZOTEMIA

- Hypovolemia
  - Gastrointestinal losses
    - Vomiting
    - Diarrhea
    - Surgical drainage
  - Renal losses
    - Osmotic agents
    - Diuretics
    - Renal salt-wasting disease
    - Adrenal insufficiency
  - Skin losses
    - Burns
    - Excessive diaphoresis
  - Hemorrhage
  - Translocation of fluid ("third spacing")
    - Postoperative
    - Pancreatitis
- Reduced effective circulating volume
  - Hypoalbuminemia
  - Hepatic cirrhosis
  - Left ventricular cardiac failure
  - Peripheral blood pooling (vasodilator therapy, anesthetics, anaphylaxis, sepsis, toxic shock syndrome)
  - Renal artery occlusion
  - Small vessel disease (malignant hypertension, toxemia, scleroderma)
  - Renal vasoconstriction (hypercalcemia, hepatorenal syndrome, cyclosporine, pressor agents)
- Autoregulatory failure
  - Nonsteroidal anti-inflammatory drugs (preglomerular vasoconstriction)
  - Angiotensin-converting enzyme inhibitors (postglomerular vasodilation)

in renal blood flow provokes a sharper decline in GFR. The mechanisms of these processes are shown in Figure 73.1. Use of nonsteroidal anti-inflammatory drugs (NSAIDs) in patients with renal hypoperfusion, for example, can lead to severe AKI [6–8]. Likewise, administration of angiotensin-converting enzyme (ACE) inhibitors in patients whose renal blood flow is obstructed by bilateral renovascular renal artery stenoses can cause severe azotemia [9].

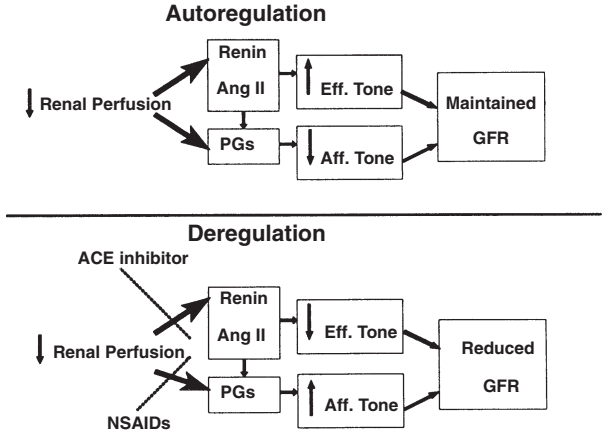

FIGURE 73.1. Diagrammatic representation of autoregulation and deregulation caused by use of either nonsteroidal anti-inflammatory drugs (NSAIDs), which lead to afferent (Aff.) vasoconstriction, or angiotensin-converting enzyme (ACE) inhibitors, which produce efferent (Eff.) vasodilation. Ang II, angiotensin II; GFR, glomerular filtration rate; PGs, prostaglandins.

Reduced renal perfusion slows down the flow of filtrate through the renal tubules, enhancing the reabsorption of urea. Because creatinine is not reabsorbed in the renal tubules, its clearance is unaffected by these nephronal factors. Thus, the clearance of urea is reduced disproportionately to that of creatinine, explaining the unusually high BUN–creatinine ratio that is often seen in prerenal states. In such situations, the BUN–creatinine ratio typically exceeds 20 to 1.

A high urea–creatinine ratio, however, is not pathognomonic of prerenal azotemia. When urea production is accelerated in catabolic states (as is seen in tetracycline and corticosteroid therapy) or by resorption of a large hematoma or gastrointestinal bleeding, BUN levels rise unless renal urea clearance can increase to meet the augmented urea burden. To establish whether a high BUN–creatinine ratio is due to increased urea production or reduced excretion, calculation of the fractional urea clearance may be useful.

The hallmark of prerenal conditions is the intense renal conservation of salt and water as reflected in the urine composition, which generally shows a low sodium concentration (U_{Na} <10 mEq per L; fractional excretion of sodium [FE_{Na}] <1%) and a high osmolality (U_{Osm} >500 mOsm per kg). Renal conservation of sodium involves both proximal and distal tubular mechanisms. A low urinary sodium concentration is expected in these states; its absence signifies a coexisting abnormality of tubular function, the effect of diuretics, or the presence of nonreabsorbable anionic substances in the urine, such as bicarbonate in patients with metabolic alkalosis, or certain penicillins, that obligate the excretion of cations like sodium. Impaired sodium reabsorption is also seen during osmotic diuresis and in certain forms of chronic renal disease.

Intrinsic Renal Disease

Reduced renal function may also result from renal parenchymal injury. Such injury may arise from glomerular, vascular, and tubulointerstitial disorders (Table 73.3) and may represent either primary kidney disease or the renal effects of an underlying systemic illness (e.g., systemic lupus erythematosus).

Glomerular and Vascular Diseases

The GFR may be abruptly reduced in acute glomerulonephritis. In poststreptococcal glomerulonephritis, the prototypic nephritic disorder, patients often present with AKI and oliguria.

Hypertension and edema result from their inability to excrete salt and water normally. The constellation of hypertension, edema, azotemia, and hematuria is known as the *acute nephritic syndrome*. Although the history of a previous sore throat or streptococcal infection may provide diagnostic clues, the urinalysis is particularly valuable. The urine may be grossly bloody or tea colored. The urinary sediment contains red blood cells (RBCs) and often RBC casts (Fig. 73.2). Similar findings are frequent in patients with other primary nephritic disorders as well as in secondary nephritides, such as those seen in systemic lupus, and bacterial endocarditis. The crescentic glomerulonephritides (rapidly progressive glomerulonephritis) can evoke the acute nephritic syndrome.

Diseases affecting either the main renal arteries or their branches may precipitate AKI. Renal artery occlusion by *acute thrombosis* or *thromboembolism* typically only causes AKI if it is bilateral or involves a solitary functioning kidney. These processes may be silent or may produce flank pain and hematuria, particularly if abrupt enough to cause renal infarction. Fever, moderate leukocytosis, and an elevated serum level of

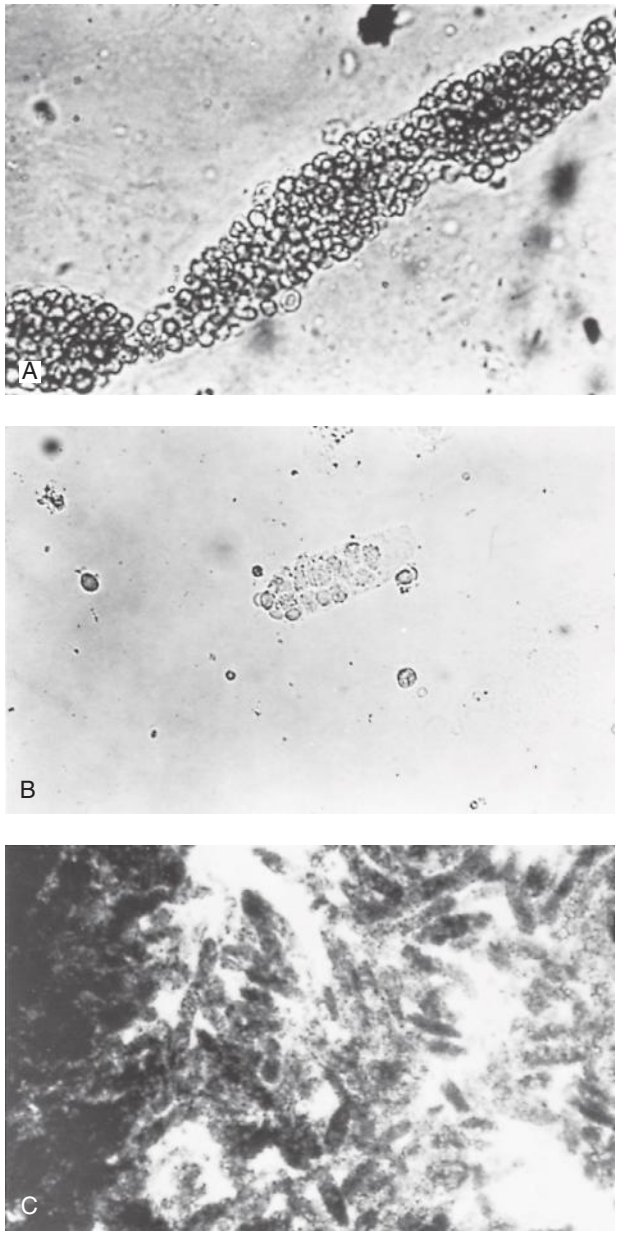

FIGURE 73.2. Typical urinary sediments from patients with parenchymal renal diseases. **A:** Sediment from patient with acute glomerulonephritis showing free red blood cells and red blood cell casts. **B:** Sediment from patient with acute interstitial nephritis demonstrating pyuria and white blood cell cast. **C:** Typical muddy brown, coarse, granular casts in a patient with acute tubular necrosis.

lactate dehydrogenase should raise the suspicion of infarction. With rare exceptions, renal arterial thromboembolism occurs only in the settings of acute myocardial infarction, atrial fibrillation, bacterial endocarditis, hypercoagulable disorders, or other cardiac valvular disease.

Acute renal vein thrombosis seldom causes renal failure unless both kidneys are simultaneously occluded. Acute flank pain and hematuria are the clinical hallmarks. Renal venous obstruction may occur as a complication of nephrotic syndrome and renal cell carcinoma.

Microscopic occlusion of smaller vessels occurs in a variety of disorders, including atheroembolic renal disease, thrombotic thrombocytopenic purpura (TTP) and hemolytic-uremic syndrome, scleroderma, postpartum kidney injury, and malignant hypertension. Scleroderma or malignant hypertension may appear as AKI, with severe blood pressure elevation due to activation of the renin–angiotensin system. These vascular disorders produce renal injury by reducing glomerular blood flow. Because the lesion is proximal to the glomerulus, the urine sediment is usually acellular and bland.

Vasculitis produces AKI either through direct involvement of the renal arterial system or by inducing glomerulonephritis. Often, microscopic polyarteritis or Wegener's granulomatosis may present with evident renal parenchymal disease, as suggested by urinary abnormalities such as microscopic hematuria, RBC casts, and proteinuria. These patients may present to the ICU when there is multiorgan involvement, such as the pulmonary disease that occurs in Wegener's granulomatosis. Fulminant presentations with severe hypoxemia and pulmonary hemorrhage may be accompanied by rapidly progressive renal dysfunction. In these cases, glomerular involvement may range from focal and segmental necrotizing glomerulitis to severe crescentic glomerulonephritis.

Tubulointerstitial Diseases

Two syndromes are responsible for most cases of parenchymal AKI in hospitalized populations: *ATN* and *acute interstitial nephritis (AIN)*.

Acute Tubular Necrosis. ATN is a syndrome that may result from renal ischemia or exposure to nephrotoxins such as aminoglycoside antibiotics, radiocontrast agents, heavy metals, and myoglobin. Although historically many other names have been applied to this syndrome, the term *acute tubular necrosis* prevails even though frank tubular cell necrosis does not appear in all cases. Historically, the pathophysiology of AKI in ATN has been attributed to three processes: (a) *obstruction of tubular lumens* by sloughed epithelial cells and cellular debris, (b) *back-leak* of filtered wastes into the circulation through the disrupted tubular epithelium, and (c) *sustained reduction in glomerular blood flow* following the inciting stimulus. Along these lines, severe cortical vasoconstriction has been noted early in the course of ATN [10], which is likely mediated by endothelial cell injury and locally acting vasoconstrictors, such as endothelin [11]. Afferent arteriolar vasoconstriction has also been described. In ATN, impaired proximal solute reabsorption increases distal chloride delivery to macular densa, which, in turn, mediates afferent constriction via the secretion of adenosine. This process is termed *tubuloglomerular feedback* [12]. However, it remains unclear whether renal vasoconstriction has a central role in the pathogenesis of ATN, since restoring renal blood flow with vasodilators in a variety of animal models of AKI does not always preserve the GFR [13]. Nonetheless, this process may be important in the initiation of certain forms of ATN such as radiocontrast toxicity (see following discussion).

As already noted, relatively modest hypoperfusion leads to prerenal azotemia, characterized by a modest reduction in urine output and GFR and preservation of tubular function, which is rapidly reversible. However, a more critical decrease in renal perfusion leads to medullary hypoperfusion and ischemic ATN, with greater reductions in GFR, abnormalities of tubular function, and often histologic evidence of tissue injury. Because recovery depends on cellular regeneration, reversal is much slower than in prerenal azotemia [14]. The most extreme form of hypoperfusion injury is cortical ischemia associated with either patchy or diffuse *cortical necrosis*, typically manifesting the most severe reduction in GFR and a much less certain prognosis for recovery of renal function. The medullary thick ascending limb segment of the loop of Henle is particularly vulnerable to ischemic and nephrotoxic insults because of a combination of low ambient partial pressure of oxygen and intense,

TABLE 73.5

PROTEIN BIOMARKERS FOR THE EARLY DETECTION OF ACUTE KIDNEY INJURY

Biomarker	Associated injury
Cystatin C	Proximal tubule injury
KIM-1	Ischemia and nephrotoxins
NGAL	
L-FABP	
Netrin-1	Sepsis, ischemia, nephrotoxins I
NHE3	Prerenal, ischemia, postrenal
α-GST	Acute rejection, proximal tubule injury
π-GST	Acute rejection, distal tubule injury
Cytokines (IL-6, IL-8, IL-18)	Delayed graft function
Actin–actin depolymerizing F	
Keratin-derived chemokine	

GST, glutathione S-transferase; IL, interleukin; KIM, kidney injury molecule; L-FABP, L-type fatty acid binding protein; NGAL, neutrophil gelatinase-associated lipocalin; NHE, sodium–hydrogen exchanger. From Ronco C, Haapio M, House AA, et al: Cardiorenal syndrome. *J Am Coll Cardiol.* 52:1527, 2008.

transport-driven oxygen consumption. Other factors, such as adenosine triphosphate depletion activation of phospholipases, cytosolic and mitochondrial calcium overload, and release of free radicals [15], may contribute to cellular damage. In experimental ATN, cytoskeletal reorganization can be demonstrated in proximal tubular cells, leading to loss of normal cell polarity. The sodium–potassium adenosine triphosphatase transport system may thus be translocated from its normal basolateral position to the apical surface of the cell, impairing reabsorptive function.

There is growing evidence that immune system plays a critical role in pathogenesis of ATN through recruitment of various inflammatory cells, cytokine release, complement activation, and induction of tubular cell apoptosis [16,17]. Adhesion molecules, such as intracellular adhesion molecule 1 (ICAM-1), appear to play a role in the development of postischemic ATN in experimental animal models. However, anti-ICAM antibody failed to protect against ischemic AKI in a clinical trial of kidney transplant patients [18]. Another regulatory molecule expressed in the kidney, the protein neutrophil gelatinase-associated lipocalin (NGAL), is released early in the course of ischemic ATN and appears to attenuate tubular cell injury and apoptosis [19]. There is considerable interest in using NGAL and other molecules as biomarkers of early kidney injury (Table 73.5) with the hope that timely diagnosis of AKI will allow clinicians to make therapeutic interventions that will ultimately improve outcomes (discussed further in "Diagnosis" section).

History of exposure to a predisposing factor, such as prolonged ischemia or toxin, can be elicited in approximately 80% of patients with ATN. Most individuals with this syndrome have the classic findings of sloughed renal tubular epithelial cells, epithelial cell casts, or muddy brown granular casts in the urinary sediment (Fig. 73.2). These findings are not seen in prerenal azotemia. In addition, calculating the fractional excretion of filtered sodium (FE_{Na}) may enable the clinician to differentiate between ATN and prerenal azotemia. The FE_{Na} expresses urinary sodium excretion as a percentage of filtered load. It provides a more precise representation of tubular sodium avidity than the urinary sodium concentration because it is not influenced by changes in urine concentration or flow rate. The FE_{Na} is very low in prerenal azotemia as a result of active sodium reabsorption by the renal tubules. When frank tubular damage has occurred, as in ATN, the tubules can no longer reclaim sodium efficiently, and the FE_{Na} is generally high (Fig. 73.3). See "Diagnosis" section for more detail on the FE_{Na}. Urinary concentration is also impaired in tubular necrosis; as a result, urinary osmolality approximates that of plasma, and the BUN–creatinine ratio is less than 20.

Acute Interstitial Nephritis. The term *acute interstitial* (or *tubulointerstitial*) *nephritis* encompasses a collection of disorders characterized by acute inflammation of the renal interstitium and tubules. Depending on the specific nature of the condition, the inflammatory infiltrate may consist of a combination of neutrophils, eosinophils, and lymphocytes or plasma cells. Most cases of AIN represent an allergic reaction with eosinophilia and skin eruptions, usually induced by medication. Interstitial disease can also occur as a result of infectious agents, including brucellosis, leptospirosis, legionella, toxoplasmosis, and Epstein–Barr virus.

These disorders are to be distinguished from the familiar entity *acute pyelonephritis*. Acute pyelonephritis is a suppurative

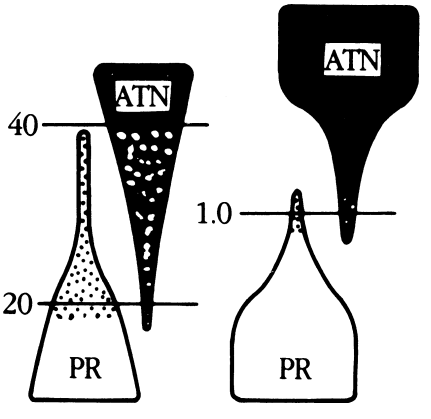

FIGURE 73.3. Diagnostic parameters in acute renal failure. Two laboratory tests used to distinguish prerenal (PR) azotemia from acute tubular necrosis (ATN) are shown. **Left:** Urinary sodium concentration (U_{Na}, mEq per L). **Right:** Fractional excretion of sodium (FE_{Na}, %). Area within each symbol denotes the proportion of patients with each condition correlated with the laboratory parameter. Note that although considerable numbers of patients with PR and ATN fall in an intermediate zone of U_{Na} (20 to 40 mEq per L), the FE_{Na} almost completely differentiates the two groups. [Adapted from Rudnick MR, Bastl CP, Elfinbein IB, et al: The differential diagnosis of acute renal failure, in Brenner BM, Lazarus JM (eds): *Acute Renal Failure*. New York, Churchill Livingstone, 1988, p 177.]

disease of the tubulointerstitium, usually caused by bacterial infection ascending from the urinary bladder. Acute pyelonephritis rarely causes renal dysfunction. AIN, however, is an important cause of AKI and is discussed in detail later.

Postrenal Azotemia

The term *postrenal azotemia*, or *obstructive uropathy*, refers to azotemia caused by obstruction of urine flow from the kidneys. Renal outflow obstruction has many causes, but the most common causes are prostatic enlargement, nephrolithiasis, and genitourinary tumors. For obstruction to produce azotemia, both kidneys must be involved because one normally functioning kidney is sufficient to maintain a near normal GFR. AKI may occur with unilateral obstruction in a patient who has one functioning kidney or in whom unilateral obstruction is superimposed on underlying CKD.

The clinical history often helps in the diagnosis of obstructive uropathy. Prior kidney stones should raise the index of suspicion for obstruction, particularly in the setting of symptoms of renal colic. AKI in an elderly man who has been experiencing urinary hesitancy most likely represents obstruction of the bladder outlet by an enlarged prostate. A history of genitourinary malignancy in an azotemic patient also makes obstruction the most likely diagnosis. AKI in the setting of painless gross hematuria and a history of NSAID use should prompt a suspicion of papillary necrosis, a condition in which sloughed-off renal papilla can cause bilateral ureteral obstruction. Finally, renal failure in a newborn infant is likely to be due to congenital anatomic ureteral obstruction.

When urine output declines precipitously or ceases entirely (anuria), complete obstruction of the urinary tract must be ruled out. Such an obstruction is likely to be located at the bladder outlet because the probability of simultaneous obstruction in both ureters from any cause is remote. If the patient has only one kidney (e.g., due to previous nephrectomy, unilateral renal disease, or congenital solitary kidney), however, anuria may occur with unilateral ureteral obstruction. Even though complete obstruction is a common cause of anuria, partial obstruction is not always associated with a decline in urine output. With partial obstruction, damage to the kidney may impair the ability to concentrate urine, resulting in a polyuric state (acquired nephrogenic diabetes insipidus) [20,21]. In patients with complete unilateral obstruction of a ureter, the contralateral kidney often sustains a normal urine output.

As discussed later, urologic causes of AKI are best diagnosed by renal imaging techniques. The urine chemistry is generally of little help in diagnosing obstructive uropathy. Likewise, the urinalysis provides only indirect evidence of a possible cause of AKI. Hematuria reflects trauma to the urinary epithelium caused by the obstructing lesion. Crystals (calcium oxalate or uric acid) in the urine sediment may suggest a kidney stone.

CLINICAL SYNDROMES ASSOCIATED WITH AKI IN THE INTENSIVE CARE SETTING

With the higher level of acuity of illness, and more radical approaches to surgical and pharmacologic therapeutics, the incidence of AKI is increasing. As with other areas of clinical medicine, patterns of presentation often can be recognized and can lead the physician to the most likely diagnoses. The following section explores in greater detail the specific AKI syndromes most commonly encountered in the ICU (listed in Table 73.6).

TABLE 73.6

INTENSIVE CARE SYNDROMES ASSOCIATED WITH ACUTE KIDNEY INJURY (AKI)

Ischemic AKI
Extracellular volume depletion
Postoperative (particularly cardiac surgery)
Severe ventricular dysfunction or cardiogenic shock
Sepsis
Pancreatitis
Trauma
Burns
Acute bilateral cortical necrosis
Nephrotoxicity and drug-induced AKI
Myoglobinuric AKI
Radiocontrast nephropathy
Drugs (see Table 73.13)
Renal vascular disease
Major vessel disease
Renal artery embolism or thrombosis
Renal vein thrombosis
Microvascular disease
Atheroembolism
Vasculitis
Scleroderma
Cancer related
Obstructive uropathy
Hypercalcemia
Tumor-lysis syndrome
ATN secondary to chemotherapy
Renal dysfunction with liver disease
Prerenal azotemia
ATN
Hepatorenal syndrome

ATN, acute tubular necrosis.

Ischemic Acute Kidney Injury

The most common forms of AKI in the ICU result from renal hypoperfusion. Because frank hypotension is documented in fewer than half of these cases, the causal events may often be overlooked or obscured by multiple factors. Frequently, more than one causal factor is necessary to provoke AKI. For example, the presence of hypovolemia enhances the risk for AKI due to nephrotoxic insults.

Extracellular Volume Depletion

Extracellular volume depletion accounted for approximately 17% of cases of AKI in a prospective study of AKI in a major hospital [14]. In most instances, urinary losses are the cause of hypovolemia. Injudicious use of diuretics and the osmotic diuresis that accompanies diabetic hyperglycemia are the most common etiologies. Cessation of diuretic therapy and volume repletion lead to rapid recovery; consequently, the mortality is quite low [14].

In rare instances, gastrointestinal losses of substantial magnitude may lead to AKI. (In the developing world, however, this is one of the most common causes of AKI and the major cause of morbidity and mortality in epidemic cholera.) In such cases, the source of the gastrointestinal losses, either gastric or intestinal, may lead to distinctive electrolyte abnormalities. In the former, metabolic alkalosis mandates repletion with

chloride-rich replacement solutions (normal saline, usually with potassium chloride, as most patients are also hypokalemic). With intestinal losses of fluid, metabolic acidosis often ensues, and appropriate replacement may consist of a buffer solution of either isotonic bicarbonate or lactate-containing (Ringer's) solution in combination with saline. (This is more fully discussed in Chapter 71.)

Transdermal fluid losses usually occur in the setting of major burns, with the degree of hypovolemia and the severity of AKI corresponding to the extent of thermal injury (body surface-area involvement). Significant burns can lead to severe hypovolemia as a result of massive evaporative and exudative fluid loss across the damaged epidermis as well from redistribution of fluid due to edema in the injured tissues. This hypovolemia can stimulate a sympathetic nerve-mediated response with resultant renal vasoconstriction. In some instances, the severity of renal vasoconstriction, superimposed on hypovolemia, culminates in ATN. In addition, deeper thermal injury with skeletal muscle involvement may induce myoglobinuric AKI (see following discussion). Dermal losses of fluid are also seen in the setting of hyperthermia and heat stroke. The evaporative loss of sweat, which is hypotonic, leads to a hypertonic dehydration in these cases. Replacement with half-normal saline corrects free water and sodium deficits.

Postoperative

Postoperative AKI has long been recognized as a common complication of major vascular, abdominal, and open-heart surgery. The pathogenesis of postoperative renal dysfunction varies with the type of the surgery and the preoperative condition of the patient. AKI following abdominal surgery is often the result of translocation of fluid into the peritoneal cavity. In this phenomenon, third spacing causes intravascular hypovolemia and subsequent renal hypoperfusion. AKI is uncommon in patients undergoing routine abdominal surgery, but the risk is substantial in surgery for obstructive jaundice; this complication may develop in approximately 10% of patients [22]. Major vascular surgery, particularly aortic repairs, is also frequently complicated by AKI, especially in the setting of a ruptured aortic aneurysm [23]. Elective repair of an aortic aneurysm is seldom associated with AKI unless cross clamping is placed above the renal arteries. Although the definition of AKI and its incidence varies among studies, cardiac surgery appears to generate most of the cases in the acute care hospital. In a prospective study, cardiac surgery accounted for nearly two thirds of the postoperative AKI with an overall incidence of 15% [14]. Repeated episodes of AKI and sepsis complicating AKI are associated with substantially higher mortality (85%) after surgery.

Myers and Moran [10] have described three distinct clinical patterns of AKI following open-heart surgery. The abbreviated pattern, observed in 80% to 90% of patients, usually has an abrupt onset after surgery, followed by a brief and mild rise in the serum creatinine, peaking by 3 to 4 days, after which recovery is rapid. This form of AKI is frequently associated with the use of vasoconstrictors, such as norepinephrine and epinephrine, in the immediate postoperative period. The overt form is associated with a more severe reduction in GFR and rise in serum creatinine, which peaks 1 to 2 weeks after surgery. This is generally associated with poor cardiac performance following surgery, whereas recovery is associated with improved ventricular function. The protracted form of AKI generally follows a second insult after surgery, such as sepsis or pericardial tamponade, and is associated with prolonged AKI and a poor prognosis.

Several predisposing factors for the development of postoperative AKI have been identified, which can be used to stratify risk (Table 73.7). These include emergent surgery, an elevated preoperative serum creatinine, the use of an intra-aortic balloon pump, and combined coronary artery bypass graft and valvular surgery [24]. Still, it is often difficult to prospectively identify those patients at heightened risk for perioperative AKI, especially since 40% of patients who develop AKI do not have frank perioperative hypotension or evidence of shock. Other factors appear to be important in the development of AKI. For example, aprotinin, an antifibrinolytic agent used until recently to decrease perioperative blood loss in cardiac surgery patients, tends to increase AKI and postoperative mortality [25]. Prolonged cardiopulmonary bypass appears to induce oxidative stress, embolism, and systemic inflammation, thus contributing to AKI [26]. An improved mortality and reduced incidence of AKI is observed with the use of "off-pump" technology in one large observational study [27]. Prospective, randomized trials are underway to study the effects of the off pump cardiac surgery.

A number of methods have been used to try to protect kidney function in patients undergoing surgery. Administration of "low-dose" dopamine has long been advocated for the prevention of AKI but has fallen out of favor due to the lack of efficacy [28]. A meta-analysis of fenoldopam, a selective dopamine receptor agonist, demonstrated a reduction in mortality and the need for dialysis in cardiac surgery patients [29]. A large, randomized, prospective trial of preventive role of fenoldopam is underway. Nesiritide, a recombinant human B-type natriuretic peptide, which increases diuresis, natriuresis, and afterload reduction, was studied in a double-blind, randomized trial of 300 patients with mostly preserved renal function undergoing coronary artery bypass graft surgery [30]. The use of nesiritide was associated with improved postoperative serum creatinine and reduced length of hospital stay as compared with the placebo. Nevertheless, significant concerns remain regarding the safety of nesiritide, especially in patients with acute decompensated heart failure (ADHF) and reduced renal function (discussed later in the chapter). Several other strategies, including perioperative *N*-acetylcysteine and mannitol administration, have not been shown to be effective for the prevention of postoperative AKI [31,32]. The use of calcium channel blockers, ACE

TABLE 73.7

A CLINICAL SCORE TO PREDICT AKI REQUIRING DIALYSIS AFTER CARDIAC SURGERY

Risk factor	Points
Female gender	1
Congestive heart failure	1
Left ventricular ejection fraction <35%	1
Preoperative use of intra-aortic balloon pump	2
Chronic obstructive pulmonary disease	1
Diabetes requiring insulin	1
Previous cardiac surgery	1
Emergency surgery	2
Valvular surgery only	1
Coronary artery bypass graft surgery plus valvular surgery	2
Other cardiac surgeries	2
Preoperative serum creatinine 1.2 to <2.1 mg/dL	2
Preoperative serum creatinine ≥2.1 mg/dL	5

Minimum score, 0; maximum score, 17. Risk of development of AKI requiring dialysis increases with higher score. Frequency of AKI requiring dialysis for score of 0–2 point is 0.5%, 3–5 points is 2%, 6–8 points is 8%, 9–13 points is 22%.
From Thakar CV, Arrigain S, Worley S, et al: A clinical score to predict acute renal failure after cardiac surgery. *J Am Soc Nephrol* 6:162, 2005.

inhibitors, or diuretics has been disappointing in this context as well [33]. In fact, perioperative furosemide use has been associated with detrimental effect on renal function after cardiac surgery [34]. Furosemide should be used only in patients with definite volume overload.

Prevention of postoperative renal failure still hinges on withdrawal of vasopressors as early as safely possible and maintenance of adequate perioperative intravascular volume. Identification of modifiable risk factors for the prevention of postoperative AKI is paramount. A retrospective study of 3,500 patients identified three potentially modifiable risk factors associated with AKI after cardiac surgery, such as preoperative anemia, perioperative RBC transfusions, and the need for surgical reexploration [35].

Cardiogenic Shock and Acute Decompensated Heart Failure

Our understanding of "cardiorenal syndrome" is evolving beyond the concept of low cardiac output causing renal dysfunction. We know that approximately half of patients with ADHF have preserved left ventricular function [36]. In the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE), optimization of hemodynamics did not prevent AKI, further suggesting that reduction in cardiac output does not fully explain the development of impaired renal function [36].

A complex bidirectional relationship emerges, whereby heart failure and associated renal dysfunction affect each other. In addition to the traditional hemodynamically mediated AKI due to low cardiac output, the heart and the kidney are simultaneously affected by activation of the sympathetic nervous and renin–angiotensin–aldosterone systems. Such activation results in systemic vasoconstriction, salt and water retention, and volume overload, further exacerbating kidney dysfunction and heart failure. In addition, the immune system affects renal and cardiac function through monocyte-mediated endothelial activation, cytokine release, and apoptosis induction [16,17,37]. Furthermore, CKD, a risk factor for coronary artery disease [38], contributes to volume overload, diuretic resistance, and poor prognosis in CHF [39] and ADHF [36]. Here, we will focus on acute ADHF with AKI as a common clinical problem in the ICU setting.

ADHF is frequently complicated by AKI. The Acute Decompensated Heart Failure Registry (ADHERE) of more than 30,000 patients with ADHF suggests that AKI has poor prognostic implications and predicts mortality in this patient group [40]. In one study, more than a quarter of patients with ADHF developed AKI as defined by a rise in serum creatinine of 0.3 mg per dL. However, even this relatively small rise was associated with 7.5-fold increase in hospital mortality [41].

Traditional treatment strategies of ADHF include diuresis, afterload reduction, and administration of inotropic agents. However, these patients are frequently diuretic resistant and hypotensive. The use of ACE inhibitors is often limited by AKI and hyperkalemia. Recently, nesiritide, a recombinant B-type natriuretic peptide, was approved for management of symptomatic ADHF [42]. However, a meta-analysis of five randomized clinical trials in more than 1,200 patients with ADHF suggested nesiritide was associated with worsening of renal function [43]. New trials are ongoing to further investigate the risk and benefit of nesiritide. Tolvaptan, a vasopressin antagonist, has been studied in a large international randomized trial of more than 4,000 heart failure patients [44]. Tolvaptan was statistically better then placebo at improving dyspnea, edema, and weight loss but did not significantly improve the rate of death and rehospitalization for heart failure.

Inotropic agents such as dobutamine and milrinone are used in the treatment of ADHF. Dobutamine acts primarily on β_1-adrenergic receptors, with minimal effects on β_2 and α_1 receptors. Dobutamine increases cardiac output and stroke volume and decreases systemic vascular resistance and pulmonary capillary wedge pressure. The 2004 ACC/AHA STEMI guidelines suggest using dobutamine in patients with hypotension who do not have clinical evidence of shock [45]. Milrinone is a phosphodiesterase inhibitor that increases myocardial contractility, reduces systemic vascular resistance, and improves left ventricular diastolic relaxation. However, inotropes increase myocardial oxygen consumption and can worsen myocardial ischemia, and their use has been limited by arrhythmia development and adverse outcomes. In a large prospective, randomized trial, milrinone infusion was associated with increased hypotension and atrial arrhythmias as well as a trend toward increased mortality [46]. The use of inotropes is limited to patients with ADHF and low cardiac output who fail or cannot tolerate diuretic and vasodilator therapy. Additional information on the use of inotropes can be found in Chapter 33 of the "Cardiovascular Problems and Coronary Care" section.

Other strategies for diuretic-resistant patients with ADHF include mechanical fluid removal with ultrafiltration or paracentesis. The use of ultrafiltration in the ICU setting is discussed in "Renal Replacement Therapies" section of the text. Mullens et al. suggested that elevated intra-abdominal pressures in ADHF may play a role in the pathogenesis of renal dysfunction [47]. The reduction of intra-abdominal pressure from approximately 13 to 7 mm Hg by paracentesis was associated with a reduction in serum creatinine from 3.4 to 2.4 mg per dL in diuretic-resistant patients.

Sepsis

Sepsis is among the most common causes of AKI. In one large series of patients with ATN, sepsis was believed to be the cause in 15%, with a mortality rate of 40% [48]. The association between septicemia and AKI is confounded by the experience that renal dysfunction due to other causes is often complicated by infection. Although the incidence of sepsis in patients with AKI has been reported as high as 75% [49], only one third of patients have clinically apparent septicemia at the outset of renal dysfunction [50].

AKI may develop in a setting of sepsis through multiple mechanisms. As discussed previously, inflammation appears to play a significant role. In animal models, sepsis can cause renal impairment even in the absence of hypotension [51]. Clinically, it is likely that endotoxin causes a reduction in GFR through hemodynamic mechanisms, including vascular pooling and renal vasoconstriction, which are mediated by local vasoconstrictors such as thromboxane and endothelin. Although cardiac output is often elevated in patients with sepsis, systemic vasodilation coupled with renal vasoconstriction can shunt perfusion away from the kidneys. Vascular pooling and third spacing generally necessitate volume expansion with isotonic saline. Because myocardial suppression, oliguria, and capillary leakage may accompany sepsis, it is essential to monitor the administration of fluids closely.

Pancreatitis

Pancreatitis may occur in association with various causes of AKI but can itself induce ATN. This is a rare phenomenon and is generally seen in patients with severe or hemorrhagic pancreatitis with serum amylase values of more than 1,000 U per L. Mortality may approach 70% to 80% in this setting, especially in those with multiorgan failure.

Trauma

AKI associated with severe trauma generally reflects the combination of acute volume depletion, hemorrhage, and

myoglobinuria (see following discussion). Survival after trauma is markedly reduced when complicated by AKI.

Acute Bilateral Cortical Necrosis

Acute bilateral cortical necrosis is rare. Unlike ATN, in which only tubular elements are involved, in acute cortical necrosis, glomeruli and tubules are destroyed by a process in which cortical vessels may be occluded with fibrin thrombi. Cortical necrosis usually occurs after profound hypotension. Approximately two thirds of cases are related to obstetric complications, including abruptio placentae, preeclampsia and eclampsia, septic abortion, and amniotic fluid embolism [52]. Nonobstetric cortical necrosis is most common in shock, sepsis, and disseminated intravascular coagulopathy, but isolated cases have been reported with snakebites [53], arsenic ingestion [54], and hyperacute renal allograft rejection [55]. The pathogenesis of AKI in these conditions involves the hemodynamic insults of hypoperfusion and renal vasoconstriction and formation of fibrin thrombi in the renal microvasculature.

Typically, patients with bilateral cortical necrosis have anuric AKI. Although the diagnosis may be suspected early in the course of renal injury, ATN remains far more likely. When renal function fails to recover after several weeks, cortical necrosis may be confirmed by a renal biopsy. Other diagnostic tests are less specific. Renal scintigraphy most often demonstrates complete absence of isotope in the region of the kidneys. Computed tomography (CT) with contrast enhancement may demonstrate similar findings, indicating absence of perfusion to the renal cortex. Renal angiography shows patency of the main renal arteries and either a complete absence of cortical filling or a mottled nephrogram. Given the severity of the inciting disorder, mortality is high in acute cortical necrosis, with fewer than 20% of patients surviving. At least 25% of survivors eventually require maintenance dialysis [50].

Nephrotoxicity and Drug-Induced Acute Kidney Injury

Many cases of AKI in the ICU can be linked to the effects of endogenous and exogenous nephrotoxins.

Myoglobinuria and Hemoglobinuria

Rhabdomyolysis is often associated with leakage of myocyte contents, particularly the pigment protein myoglobin, into the plasma. Myoglobin, with a molecular weight of approximately 17,000 daltons, is freely filtered by the glomerulus. In the distal nephron, myoglobin forms proteinaceous casts that obstruct urine flow. Myoglobin may also exert direct cytotoxic effects on tubular epithelium through the generation of reactive oxygen species.

Myoglobinuric AKI is a consequence of massive skeletal muscle injury of diverse causes. Traumatic rhabdomyolysis occurs in the setting of direct mechanical injury (crush syndrome), burns, or prolonged pressure. Myoglobinuric renal failure is an important cause of morbidity in virtually all wide-scale human catastrophes. Indeed, much of what is known about the syndrome derives from experiences with victims of wars and natural disasters. Crush injuries during the Armenian earthquake of 1988 necessitated emergent mobilization of dialysis resources on a massive scale [56].

Nontraumatic rhabdomyolysis can occur with toxic, metabolic, and inflammatory myopathies, vigorous exercise, severe potassium and phosphate depletion, and hyperthermic states such as the neuroleptic malignant syndrome and malignant hyperthermia. Lipid-lowering drugs currently represent one of the most common causes of rhabdomyolysis. The use of heroin and amphetamines [57,58] has been reported in association with rhabdomyolysis.

As with other forms of AKI, the prognosis depends largely on the gravity of the predisposing condition; AKI following massive trauma can be expected to run a longer course than that associated with nontraumatic causes, such as drugs. In particularly severe cases, oliguria and dialysis dependence may persist for weeks.

Clinical signs and symptoms of muscle injury, such as muscle tenderness, are absent in at least half of cases of significant nontraumatic rhabdomyolysis. The diagnosis is suggested by markedly elevated serum levels of muscle enzymes with serum creatine kinase levels usually higher than 5,000. The serum levels of phosphate and potassium are also typically elevated in rhabdomyolysis because lysis of muscle cells causes release of intracellular contents into the blood. A fall in the serum calcium is quite common. Rebound hypercalcemia often occurs during the recovery phase.

The therapy of myoglobinuria is similar to that of other forms of AKI, but there are several particular considerations. The tubular toxicity of myoglobin is enhanced when urine flow rates are low, urine is concentrated, and urinary acidification is maximal. It is therefore important in the early phases of the illness to ensure that the patient is in a volume-replete state and maintaining a rapid diuresis (i.e., urine output of at least 150 mL per hour). To this end, isotonic fluids may be administered. Most experts recommend the administration of bicarbonate-rich fluids to alkalinize the urine above a pH of 6.5 so as to improve the solubility of myoglobin. Diuresis may be enhanced with concurrent administration of loop diuretics. Some have argued that loop diuretics may introduce the potentially adverse effect of increasing urinary acid excretion and have advocated the use of osmotic diuretic agents such as mannitol [59]. Mannitol, however, has the potential drawback of causing intravascular volume overload in patients whose kidneys may already have impaired urine output.

Hemoglobinuria can also result in AKI. The pathophysiologic mechanisms are similar to those involved in myoglobinuric AKI. Hemoglobinuric renal failure is relatively rare. Hemoglobin, with a molecular weight almost four times that of myoglobin, is less readily filtered. Furthermore, when hemoglobin is released into the plasma, it binds to haptoglobin, forming a bulky, nonfilterable molecular complex. Only when the haptoglobin binding capacity is saturated (at plasma hemoglobin concentrations >100 mg per dL) does hemoglobin appear in the tubular fluid. Thus, only massive intravascular hemolysis, as may occur with fulminant transfusion reactions, autoimmune hemolytic crises, and mechanical hemolysis [60] from a dysfunctional prosthetic heart valve (Waring blender syndrome), can induce AKI.

Radiocontrast-Induced Nephropathy

The administration of intravascular radiocontrast agents leads to a syndrome of rapidly developing AKI. Contrast-induced nephropathy (CIN) is commonly defined as an absolute increase in serum creatinine of 0.5 mg per dL or a relative increase of 25% from the baseline within 48 to 72 hours of contrast exposure. The serum creatinine level begins to rise 12 to 24 hours and peaks approximately 4 days after the procedure [61]. Some patients develop a transient increase in urine output as a result of contrast-induced osmotic diuresis, followed by oliguria. The majority of patients are nonoliguric and do not require dialysis. Some, but not all, studies identified an increased mortality risk in patients with CIN [62–64]. In patients who have undergone endovascular procedures, CIN must be differentiated from atheroembolic disease, which has a significantly worse prognosis (discussed below).

TABLE 73.8

RISK FACTORS ASSOCIATED WITH RADIOCONTRAST NEPHROPATHY

Preexisting renal insufficiency
Diabetic nephropathy, with renal insufficiency
Volume depletion
Diuretic use
Large contrast dose (>2 mL/kg)
Age >60 y
CHF
Hepatic failure
Multiple myeloma (with high osmolar contrast agent)
Use of intra-aortic balloon pump

TABLE 73.9

PREVENTIVE MEASURES FOR RADIOCONTRAST NEPHROPATHY

Volume expansion with normal saline or isotonic bicarbonate (3 mL/kg bolus over 1 h prior to the procedure, followed by 1 mL/kg/h for 6 h postexposure)
Limit radiocontrast load to ≤1 mL/kg in high-risk patients
Avoid high osmolar contrast agents
Discontinue diuretics, ACE inhibitors, and nonsteroidal anti-inflammatory drugs for 24 h postprocedure
N-acetylcysteine (4 doses of 600–1,200 mg PO every 12 h with 2 doses before and 2 doses after procedure)

Prospective studies report that the incidence of radiocontrast-induced kidney injury ranges from 1% to more than 50%. Some of this variance in frequency can be attributed to the disparity in the definitions of AKI, the number of associated risk factors, and the type of procedure performed [65]. The incidence appears to be low in patients with normal renal function, even in the presence of diabetes. Preexisting CKD, however, particularly in patients with diabetes, confers a 6- to 10-fold increased likelihood of radiocontrast-induced AKI [66,67]. Contrast-enhanced CT is associated with a lower risk of CIN as compared with coronary angiography. Noncoronary angiography had the highest incidence of CIN in a study of 660 military veterans, reaching 15% in patients with GFR less than 60 mL per minute per 1.73 m^2 [68]. Other risk factors are listed in Table 73.8.

There are several mechanisms by which radiocontrast-induced renal injury may develop. Hemodynamic factors are believed important, as contrast exposure causes initial vasodilation followed by prolonged vasoconstriction of the renal circulation. The finding of a low FE_{Na} in some patients with contrast-induced AKI and the tendency toward rapid recovery suggest a role for reversible vasoconstriction. The intensity and duration of the vasoconstriction may be influenced by the underlying characteristics of the renal microcirculation. Endothelial factors that promote vasoconstriction of preglomerular vessels, such as endothelin, may participate in the pathogenesis of radiocontrast-induced nephropathy [11,69]. Tubular adenosine receptors appear to be stimulated by radiocontrast agents in animal models [70,71]. Adenosine induces afferent glomerular vasoconstriction and reduction in GFR. However, the protective effect of theophylline, an antagonist of adenosine receptors, was not statistically significant in the meta-analysis of available trials of CIN prevention [65]. Other postulated mechanisms of radiocontrast-induced nephropathy include the generation of reactive oxygen species and the direct cytotoxic effect of the contrast media, especially with highly osmolar agents [72].

Because there is no specific treatment for radiocontrast-induced nephropathy other than supportive measures, attention has focused on methods of prevention. The best preventive measure is avoidance of radiocontrast and use of an alternative noncontrast imaging procedure if at all possible.

A number of prophylactic measures (listed in Table 73.9) have been promoted. Experimental data and retrospective clinical studies suggest that radiocontrast injury is augmented by preexisting hypovolemia, particularly in the presence of prostaglandin inhibitors [73–76]. Therefore, modest hydration before the procedure and avoidance of diuretics and NSAIDs are justifiable.

Reports suggest that pharmacoprophylaxis of radiocontrast nephropathy may be possible. In a German study, *N*-acetylcysteine (NAC) was given to patients with CKD once before and once after they underwent angiography. The incidence of radiocontrast nephropathy in these patients was 2%, compared with 9% in an untreated control group. Both groups received concomitant hydration, and low-osmolality contrast medium was used [77]. Some, but not all, subsequent studies have confirmed these results [78,79]. Maranzi et al. [80] compared two different regimen of NAC in patient undergoing emergent angioplasty for STEMI. Patients receiving a high dose of NAC (1,200 mg IV prior to procedure, followed by 1,200 mg orally for four more doses) had a significantly lower incidence of CIN. The benefit of NAC remains controversial as conflicting results continue to emerge from other studies [65,81]. However, NAC appears to be a low risk intervention and is frequently used. We typically give NAC 1,200 mg orally for two doses before and two doses after the contrast exposure.

A nonpharmacologic prophylactic intervention of current interest is urinary alkalinization. In the study by Merten et al. [82], increases in serum creatinine of greater than 25% of the baseline level were significantly less likely to occur in patients receiving isotonic sodium bicarbonate (three 50-mEq ampules of sodium bicarbonate in 1 L of 5% dextrose in water administered at a rate of 3 mL per kg per hour for 1 hour before and at 1 mL per kg per hour for 6 hours after the radiocontrast exposure) than in control patients. A recent study of 326 patients at medium to high risk for CIN compared various strategies of prevention, including volume expansion with isotonic bicarbonate versus normal saline. This study suggested that isotonic bicarbonate may be more effective than normal saline [83]. Another randomized, controlled trial of 500 patients undergoing coronary angiography demonstrated no benefit of bicarbonate (3 mL per kg per bolus, followed by 6-hour infusion at 1 mL per kg per hour) over normal saline (1 mL per kg per hour for 12 hours before and after contrast exposure) [84]. There is no consensus on the best type of fluid for volume expansion due to conflicting data from other trials [85,86]. However, no clear risk of bicarbonate use has been demonstrated. We commonly use isotonic bicarbonate bolus, 3 mL per kg over 1 hour before administration of contrast agent, followed by 1 mL per kg per hour infusion for 6 hours after procedure.

Fenoldopam, a vasodilatory analog of dopamine initially thought to be protective against radiocontrast-induced nephropathy, has recently been shown to be without benefit [87].

Low-osmolality radiocontrast formulations (600 to 800 mOsm per kg) have been shown to be less nephrotoxic then high osmolar agents (>1,400 mOsm per kg) and are now commonly used in all patients [88]. However, iso-osmolar agents, such as iodixanol, have not been shown to have a clear additional benefit as compared with low-osmolar agents in three

small, randomized, controlled trials [89–91] of patients undergoing contrast enhanced CT and coronary angiography.

Removal of contrast media by hemodialysis or hemofiltration to prevent CIN was studied in several small trials. A meta-analysis of these trials revealed no benefit and even suggested harm. The relative risk of CIN in that study was 1.35 (CI, 0.93 to 1.94) [92]. Three subsequent clinical trials yielded conflicting information [93–95]. Taken together, these data cannot justify the routine use of prophylactic extracorporeal modalities following radiocontrast exposure.

Acute Phosphate Nephropathy

Oral sodium phosphate (OSP) is a hyperosmolar laxative used in preparation for colonoscopies and bowel surgery. OSP causes severe hyperphosphatemia, especially in those with underlying reduced kidney function and volume depletion. A transient AKI occurring immediately after phosphate OSP administration is likely the result of hemodynamic alterations due to volume depletion and may not represent a true acute phosphate nephropathy (APN). AKI occurring days to weeks after OSP administration is likely caused by increased intratubular phosphate concentration, calcium phosphate precipitation, tubular obstruction, and direct tubular injury. Biopsy findings in these patients reveal calcium phosphate deposition in the tubules and interstitium, as well as interstitial inflammation and ATN [96].

The incidence of APN is uncertain due to heterogeneity of the study population, variability in the definition of AKI, and underrecognition of the condition. The largest observational study of almost 10,000 patients who underwent colonoscopy with OSP preparation revealed 114 cases of AKI, which was defined as 50% increase in serum creatinine within 1 year [97]. In another retrospective study, the incidence of AKI following OSP was 6.3%, which was associated with the use of ACEI and ARBs [98].

The prognosis of APN is poor, since kidney function rarely recovers completely. Most patients are left with CKD or progress to ESRD. In the study by Hurst et al. sited above, creatinine returned to baseline in 16 of 114 patients [97]. However, since no biopsies were performed, those who recovered may have had ATN without APN.

There is no specific treatment for APN. OSP should be avoided in patients with reduced kidney function for whom polyethylene glycol is the preferred bowel purgative. It is essential to maintain adequate intravascular volume prior to the procedure, particularly in the elderly, patients with diabetes, hypertension, or those who use medications that reduce renal perfusion such as NSAIDs or ACEI/ARBs [99].

Hydroxyethyl Starch

Hydroxyethyl starch (HES) is a colloid volume expander used in the ICU setting. The mechanism of HES-induced AKI is not completely understood. Most types of HES preparations have a molecular weight between 130 and 200 kDa which result in delayed renal clearance. HES administration is associated with an osmotic tubular injury, increased inflammation, and interstitial fibrosis in an isolated porcine renal perfusion model [100]. A multicenter, randomized trial by Schortgen et al. [101] compared HES with a gelatin-based colloid and found a higher incidence of AKI in the HES group. Although this trial was criticized for its methodology, another prospective trail of 537 patients with sepsis demonstrated a higher incidence of AKI and requirement for renal replacement therapy after HES treatment as compared with a group given lactated Ringer's solution [102]. Lower molecular weight HES may not have the same nephrotoxicity as the higher molecular weight compounds [103] but should be used with caution.

Abdominal Compartment Syndrome

A variety of critical illness can lead to the intra-abdominal hypertension (IAH) and abdominal compartment syndrome (ACS), such as intra-abdominal hemorrhage, peritonitis, or "third spacing" of fluid into the abdominal cavity associated with abdominal surgery, ileus, or pancreatitis, as well as overdistention with gas following laparoscopy. IAH is defined as an intra-abdominal pressure of more than 12 mm Hg measured by a bladder transducer on three separate occasions at least 4 hours apart. ACS is defined as an intra-abdominal pressure of more than 20 mm Hg, associated with one or more organ system failure [104]. The increase in intra-abdominal pressure leads to visceral ischemia, including AKI. The precise incidence of AKI resulting from ACS is unknown but appears underreported [105]. Treatment usually requires urgent surgical decompression of the abdomen.

Drug-Induced Syndromes

Hospitalized patients, particularly those in ICUs, are exposed to numerous pharmacologic agents. Since many drugs are capable of inducing abnormalities in renal function, the appearance of AKI in any patient should prompt the clinician to investigate a possible drug-related cause. Drug-induced AKI has four major syndromes (Table 73.10).

Acute Tubular Injury. Acute tubular injury syndrome is caused by drugs with direct nephrotoxic effects; the renal tubular epithelium is most often affected. Such agents include aminoglycoside antibiotics, heavy metals, certain cephalosporins, and amphotericin B [106]. The incidence of tubular injury varies among these drugs and ranges from 10% to 15% for tobramycin, from 20% to 30% for gentamicin, and as high as 50% for cisplatin. The new antiviral agent foscarnet has been found to have an incidence of nephrotoxicity of up to 65% [107]. Volume contraction, preexisting CKD, and liver disease enhance the risk of drug-induced tubular injury. Logically, the risk of nephrotoxicity is reduced by ensuring that patients are well hydrated before therapy. If possible, nonnephrotoxic therapeutic alternatives should be sought in patients with underlying renal and hepatic disease.

Tubular injury is almost always reversible after withdrawal of the inciting agent, although recovery may take several days to 2 weeks. Occasionally, specific renal tubular functional abnormalities may persist; these include magnesium and

TABLE 73.10

SYNDROMES OF DRUG-INDUCED KIDNEY INJURY

Acute tubular injury
Aminoglycoside antibiotics
Cephalosporin antibiotics
Antifungal agents (amphotericin)
Antiviral agents (foscarnet)
Heavy metals (cisplatin)
Intratubular microobstruction
Methotrexate
Acyclovir
Sulfamethoxazole
Dextran
Acute interstitial nephritis (see list in Table 73.13)
Autoregulatory failure
Angiotensin-converting enzyme inhibitors
Nonsteroidal anti-inflammatory drugs

potassium wasting, renal tubular acidosis, and mild impairment of renal-concentrating ability.

Intratubular Microobstruction. A second form of acute nephrotoxicity is caused by drugs that precipitate in and obstruct the nephrons. Such agents are generally poorly soluble at low pH, as characterizes the distal tubular fluid. This syndrome has been reported in patients receiving relatively high doses of intravenous methotrexate, acyclovir, low-molecular-weight dextran, and sulfamethoxazole. It has also been described in the setting of oral therapy with NSAIDs such as sulindac. Other NSAIDs, presumably because of their uricosuric properties, can precipitate tubular blockade with uric acid crystals, in a manner analogous to that of the tumor lysis syndrome (see following discussion).

Prevention of microobstructive AKI necessitates optimal hydration of the patient and maintenance of a high urine flow rate. Urinary alkalinization may be of benefit, depending on the nature of the obstructing agent. The syndrome is usually readily reversible and short lived.

Acute Interstitial Nephritis. An enlarging list of drugs has been associated with the syndrome of AKI accompanied by allergic manifestations such as skin rash, noninfectious fever, and eosinophilia (Table 73.11). As an allergic phenomenon, AIN has a more variable course than do syndromes of direct nephrotoxicity. Clear dose-risk relationships are lacking, and cases may vary widely in the time of onset following exposure to the inciting agent (days to years), the severity of the renal injury, and the time required for reversal following withdrawal of the drug (days to months). In addition to hematuria and pyuria, the urine sediment may show a preponderance of eosinophils [108,109]. White blood cell casts are a common finding (Fig. 73.2). The pathogenesis of AKI in this disorder is poorly understood. The renal histopathology early in the course of the disease shows mainly interstitial infiltration with inflammatory cells, often (but not always) eosinophils.

Although steroids have never been shown to reduce morbidity in a controlled trial, most experts use them in severe cases of AIN (i.e., those in which supportive dialysis may become necessary). See the Treatment section for more details on management of AIN.

A variant form of AIN is occasionally encountered in patients who take NSAIDs, particularly fenoprofen, meclofenamate, tolmetin, and indomethacin. The hallmarks of allergy, drug rash, eosinophilia, and eosinophiluria are absent. The urinalysis is nonspecific; some cases are marked by nephrotic range proteinuria. The renal pathology shows interstitial inflammation and normal-appearing glomeruli. As with classic allergic interstitial nephritis, this disorder regresses after cessation of therapy with the offending agent. Patients who have had this disorder should probably be considered at risk for recurrence with other NSAIDs [8].

TABLE 73.11

DRUGS MOST OFTEN IMPLICATED IN ACUTE INTERSTITIAL NEPHRITIS

- Antibiotics
  - Penicillinase-resistant penicillins
  - Cephalosporins
  - Ampicillin
  - Amoxicillin
  - Penicillin G
  - Sulfonamides and sulfa-trimethoprim
  - Rifampin
  - Ethambutol
  - Tetracycline
- Diuretics
  - Furosemide
  - Thiazides and related compounds
- Nonsteroidal anti-inflammatory drugs
  - Ibuprofen
  - Indomethacin
  - Fenoprofen
  - Naproxen
  - Phenylbutazone
  - Mefenamic acid
  - Tolmetin
- Miscellaneous drugs
  - Diphenylhydantoin
  - Cimetidine
  - Methyldopa
  - Allopurinol
  - Captopril

Hemodynamic or Autoregulatory Failure. The final form of drug-related AKI pertains to drugs that cause abnormalities of glomerular blood flow. Two pathophysiologic subsets of hemodynamically mediated AKI may be identified, depending on whether the main action of the drug is on the afferent or efferent glomerular arteriole. When the medication increases afferent vasoconstriction, autoregulation of renal blood flow is impaired, and prerenal azotemia develops. This effect may be seen in association with NSAIDs, which reduce the synthesis of vasodilatory prostaglandins [110], or drugs that directly constrict the preglomerular vessels (i.e., vasopressors and possibly radiocontrast agents). When preglomerular vasoconstriction is severe and prolonged, frank ischemic tubular necrosis may result. More often, a rapidly reversible, prerenal form of AKI occurs.

The other subset of hemodynamically mediated, drug-induced renal failure is seen in association with ACE inhibitors, which block the formation of angiotensin II from angiotensin I. In addition to their role as antihypertensives, these are commonly used as afterload reducers for the treatment of congestive heart failure. When used in this setting, they may engender an improvement of renal perfusion, as reduced peripheral vascular resistance leads to reduced left ventricular impedance. Under conditions of attenuated and fixed renal blood flow, however (as would occur with bilateral renal artery stenosis), ACE inhibitors may cause a sharp reduction in GFR [9,111].

These syndromes are encountered almost exclusively in patients with significant underlying impairment of renal perfusion or function. Unless severe renal ischemia has occurred, renal function should rapidly return to baseline levels after withdrawal of the responsible drug.

Renal Vascular Disease

Major Renal Vascular Disease

Renal vascular disease is divisible into major vascular and microvascular syndromes. Major renal vascular disease is an unusual cause of AKI. In a prospective series from a major teaching hospital, renal artery occlusion accounted for only 1 of 129 reported cases of AKI [14]. Renal artery occlusion does not produce AKI unless it is bilateral or occurs in a solitary functioning kidney. The sudden appearance of flank pain and a rising serum creatinine should lead the physician to consider acute renal artery embolism or thrombosis. The differential diagnoses in this scenario include nephrolithiasis, pyelonephritis (with or without urinary obstruction), and renal vein

thrombosis (RVT). Pain, however, is not a sine qua non of renal artery occlusion. In a series of cases of renal artery embolism, 5 of 17 patients experienced no flank or abdominal pain [112].

Renal artery emboli occur most frequently in the setting of cardiac disease, particularly in patients with arrhythmias or mural cardiac thrombi. Frequently, multiple organs are involved, including brain, lung, and spleen. AKI is more likely to occur with a distribution of emboli to both kidneys, although azotemia has been reported with a unilateral embolus [112].

If the thrombus or embolus involves a solitary functioning kidney, oligoanuria and a rising level of azotemia can be expected. In a series of 17 cases of renal embolism, 15 patients experienced a rising serum creatinine. Seven of nine patients in whom urine volumes were recorded were either anuric or oliguric [112]. In addition to flank pain and diminished urine volume, at least 50% of patients experience nausea or fever, or both. The urinalysis is not specific. Leukocyturia, hematuria, and low-grade proteinuria have been found, as has a bland urine sediment. Radionuclide scanning often demonstrates patchy uptake of isotope or, in the case of total occlusion, no isotopic uptake. CT may demonstrate similar findings of diminished contrast uptake either by the whole kidney or localized wedge-shaped areas of nonperfusion.

Accurate diagnosis of renal arterial disease requires radiologic imaging. Renal artery duplex scan may reveal the absence of Doppler signal if total occlusion occurs, but provides only limited anatomical information if stenosis is present. The renal artery duplex is not as sensitive or specific for the diagnosis of stenosis as compared with angiography or magnetic resonance arteriography. Angiography provides the most accurate anatomic information, but it is also the most invasive test.

Occlusion of the renal artery does not inevitably lead to infarction. Particularly in patients with slowly developing atherosclerotic disease, collateral circulation via capsular or ureteric vessels may protect the kidney from infarction even though renal arterial blood flow is inadequate to maintain function. Surgery may be preferable in patients with renal artery thrombosis, although supportive care with anticoagulation has been the preferred treatment for renal arterial embolism. Recent reports of successful treatment with fibrinolytic agents (either urokinase or streptokinase) have led some to consider this the preferred treatment for renal artery occlusive disease, particularly in patients for whom surgery represents too great a risk.

Renal Vein Thrombosis

RVT is an uncommon cause of AKI. Bilateral renal vein occlusion occurs most commonly in severe dehydrated children. In adults, it usually accompanies nephrotic syndrome or may occur in patients with renal cell carcinoma. Hypercoagulable conditions, sickle cell disease, pregnancy, use of oral contraceptives, or trauma may also cause RVT. RVT generally does not cause AKI unless it is acute and bilateral or occurs in a solitary kidney. Flank pain and microscopic hematuria are the usual clinical manifestations in acute RVT. Duplex venography and CT scan can often establish the diagnosis and are less invasive than radiocontrast renal venography. Treatment usually consists of anticoagulation, although fibrinolytic therapy should be considered in patients with AKI and RVT.

Atheroembolic Renal Disease (Cholesterol Emboli)

Atheroembolic renal disease is increasingly recognized as a cause of AKI; it is probably still underdiagnosed. Atheroembolic disease is often found on postmortem examination. It is important to distinguish this syndrome from renal arterial thromboembolism.

Cholesterol embolization occurs only in patients with severe aortic atherosclerosis, usually after trauma to the wall of the aorta such as with aortography, major vascular surgery, or blunt trauma to the abdomen [113]. Atheroemboli may also occur spontaneously, particularly in patients with diabetic macrovascular disease and those receiving anticoagulant therapy. Diffuse occlusion of the microvasculature by atheroemboli leads to tissue damage in either a subacute or acute fashion. Patients may experience relatively minor abnormalities such as infarction of the tip of a single toe. Renal involvement is particularly common when diffuse embolization accompanies major arteriography or aortic surgery. Involvement of other visceral organs, including the pancreas, bowel, spleen, retina, and brain, may also occur. Typically, the cholesterol emboli form needlelike occlusions in small vessels, which then develop a chronic inflammatory response that can include the formation of a granulomatous reaction [113]. Extensive infarction of bowel or sudden neurologic abnormalities may bring the patient to the ICU, where, in addition to the presenting findings, AKI is noted. In the kidney, occlusion of a sufficient proportion of the microvasculature results in varying degrees of azotemia. The azotemia may be sudden, after the precipitating event, or may develop more slowly and may follow a stuttering course marked by acute deterioration with intervening periods of incomplete recovery. The latter course helps to distinguish this diagnosis from that of radiocontrast nephropathy, which typically occurs within 24 to 48 hours after arteriography.

The diagnosis is often missed unless there are peripheral signs of involvement such as blue distal digits or livedo reticularis of the lower extremities. A more subtle and less frequently observed physical manifestation is the finding of visible cholesterol emboli in the retinal vessels (Hollenhorst plaques). Less specific manifestations include peripheral eosinophilia and hypocomplementemia. The urine sediment is nonspecific.

Patients with atheroembolic renal disease experience the full spectrum of renal dysfunction, from minor degrees of azotemia to full-blown, irreversible renal failure. After an initial rise in serum creatinine, there may be an improvement in GFR over several weeks, probably attributable to nephron adaptation with hyperfiltration in remnant glomeruli. No specific management is available for atheroembolic renal disease. Management of renal failure, including dialytic therapy, may be indicated. Use of anticoagulants may worsen this condition.

Thrombotic Microangiopathies

Thrombotic microangiopathies are a group of disorders associated with AKI. These disorders can be seen in the ICU setting and include TTP, hemolytic uremic syndrome (HUS), scleroderma renal crisis, malignant hypertension, and antiphospholipid antibody syndrome. AKI, thrombocytopenia, and microangiopathic hemolytic anemia are common clinical features of these disorders. Histologically, occlusion of the preglomerular and glomerular microvasculature by platelet microthrombi is observed and accounts for the rapid deterioration in renal function. Clinical and histopathologic features of malignant hypertension are seen occasionally.

TTP and HUS, which were previously thought of as the same entity with different clinical presentation, are now considered separate diseases based on different pathogenesis [114]. TTP often presents with a pentad of fever, thrombocytopenia, microangiopathic hemolytic anemia, AKI, and neurological abnormalities. In TTP, an abnormally enlarged von Willebrand Factor (vWF) leads to platelet activation and aggregation, microthrombi formation, and ischemia. This disorder is linked to a diminished activity of a vWF cleaving protein belonging to a family of zinc metalloproteinases called ADAMTS (a disintegrin and metalloprotease with thrombospondin type 1 repeat). Decreased activity or mutations of ADAMTS13 protein are observed in recurrent and familial forms of TTP [115]. TTP can also be seen with certain infections, such as HIV. Several

medications are associated with TTP, including clopidogrel, cyclosporine, and chemotherapeutic agents, such as cisplatinum, bleomycin, and others (for additional details, see Chapter 114).

In HUS, hematological and renal features predominate, and ADAMTS13 activity is normal. HUS is associated with a variety of infectious diseases, such as enteric infections, particularly with *Escherichia coli* 0157:H7, Mycoplasma, Legionella, and Coxsackie A and B viruses. Clinical presentation of HUS has a diarrheal and a nondiarrheal form. In the diarrheal form, a Shiga-like toxin is postulated to cause AKI by entering the circulation, binding to the proximal tubular cells as well as arteriolar and glomerular capillary endothelium and causing inflammation and platelet activation. The pathogenesis of the nondiarrheal form is not well understood. A rare familial form of nondiarrheal HUS exists, which is characterized by loss of activity of complement factor H. A deficiency in prostaglandin I2, abnormalities in coagulation cascade, and endothelial cell damage have been implicated in some forms of nondiarrheal HUS [116–118].

Treatment of thrombotic angiopathies varies greatly. TTP is a medical emergency, requiring prompt and aggressive plasmapheresis and plasma exchange to provide the missing enzyme and to remove vWF cleaving protein inhibitor. If untreated, mortality reaches to 90%. Treatment of HUS is largely supportive. There is no proven benefit to plasmapheresis, factor H replacement, or the use of fibrinolytics and antithrombotic agents in HUS [119,120]. See Chapter 114 of "Hematologic and Oncologic Problems in the Intensive Care Unit" section for further discussion of TTP and HUS and their treatment.

Autoimmune diseases associated with thrombotic microangiopathies are discussed in the Rheumatology section. Briefly, the mainstay of therapy for antiphospholipid antibody syndrome, which is frequently associated with SLE, is anticoagulation. Scleroderma renal crisis is treated with ACE inhibitors. See Hypertension chapter for the discussion of malignant hypertension.

Acute Kidney Injury in the Cancer Patient

AKI is a relatively common complication in patients with neoplastic diseases. Many malignancies cause hypercalcemia, a well-defined cause of AKI. Hypercalcemia may induce AKI through alterations in renal hemodynamics (afferent arteriolar vasoconstriction and diminished GFR) and by causing volume depletion. The pathogenesis and therapy of hypercalcemia of malignancy are described in greater detail in Chapters 106 and 118.

The term *tumor lysis syndrome* refers to the sudden release of tumor cell contents in response to induction chemotherapy. These intracellular products include phosphates, uric acid, and other purine metabolites. They may cause diffuse tubular microobstruction once they enter the nephron, which results in sudden onset of AKI. The syndrome occurs almost exclusively in patients with hematologic and lymphoproliferative malignancies, especially when the tumor cell mass is large and cell turnover high. Patients at risk for this syndrome should routinely receive prophylaxis before the initiation of chemotherapy, including volume expansion and pretreatment with allopurinol or rasburicase. Rasburicase, a recombinant uricolytic enzyme product, has been introduced to prevent severe hyperuricemia in this setting. The value of alkalinizing the urine by administration of bicarbonate is debatable. The increased urine pH achieved has the advantage of promoting the conversion of uric acid to urate which has increased solubility. However, alkalinization may promote the precipitation of calcium and phosphate in various soft tissues including the kidney. To date, there are no studies showing improved outcomes with alkalinization [121].

A reasonable approach would be to limit hydration with bicarbonate-based solutions to patients with tumor lysis syndrome who also have a significant metabolic acidosis [122]. Of note, once the tumor lysis syndrome becomes established, the resulting oliguria and AKI may further complicate therapy. This often requires a delicate balance between continued hydration and intermittent diuretics to maintain urine output and to avoid volume overload.

A number of commonly used antineoplastic agents have renal side effects and can cause AKI. Principal among these is cisplatin, which, like other heavy metals, can induce ATN [123]. The incidence of this complication is less with the newer analog carboplatin. Saline loading of patients who are about to receive platinum-containing chemotherapeutic agents helps reduce the risk of AKI. High-dose (>2 g per day) methotrexate therapy can cause AKI; the mechanism is believed to be tubular microobstruction from intraluminal crystallization of methotrexate metabolites. As is usually the case with renal injury syndromes that arise through this mechanism, maintenance of a forced diuresis is usually effective prophylaxis.

Many neoplasms involve the ureteric bed or periureteric lymph nodes. Obstructive uropathy must be considered in any case of unexplained AKI in an oncologic patient, particularly one with lymphoma or with prostatic, colorectal, or cervical carcinoma. Such obstructions are usually readily detectable by ultrasonographic examination. If the sonogram fails to detect hydronephrosis but obstruction is strongly suspected, further imaging can be completed to determine the patency of the ureters. These tests may include CT Urogram, MR Urogram, and retrograde cystoureterography. One must carefully consider the patient's GFR and their ability to receive various contrast solutions before selecting a test. In cases in which urethral obstruction is confirmed, nephrostomy drainage is often required. Ureteral stents can be considered but may fail if extrinsic compression remains present. Regardless, such drainage measures may only be needed temporarily in tumors that respond sufficiently to radiation or chemotherapy [124].

Multiple myeloma is a neoplasm that is especially frequently complicated by AKI. Patients with this disease may develop renal injury from several mechanisms. Hypercalcemia is very common in myeloma. In addition, the paraproteins, particularly light chains (Bence-Jones proteins), can be directly nephrotoxic. Finally, filtered paraproteins can form occlusive casts within the urinary space (cast nephropathy).

Tumor infiltration of the renal parenchyma is an unusual cause of AKI, despite the frequency of metastases to the kidneys. Imaging studies should reveal kidney enlargement. Successful reversal with radiation or chemotherapy is unusual. Decisions regarding the use of dialysis in patients with widespread metastatic disease must be based on a realistic appraisal of the prognosis of the underlying disease and on the patient's wishes.

Renal Dysfunction in Patients with Liver Disease

Renal dysfunction is extremely common in patients with advanced liver disease. The most common renal syndrome associated with liver disease is prerenal azotemia. Circulatory redistribution associated with portal hypertension, hypoalbuminemia, and neurohumoral influences that are active even in the incipient stages of liver disease combine to reduce renal perfusion. In addition, evidence has also been shown that the increase in intra-abdominal pressure due to ascites may exert an adverse effect on renal hemodynamics. The balance between control of ascites and peripheral edema and prevention of prerenal azotemia may be difficult. Patients with progressive prerenal azotemia are typically initially managed by holding

diuretics. In patients who do not respond to this therapy or in individuals with more severe intravascular depletion, volume expansion with normal saline can be used. In patients with edema and ascites, albumin may be given to avoid further exacerbating volume overload. In patients with significant anemia, packed RBCs may be the ideal form of colloid. Despite adequate volume expansion, a subgroup of patients may not respond to this therapy and will go on to be diagnosed with hepatorenal syndrome (HRS).

Endless debate has centered around the proper definition of the HRS and its specific relationship to prerenal azotemia. In general, HRS can be considered a form of prerenal azotemia, associated with severe hepatic dysfunction, that is not responsive to an "adequate" volume challenge. It is usually seen in advanced cirrhosis, but it has also been reported in patients with acute hepatitis [125] or hepatic neoplasm [126,127]. Onset of the syndrome may be sudden or insidious. Type 1 HRS is defined as at least a 50% lowering of creatinine clearance to a value less than 20 mL per min or at least a twofold increase in serum creatinine to a level of greater than 2.5 mg per dL in less than a 2-week period [128]. In contrast, type 2 HRS is a chronic process that results in a slow decline in GFR over months to years. A more specific definition has been published by the International Ascites Club as detailed in Table 73.12 [129].

The pathogenesis of the HRS can be explained by a complex set of events that initially starts with the development of portal hypertension in a patient with liver injury. The increase in portal pressure causes the release of local vasodilators, which result in splanchnic arterial vasodilation. The decrease in vascular resistance in the splanchnic beds leads to a drop in systemic perfusion pressure. The body responds with compensatory activation of the sympathetic nervous system and the renin–angiotensin system that in turn results in severe vasoconstriction in the renal cortex and diminished GFR. This explanation is supported by the following findings: (i) The kidney's ability to retain salt and water suggests a hemodynamic alteration rather than parenchymal injury. (ii) Postmortem angiography of hepatorenal kidneys demonstrates severe vasoconstriction within the renal cortex (Fig. 73.4). (iii) Finally, the process can reverse when the involved kidney is transplanted into a recipient with normal liver function.

The vasodilatation in the splanchnic vascular beds that initiates HRS has been the target of several therapies including combined treatment with midodrine and octreotide. Midodrine (a selective α_1-adrenergic agonist) and octreotide (a somastatin analog) work together to increase vascular resistance in the

TABLE 73.12

DEFINITION OF HEPATORENAL SYNDROME [129]

- Cirrhosis with ascites
- Serum creatinine >1.5 mg/dL
- No improvement of serum creatinine after 2 d with diuretic withdrawal and volume expansion with albumin. The recommended dose of albumin is 1 g/kg of body weight per day up to a maximum of 100 g/d
- Absence of shock, ongoing bacterial infection, current or recent treatment with nephrotoxic drugs, gastrointestinal or renal fluid loss
- Absence of parenchymal disease as indicated by proteinuria <0.5 g/d, microhematuria (>50 red blood cells per high power field) no abnormalities on renal ultrasound.

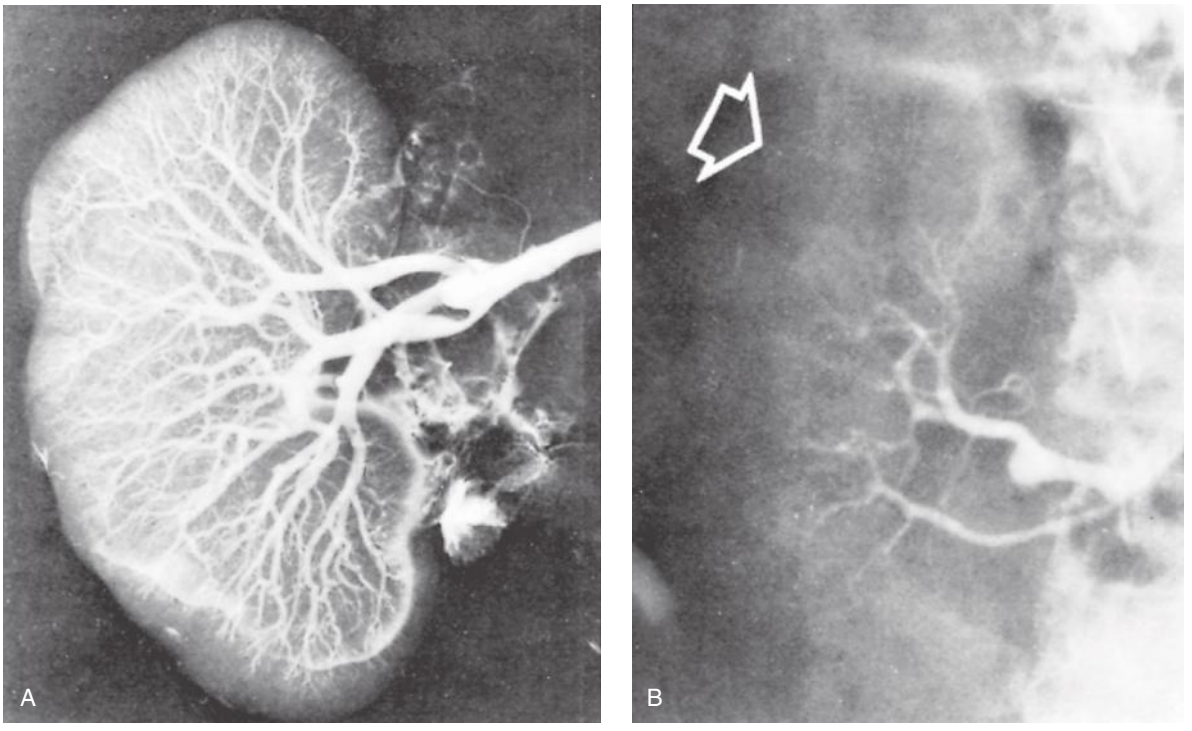

FIGURE 73.4. Angiographic pattern in hepatorenal syndrome with severe renal cortical vasoconstriction. Premortem (**A**) and postmortem (**B**) angiograms of a representative patient are shown. The arrow points to severe cortical vasoconstriction; it is a process that appears to reverse when the involved kidney is transplanted into a hepatically intact host. [Reprinted from Battle DC, Arruda JA, Kurtzman NA: Hyperkalemic distal renal tubular acidosis associated with obstructive uropathy. *N Engl J Med* 304:373, 1981, with permission].

splanchnic beds, which in turn decreases the ongoing renal vasoconstriction present in patients with HRS [130,131].

Midodrine (started at 10 mg orally three times a day) and octreotide (started at 100 μg subcutaneously three times a day) are often combined with albumin with the goal of increasing mean arterial blood pressure by 15 mm Hg. Other therapies such as epinephrine and vasopressin analogs, such as terlipressin, have been used. These therapies have not been evaluated in large clinical trials, and concerns regarding both safety (especially for ischemic complications) and effectiveness remain [132,133].

Hepatic disease predisposes patients to ATN of the other causes (i.e., nephrotoxic drug exposure, radiocontrast exposure, hypotension, and sepsis). Patients with severe hepatic disease often have one or more of these risk factors. Furthermore, hyperbilirubinemia may predispose to AKI through the actions of bile on renal tubules [134] and the renal and systemic hemodynamics [135]. Although the urinary sediment in most cases of ATN is distinctive, showing renal tubular epithelial cells and muddy brown granular casts, jaundiced patients without tubular necrosis may manifest pigmented granular casts simply as a direct result of the interaction of bilirubin with tubular cells [134]. The diagnosis of ATN can be further complicated by the finding of a low FE_{Na}. Patients with ATN typically have a FE_{Na} of greater than 2% as a result of tubular injury impairing sodium reabsorption. Because of the extreme nature of sodium avidity in the setting of cirrhosis, patients may have a FE_{Na} of less than 1% despite renal tubular injury.

Management of cirrhotic patients with sodium and volume overload is extremely challenging. Cirrhotic patients are in a tenuous physiologic state; they have little tolerance for small deviations, either positive or negative, from their optimal state of fluid balance. In both prerenal and hepatorenal states, urinary sodium excretion is reduced (usually <20 mEq per day). Sodium balance must be regulated with dietary restriction or diuretics, or both, if ascites and edema are to be controlled. When oliguria develops in patients with advanced cirrhosis, conventional therapy may fail to achieve adequate diuresis. High doses of intravenous diuretics, in combination or as continuous infusions, can be used. Since aldosterone appears to play a significant role in the sodium retention of cirrhosis, spironolactone may be a useful adjunct in diuretic therapy. Although patients with significant peripheral edema can often tolerate as much as a net diuresis of 3 L per day, those with ascites but no edema should be managed more cautiously to avoid AKI.

In patients with significant ascites that is refractory to diet and diuretic therapy, large volume paracentesis (LVP) can help alleviate abdominal pressure and reduce respiratory symptoms. Patients can have up to 4 L of peritoneal fluid removed safely with paracentesis, but simultaneous albumin infusions (8 g of albumin per liter removed) should be administered in patients undergoing larger volume removal to avoid hypotension and possible AKI [136–138]. Although LVP does offer the convenience of rapid resolution of ascites, it does lead to protein loss and carries the risk of procedural complications.

Peritoneovenous shunts, such as the Denver and LeVeen shunts, have been used to infuse ascitic fluid into the central circulation. While reversal of the HRS [139] and recovery can occur after portosystemic [140,141] or peritoneovenous [142–149] shunting procedures, overall results have been mixed [150]. In light of the high perioperative complication rate and the lack of data showing increased survival, the procedure is rarely used. Repetitive paracentesis remains a much more commonly employed method of palliating ascites.

The biochemical abnormalities that characterize AKI in the patient with hepatic disease are the same as those found in other settings, with a few special considerations. Azotemic patients with hepatic failure have increased metabolic substrate for ammonia production and therefore are at heightened risk for encephalopathy. Potassium depletion, a common electrolyte imbalance in cirrhosis, further enhances ammonia synthesis. Since cirrhosis is often associated with diminished perfusion pressure, hyponatremia may develop in response to increased antidiuretic hormone (ADH) levels and decreased capacity to excrete free water. Patients with significant hyponatremia should have their water intake restricted to less than 1,500 mL per day.

Acid–base disturbances are common and varied in patients with advanced hepatocellular disease. Respiratory alkalosis can occur as a result of increased progesterone levels stimulating hyperventilation. The use of diuretics as well as the presence of secondary hyperaldosteronism can cause a metabolic alkalosis that can aggravate hepatic encephalopathy. As plasma pH rises, ammonium ions lose protons to the plasma; the resulting ammonia penetrates the blood–brain barrier more readily.

Although the finding of metabolic alkalosis is common, acid–base disturbances can rapidly change in the cirrhotic patient. Patients with diarrhea may develop a nonanion gap acidosis. Or in patients with severe hypotension, a high anion gap metabolic acidosis related to lactic acid may develop. Lactic acidosis may be particularly severe in patients with liver disease because extraction and metabolism of lactic acid from the blood depend largely on hepatic function. In patients with a metabolic alkalosis, the subsequent development of a metabolic acidosis may be missed, as the bicarbonate may be in the normal range. This is a particularly treacherous combined acid–base disturbance because a near-normal serum pH may belie the true extent of the acidosis. As the acidosis worsens, the pH may plummet because of depletion of the bicarbonate buffer system, deficiencies of protein buffers, and inability to maintain adequate respiratory compensation.

DIAGNOSIS OF ACUTE KIDNEY INJURY

History and Physical Examination

Because the symptoms of renal injury are nonspecific, the history provided by the patient is not always of diagnostic help. In patients with CKD, the history may be useful in establishing whether renal dysfunction is truly a progressive, long-standing problem versus AKI. For example, a patient with long-standing loss of appetite and pruritus is more likely to have CKD than AKI. In these cases, the background information often elicits evidence of previous renal or urinary abnormalities such as hypertension, proteinuria, or a history of diabetes mellitus. A thirsty patient, or one in whom daily weight loss has been documented, may have volume depletion causing prerenal azotemia. The avenues of fluid loss are usually identifiable. Exposure to nephrotoxic agents or a recent episode of sustained hypotension suggests the possibility of ATN. Symptoms of renal colic, abnormal voiding pattern, or a history of genitourinary malignancy point toward an obstructive cause.

The physical examination often furnishes some diagnostic information, particularly regarding volume status. Diminished skin turgor, sunken eyes, dry mucous membranes, the absence of axillary sweat, or orthostatic hypotension supports a diagnosis of prerenal azotemia. In disorders characterized by reduced effective circulatory volume, such as congestive heart failure and nephrotic syndrome, prerenal azotemia may exist in the setting of an expanded extracellular volume. Hypertension in patients with AKI should raise suspicion of intrinsic renal disease. The clinician must be alert for signs of systemic disease that can cause acute renal injury, including vasculitis, endocarditis, and sepsis. Bladder distention and prostatic enlargement point to an obstructive cause. A full discussion of

relevant history and physical findings for the different causes of AKI is beyond the scope of this chapter.

Urine Tests

The laboratory workup should commence with a urinalysis. The measurements of urine osmolality, electrolytes, and creatinine concentration are simple and useful, particularly in differentiating between ATN and prerenal azotemia. Urine specific gravity can be measured at the bedside while the results of the more accurate urine chemistry tests are pending. A high urine specific gravity generally correlates with a concentrated urine and is expected in prerenal azotemia, except in the presence of diuretics.

The familiar dipstick tests provide a readily available method for determining whether the urine contains protein or heme pigments. When positive, they should raise the suspicion of intrinsic renal pathology. As the dipstick test for protein measures only albuminuria, Bence-Jones proteins will not be detected. Light chains can be made to precipitate in urine by adding sulfosalicylic acid to the specimen and heating it to 60°C.

Formed elements in the urine sediment yield invaluable information about the nature of AKI, particularly in intrinsic renal disease. The significance of hematuria, pyuria, renal tubular epithelial cells, and casts in the urine has already been discussed. The presence of RBC casts distinguishes the hematuria associated with glomerulonephritis from that of postrenal or urologic causes. Broad and waxy casts suggest that renal disease is chronic. Virtually any lesion that can cause obstruction in the genitourinary tract can produce hematuria. Crystalluria often occurs in association with obstruction due to renal calculi or medications

The FE_{Na} can indicate the degree of renal sodium avidity, which generally reflects renal perfusion. A value of less than 1% typically indicates prerenal azotemia. However, this test can be confounded by concomitant diuretic therapy, common situation in critically ill patients. In these situations, the FEUrea can be used instead, since urea clearance is unaffected by diuretics. The FEUrea is calculated via the same formula, but substituting urea for sodium and a value of less than 35% is suggestive of renal hypoperfusion (see Table 73.13 for additional details [151–154]).

Blood Tests

Clearly, measurement of the BUN and creatinine is essential to identifying and monitoring AKI. As noted, the ratio of BUN to creatinine carries some diagnostic value, as a high value (>20:1) may indicate prerenal azotemia. Serial blood chemistries will help identify acid–base and electrolyte disturbances common with AKI (discussed later in the chapter). Anemia may suggest underlying CKD. Eosinophilia frequently accompanies AIN.

Specialized serologic tests may help answer specific diagnostic questions. The presence of antinuclear antibodies is consistent with autoimmune nephropathy such as lupus nephritis or scleroderma, both of which may cause AKI. The serum protein electrophoresis or immunoelectrophoresis may aid in the diagnosis of multiple myeloma, which may present as AKI of uncertain cause [155].

Estimates of GFR may be helpful in assessing the severity of AKI as well as for adjusting medication dosages. However, these formulas have limited utility in the early phases of AKI, since the calculations are based on the assumption that serum creatinine reflects a steady state. For example, the creatinine of a patient with AKI from complete loss of renal blood flow will take many days to rise to steady state even though the GFR is negligible from the outset. Estimates of GFR in the first few days will grossly overestimate the patient's residual renal function. See Table 73.13 for equations used to estimate GFR.

TABLE 73.13

FORMULAS FOR ESTIMATING RENAL FUNCTION

Fractional Excretion of Sodium (FE_{Na}) [151]

The FE_{Na} is the proportion of the filtered load of sodium excreted:

$$FE_{Na} = U_{Na}/P_{Na} \times P_{cr}/U_{cr} \times 100$$

Urine sodium (U_{Na}) and plasma sodium (P_{Na}) are expressed as millimoles and urine creatinine (U_{cr}) and plasma creatinine (P_{cr}) are expressed as milligrams per deciliter.

Cockcroft–Gault equation [152]

Creatinine clearance (CrCl) can be estimated by using the Cockcroft and Gault formula which uses the patient's age and body weight, where weight is expressed in kilograms and plasma creatinine (P_{cr}) is expressed as milligrams per deciliter:

$$C_{cr} = (140 - \text{age}) \times \text{weight}/(P_{cr} \times 72)$$

Abbreviated MDRD equation [153]

A series of derivations based on data from the MDRD study have yielded several equations that more accurately represent GFR serum creatinine concentration (SCr) measured in milligrams per deciliter.

$$\text{GFR, in mL/min per 1.73 m}^2 = 186.3 \times \text{SCr}^{(\exp[-1.154])} \times \text{age}^{(\exp[-0.203])} \times (0.742 \text{ if female}) \times (1.21 \text{ if black})$$

CrCl determined by 24-h urine collection [154]

CrCl can be estimated by collecting a urine sample for 24 h. This formula tends to overestimate the true GFR by at least 10% and some cases significantly more, as some of the creatinine in the urine is derived from tubular secretion.

Urine creatinine (U_{cr}) and plasma creatinine (P_{cr}) are expressed as milligrams per deciliter. U_v is 24-h urine volume in mL.

$$\text{CrCl mL/min} = (U_{cr} \times U_v)/(P_{cr} \times 1{,}440)$$

GFR, glomerular filtration rate; MDRD, Modification of Diet in Renal Disease.

Radiography

Various radiographic techniques may contribute to the evaluation of AKI. The abdominal flat plate (kidneys and urinary bladder) is an easily obtained study that can help establish the presence and size of both kidneys. If both kidneys are small, azotemia may be of a chronic nature. Radiopaque stones may be identified on abdominal plain films.

Renal ultrasonography, a safe, quick, high-yield procedure, is probably the first radiologic test that should be ordered in the evaluation of any azotemic patient. It permits the identification and measurement of both kidneys and is very sensitive for detecting obstructive uropathy (Fig. 73.5). Helical CT, with or without contrast, is a versatile and high-yield technique for establishing the size of the kidneys and recognizing hydronephrosis (Fig. 73.6). The contrast agent administered during the test can itself produce severe impairment of renal function in patients with renal insufficiency, hypovolemia, or multiple myeloma. It should therefore be avoided when any of these conditions is suspected. Magnetic resonance imaging

TABLE 73.14

PREDIALYSIS MANAGEMENT OF ACUTE KIDNEY INJURY

Fluid balance
- Weigh patient daily
- Monitor input and output
- In volume-depleted patients, replace extracellular fluid with isotonic saline (or bicarbonate)
- In normovolemic or edematous patients, restrict fluid intake (~1,500 mL/d) and sodium intake (≤2 g/d)

Acid–base and electrolyte
- Avoid water overload and hyponatremia (restrict free water intake, particularly in oliguric patients)
- Restrict potassium intake (≤2 g/d) and treat hyperkalemia (see Chapters 73 and 74)
- Maintain serum bicarbonate ≥12 and 15 mM
- Use phosphate binders ($CaCO_3$) to maintain PO_4 ≤5.0 mg/dL
- Treat symptomatic hypocalcemia (see text)

Drugs
- Avoid nephrotoxins when possible
- Adjust doses of all renally excreted drugs
- Withhold nonsteroidal anti-inflammatory drugs and angiotensin-converting enzyme inhibitors in patients with prerenal conditions
- Avoid magnesium-containing drugs (e.g., antacids, milk of magnesia)

Nutrition
- Restrict protein intake to ≤0.5 g/kg/d
- Caloric (carbohydrate) intake of ≥400 kcal/d

Reduction of infectious risks
- Remove indwelling urinary catheter in oliguric, nonobstructed patients
- Strict aseptic technique and rapid removal, when feasible, of vascular catheters

offers similar data as helical CT but is less commonly used because of cost and availability. The use of gadolinium contrast should be avoided, if possible, in the setting of AKI due to the risk of nephrogenic systemic fibrosis.

Retrograde pyelography is reserved for patients in whom urinary tract obstruction is strongly suspected despite the inability to confirm this finding on other imaging techniques. It is

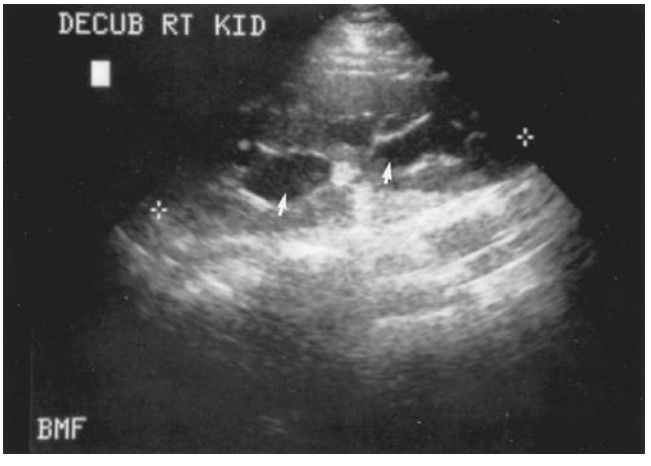

FIGURE 73.5. Sonogram with right hydronephrosis. Kidney poles are marked by crosses. Dark, echolucent areas (*arrows*) in the center represent dilated collecting system.

FIGURE 73.6. Computed tomographic scan with right hydronephrosis. **Left:** Unobstructed kidney is shown for comparison. Note enlarged pelvocaliceal system on right (*arrowhead*).

generally performed in anticipation of relieving such obstructions as soon as they are identified, usually by placement of ureteral stents.

Isotopic renal scanning provides a safe means for locating the kidneys and allows estimation of their functional capacity. Radionuclide flow studies can be used to assess the rapidity of uptake of tracer by the kidneys. A delay in uptake helps to establish the diagnosis of impaired renal perfusion, whether due to structural renovascular disease or functionally impaired renal blood flow. Prolonged retention of radioisotope by the kidneys is suggestive of outflow obstruction. Radioisotopic scanning may be particularly helpful in assessing patients with prolonged AKI for the absence of blood flow and the possible diagnosis of cortical necrosis or renal infarction (Fig. 73.7).

Renal artery duplex scanning offers an alternative method of assessing renal arterial flow. Although noninvasive, the test requires significant operator expertise. In rare instances where a vascular lesion is strongly suspected, CT angiogram or even full renal arteriography may be necessary. Arteriography is more invasive but offers the opportunity for immediate therapeutic intervention such as angioplasty or vascular stenting.

Renal Biopsy

Renal biopsy is reserved for patients who are thought to have parenchymal renal disease. The indications for renal biopsy are a matter of some controversy, but the procedure should be considered when (a) azotemia is of recent onset and unknown cause; (b) there is a possibility that the patient has a renal disease that may require drug treatment (e.g., steroids or cytotoxic drugs) as with patients with probable glomerulonephritis, vasculitis, or AIN; (c) heavy proteinuria or nephrotic syndrome is present; or (d) the biopsy result might be of prognostic importance.

COMPLICATIONS AND TREATMENT OF ACUTE KIDNEY INJURY

General Principles of Treatment

The predialysis management of AKI is outlined in Table 73.14. These steps are applicable to any patient with AKI and are quite

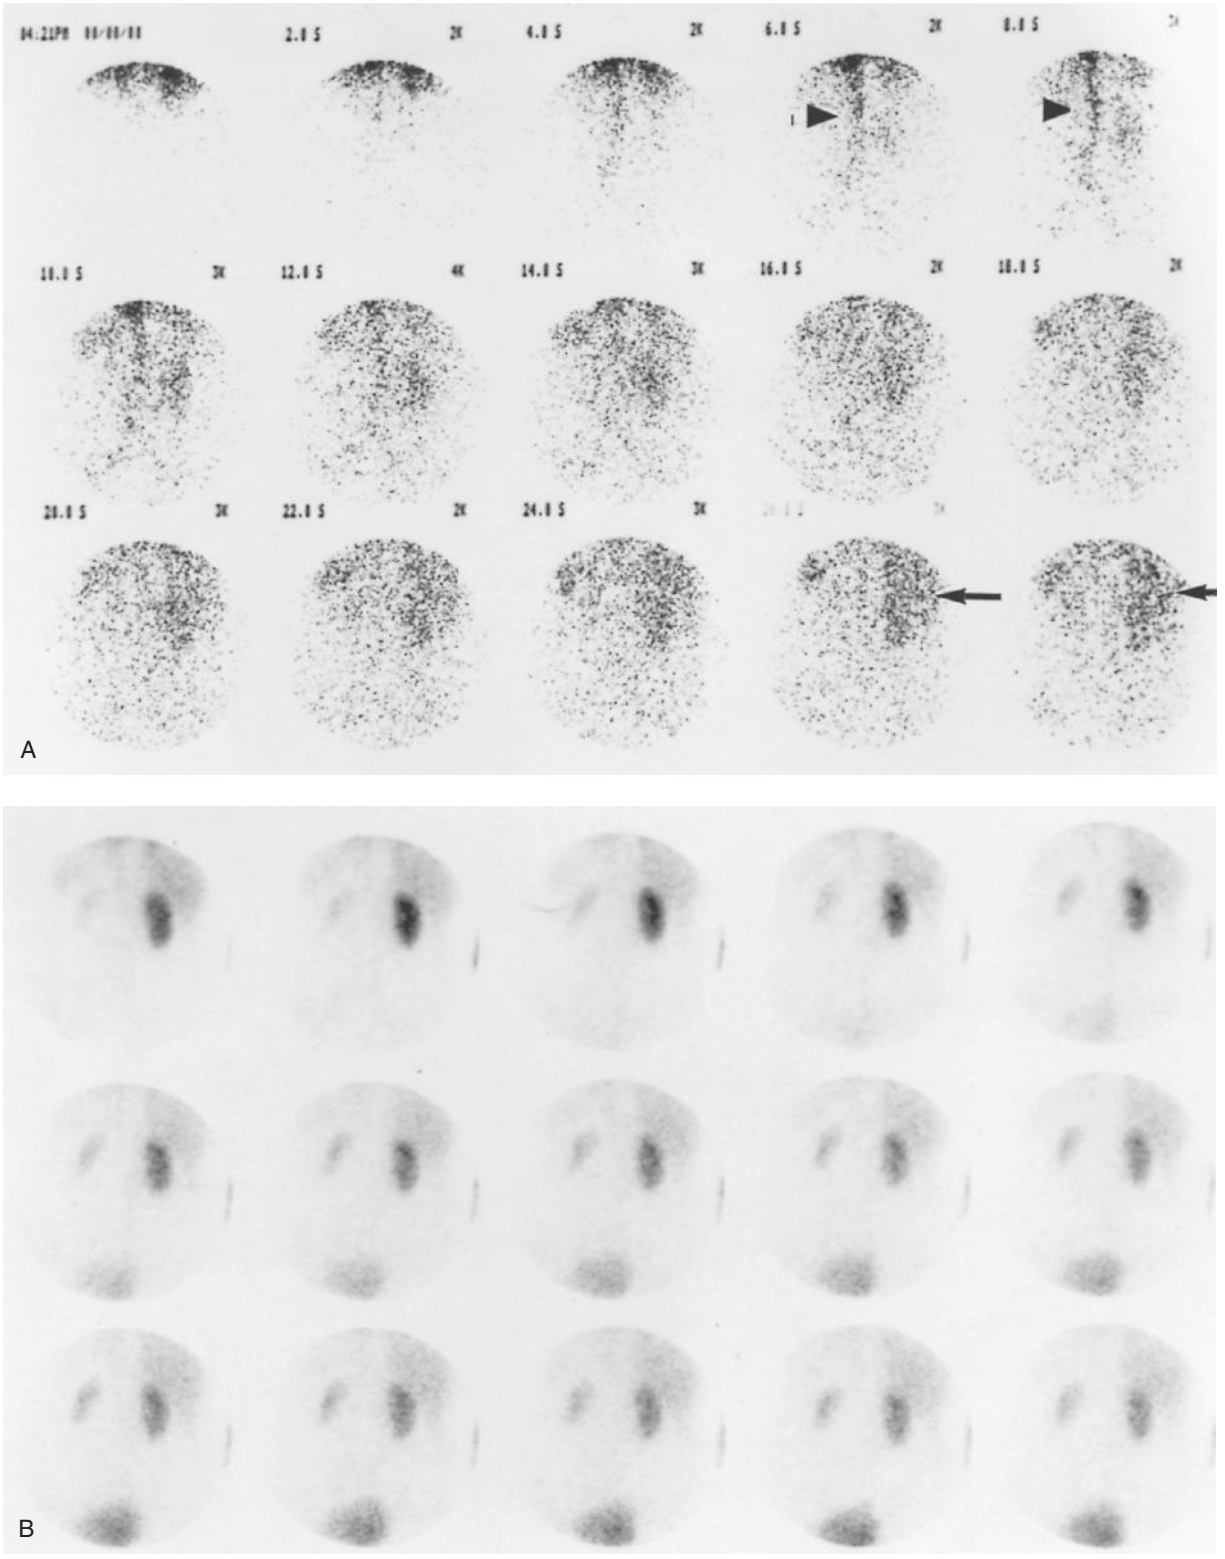

FIGURE 73.7. Renal radioisotopic scan with myelin-associated glycoprotein-3 demonstrating poor uptake of tracer in patient with left renal artery occlusion. **A:** Early flow phase in which each panel represents a 2-second interval. Scintigraphic activity is seen in proximal aorta (*arrowheads*) and right kidney (*arrows*). Note the absence of scintigraphic activity over the area of left kidney. **B:** Functional scan (1-minute intervals). Note marked diminution of scintigraphic activity over the area of the left kidney.

TABLE 73.15

SUMMARY OF EVIDENCE-BASED ADVANCES IN MANAGEMENT OF RENAL FAILURE

Topic	Findings	Reference
Causes of AKI	Meta-analysis of five randomized clinical trials in >1,200 patients suggested nesiritide was associated with worsening of renal function in patients with acute decompensated heart failure.	[43]
	Prospective trial of 537 patients with sepsis demonstrated a higher incidence of AKI and the need for renal replacement therapy in hydroxyethyl starch as compared with lactated Ringer's group.	[102]
	Oral sodium phosphate bowel purgative is associated with acute kidney injury in the observational study of 10,000 patients and should be avoided in patients with reduced kidney function in whom polyethylene glycol is the preferred bowel purgative.	[99]
Prophylaxis of radiocontrast nephropathy	In a randomized, prospective study of 78 patients with chronic renal insufficiency undergoing angiography, hydration with 0.45% saline exerted a protective effect; diuretics neutralized this effect	[76]
	In a randomized, placebo-controlled, prospective trial with 83 patients, acetylcysteine administered pre- and postradiography appeared to reduce risk.	[77]
	A randomized, double-blind, placebo-controlled trial of 200 patients with chronic kidney disease undergoing coronary angiography showed a protective effect of acetylcysteine administered orally pre- and postcontrast.	[78]
	A randomized, prospective study in 79 patients with renal insufficiency undergoing coronary angiography demonstrated no beneficial effect of prophylaxis with acetylcysteine.	[79]
	No protective effect of fenoldopam was observed in a prospective trial in which 157 patients were randomized to receive the drug and 158 patients received placebo prior to and during coronary angiographic procedures.	[82]
	In a randomized, prospective trial with 119 patients, preradiocontrast alkalinization of urine with sodium bicarbonate showed protective effect	[83]
	Saline and acetylcysteine with or without ascorbic acid with inferior to sodium bicarb with acetylcysteine in a randomized, controlled trial of 326 patients (REMEDIAL trial).	[84]
	No benefit of sodium bicarbonate vs. saline in a randomized, controlled trial of 500 patients undergoing coronary angiography.	[85]
Prophylaxis of acute tubular necrosis	In a randomized, double-blinded, placebo-controlled, multicenter trial, anaritide (atrial natriuretic peptide analog) showed no protective effect in patients with established acute tubular necrosis	[198]
	In a randomized, double-blinded, placebo-controlled, multicenter trial, recombinant insulin-like growth factor (IGF-1) showed no protective effect in patients with established ARF.	[173]

fundamental. Fluid balance should be measured during each 8-hour nursing shift with input/output recordings, and body weight should be recorded daily. Serum electrolytes and/or arterial blood gases may be needed daily or more frequently depending on the patient's status. One of the most important principles is treatment of the underlying condition that leads to the AKI. Since renal injury is most often a consequence of another primary illness, correction of that condition is essential for renal recovery. The management of AKI remains largely supportive as clinical trials of a number of agents (summarized in Table 73.15) have yielded negative or inconclusive results.

Fluid Management

Fluid management is crucial because sodium and water excretion may be limited, particularly in oliguric patients. It should not be assumed that because the patient has renal dysfunction, fluid intake must be restricted. Nonrenal losses of fluid must be carefully accounted for. While respiratory fluid losses are often minimal for patients on mechanical ventilation, insensible losses are significantly increased with high fever or dermal injury. Gastrointestinal fluid losses can be difficult to quantify. Daily weights are often the best means of assessing the net balance between intake and output.

In patients with pure prerenal azotemia attributable to hypovolemia, restoration of normal volume is usually sufficient to return BUN and creatinine to their normal levels. A normotensive, volume-depleted, azotemic patient can receive up to 1 L of saline during a 4-hour period with the expectation that renal perfusion and urine flow will improve rapidly. Volume-depleted patients with hypotension should receive more aggressive fluid resuscitation, at least until their blood pressure normalizes. This maneuver is of diagnostic as well as therapeutic benefit because rapid response to the fluid challenge establishes that azotemia is due, at least in part, to prerenal factors.

Hypovolemia may complicate intrinsic renal disease and urinary tract obstruction, superimposing a low perfusion state on the azotemia caused by these conditions. The finding of a low FE_{Na} in a patient who previously had a high FE_{Na} might indicate that, although tubular function has recovered, renal hypoperfusion persists [156]. Fluid replacement should be given using isotonic saline.

The estimate of isotonic fluid replacement should be based on the clinical findings. With orthostasis, it may be estimated that the patient is experiencing an ECF deficit of at least 10%. Fluid replacement in these circumstances should be administered regardless of the patient's urine output or the presumptive diagnosis of ATN. In either case, recovery of renal function can be hastened by rapid volume repletion.

In euvolemic patients, the following formula can be applied to estimate daily fluid requirement: daily fluid replacement (mL per day) = (urinary + extrarenal + insensible losses) − 250, where insensible losses = 500 mL per day. For febrile patients, add 500 mL per day for every degree Fahrenheit more than 101. In edematous patients requiring volume removal, the rate of diuresis should be limited to avoid exacerbating the AKI by inducing hypotension of intravascular volume depletion.

Diuretics are a mainstay of management in patients with volume overload and nonoliguric AKI. However, studies have shown no demonstrable improvement in patient survival when nonoliguric patients with AKI are treated with high-dose loop diuretics [157].

In addition, a meta-analysis of nine randomized furosemide studies to prevent or treat AKI failed to show a decreased need for dialysis or improved survival [158].

Despite the paucity of data regarding beneficial effects on renal recovery or survival, diuretics are essential for the maintenance of fluid balance in responsive patients. Loop diuretics are the principal agents and are given as intravenous bolus or through continuous infusion. However, diuretic administration may worsen renal perfusion in a patient with antecedent hypovolemia and may cause hearing loss and tinnitus in patients treated with high dosages [159]. Some data suggest that infusions are more effective and cause less toxicity [160]. Concomitant use of other diuretic agents that act at different segments of the nephron may enhance urine output. Patients with diuretic-resistant oliguria often require renal replacement therapy. This will be discussed in detail in Chapter 76.

Parenchymal Renal Disease

If renal damage occurs as a result of exposure to a drug with allergic or nephrotoxic potential, the offending agent should be withdrawn, if feasible (see Table 73.11). Although AIN usually responds to discontinuation of the culpable drug, the recovery may be protracted. The data on steroids in allergic drug-induced acute interstitial nephritis (DI-AIN) is mixed [161].

Nevertheless, the use of steroids appears to hasten recovery and reduce the likelihood of developing CKD [162]. Certainly, steroids should be considered in patients with DI-AIN associated with a significant reduction in GFR or in patients who do not promptly respond to withdrawal of the offending agent. These patients often require a renal biopsy to confirm the diagnosis. If steroids are used, the initial dose of prednisone is 1 mg per kg per day (maximum dose, 60 mg daily) for 1 to 2 weeks followed by a slow taper over 1 to 3 months, depending on the response.

The treatment of various forms of glomerulonephritis is beyond the scope of this text. Briefly, in patients with glomerulonephritis of unclear etiology, a renal biopsy may be helpful not only to aid in diagnosis but also as a means of predicting response to therapy. Specific treatment may not be required, such as in postinfectious glomerulonephritis or glomerulonephritis associated with bacterial endocarditis. In the former case, spontaneous remission usually occurs; in the latter, antibiotic treatment of the underlying condition may result in clearing of the immune complex–induced renal lesion. AKI from lupus nephritis or one of the idiopathic forms of rapidly progressive glomerulonephritis may respond to high-dose intravenous corticosteroids (pulse therapy, consisting of 1 g of methylprednisolone per day for 3 to 5 days) or a combination of oral prednisone, a cytotoxic agent (cyclophosphamide or azathioprine), and plasmapheresis [163]. The latter approach is aimed at clearing the plasma of offending antibodies (e.g., antiglomerular basement membrane antibodies), cytokines, or immune complexes while simultaneously decreasing their formation [164]. Renal injury associated with necrotizing vasculitis can be treated with corticosteroid alone, cytotoxic agents alone, or a combination of both. Cyclophosphamide is generally accepted as the treatment of choice for Wegener's granulomatosis [165].

A number of different therapies have been proposed for the treatment of ATN. Some authors have advocated the use of low-dose dopamine infusion in the treatment of established ATN. Dopamine at low doses dilates the interlobular arteries, afferent and efferent arterioles resulting in increased renal blood flow. However, recent trials have not supported its efficacy, and it is generally no longer recommended by nephrologists [166–168].

It has been speculated that the use of selective dopamine-1 receptor antagonists, such as fenoldopam, which lack α- and β-adrenergic effects, may offer better protection and treatment for AKI [169,170]. Beyond its vasodilatory actions on the renal vasculature, fenoldopam has anti-inflammatory effects that may be of particular importance in the setting of AKI. A 2007 meta-analysis of 16 randomized trials of fenoldopam versus placebo or dopamine for prevention or treatment of AKI found that fenoldopam decreased the need for renal replacement and hospital death [171]. However, because of various limitations of the study, fenoldopam is not commonly used for treatment of AKI. A large randomized study will be required to fully clarify fenoldopam's role in AKI.

A number of biopharmacologic interventions are currently being examined as potential therapeutic agents in ATN, including atrial natriuretic peptide [172], insulin-like growth factor [173], epidermal growth factor [174], and hepatocyte growth factor [175]. It has been postulated that the pathogenesis of ATN may involve inflammatory processes. Experimental data indicate that intercellular adhesion molecules (ICAMs) enable leukocytes to adhere to vascular endothelium in the kidney, from which they gain entrance to renal tissue and mediate the pathogenesis of AKI [176]. In one study, antibodies to ICAM-1 reduced inflammation and intraluminal tubular pressure in experimental renal injury [177]. In a more recent investigation, although the anti–ICAM-1 antibody prevented infiltration of the kidney by leukocytes, the course of AKI was not altered [178]. These substances have proved capable of attenuating the course of experimental toxic and ischemic AKI in animal models. In clinical trials, atrial natriuretic peptide has been shown to produce modest improvements in outcome of oliguric patients; the results, although not striking, warrant further investigation [172]. A multicenter trial of human recombinant insulin-like growth factor I failed to demonstrate any benefit to patients with AKI [173].

Treatment of Postrenal Failure

Relief of urinary obstruction is the object of therapy in postrenal AKI. Acute intervention is mandatory in the presence of complete or bilateral urinary tract obstruction, severe azotemia, or any of the metabolic or hemodynamic complications of AKI. Coexisting fever or any other evidence that urinary infection lies proximal to the obstruction requires a rapid decompression procedure to avoid bacteremic shock.

When bladder outlet obstruction is suspected, insertion of a urethral catheter should be attempted. If this is not possible, as is occasionally the case in patients with prostatic enlargement or ureteral stricture, ureteral dilation or percutaneous cystostomy should be performed. AKI due to upper urinary tract obstruction can be relieved by either the retrograde insertion of a ureteral catheter or the percutaneous placement (under ultrasonic, fluoroscopic, or CT scan guidance) of a catheter in the renal pelvis.

Obstructive uropathy is associated with defects of the distal nephron, including hydrogen ion and potassium secretion,

as well as urinary concentration. Consequently, the patient, particularly if there is prolonged high-grade obstruction, may display hyperkalemia, hyperchloremic metabolic acidosis, hypernatremia, or a combination of all three [179,180]. Water and bicarbonate replacement are often required and can be administered as a solution of 5% glucose and water to which sodium bicarbonate has been added. The patient's plasma volume and serum sodium should determine the tonicity of the administered fluid. If the patient is hypovolemic, an isotonic solution should be used. If the patient is hypernatremic, a hypotonic solution is needed. Hyperkalemia may respond to the institution of a diuresis that accompanies the relief of the obstruction and correction of the acidosis.

A diuresis often ensues after relief of urinary obstruction, particularly when prolonged. This usually reflects mobilization of urine sequestered within the dilated ureterovesicular system as well as excess ECF retained during the period of obstruction. As such, this postobstructive diuresis is considered appropriate to the preexisting volume expansion [181]. In some patients with correction of bilateral obstruction, a large diuresis and natriuresis may ensue, which result in hypovolemia and, sometimes, frank shock. The mechanism for this inappropriate diuresis is poorly understood but may involve release of a natriuretic substance [182]. These patients require fluid replacement, usually with hypotonic saline, to repair the deficit and match urinary losses. A useful technique is to measure the urinary sodium and potassium concentrations periodically to determine the composition of the replacement fluid.

Abnormal Drug Metabolism

A complete survey of all of the patient's medications should be made. Drugs, such as NSAIDs or ACE inhibitors, that may interfere with renal blood flow or GFR autoregulation should be discontinued. When possible, aminoglycoside antibiotics or other nephrotoxic drugs should be replaced with nonnephrotoxic agents. Contrast procedures should be avoided so as not to compound renal dysfunction in patients with acute or CKD. If this is not feasible, the risk should be minimized by taking prophylactic measures (see previous discussion). In addition, the dosage of drugs dependent on renal metabolism and excretion should be adjusted appropriately. Some drugs (e.g., aminoglycoside antibiotics, digoxin) are excreted almost entirely by the kidneys. If the dose or dosing interval is unchanged, reduced renal function leads to accumulation of the drug in body fluids and eventual drug toxicity. Other agents are hepatically metabolized, but the active metabolites are renally excreted (e.g., benzodiazepines). Phenytoin, independent of its excretion, may reach toxic concentrations because a larger proportion of the administered drug is displaced from albumin-binding sites in uremia. Drug doses need to be altered in most instances to account for residual renal function and the effect of dialysis on drug removal. It is important to remember that as the patient recovers renal function, upward adjustment of the dosage of renally excreted drugs is necessary. This subject is covered in detail in Chapter 75.

Nutritional Therapy

It is not our purpose to describe nutritional therapy here (see Section 15). The guidelines for nutritional therapy in AKI are similar to those in other ICU patients. Patients with AKI are often catabolic and increase their production of nitrogenous products that require excretion. The degree of catabolism reflects the level of the patient's metabolic stress and is, in turn, a function of the severity of the underlying illness. Protein and caloric requirements are much higher for patients with catastrophic illness and multiple organ system failure than for those with mild and moderate illness [183]. Although caloric replacement needs to be adequate to reduce tissue catabolism, prevent ketosis, and meet the patient's basal nutritional needs, the clinician must avoid providing excessive substrate for generation of metabolic wastes. This is particularly challenging in patients who are not yet being dialyzed; once patients are on dialysis, they are allowed a more liberal fluid intake and can receive a greater intake of carbohydrates, protein, and fat, limited only by the rate of dialytic fluid and solute removal (see Chapter 76). The use of nutritional therapy to enhance survival and recovery from AKI is controversial. Early studies suggested that recovery and survival were enhanced [184,185], but these were not confirmed by more recent controlled trials [186,187].

Hyperkalemia

Hyperkalemia is the most immediately life-threatening electrolyte imbalance encountered in patients with renal disease (see Chapter 72). In AKI, hyperkalemia arises from the inability of the kidneys to handle the excretory burden of potassium. Sources of potassium should be identified and regulated appropriately. Potassium loads may be endogenous (e.g., tissue breakdown, hematoma reabsorption) or exogenous (e.g., diet, intravenous fluids, medications). Even when the GFR is substantially reduced, the kidneys can excrete large amounts of potassium, provided that tubular secretion is intact. For this reason, hyperkalemia more often occurs in patients with parenchymal or postrenal AKI. Urine flow rate is an important determinant of tubular potassium secretion; therefore, oliguric patients are more prone to potassium imbalance than are nonoliguric patients. Many commonly used medications, including heparin, NSAIDs, and ACE inhibitors, can also inhibit tubular potassium secretion. These should be discontinued in hyperkalemic patients.

Metabolic Acidosis

The kidneys' ability to excrete metabolically produced acids may be reduced, particularly in parenchymal and obstructive disease. Because acid excretion is primarily a tubular function, the degree of acidosis may not always correlate with the degree of GFR impairment. Indeed, pure tubular acid excretion abnormalities may exist independently of azotemia (renal tubular acidosis). Metabolic acidosis that results from failure of the tubules to excrete hydrogen ions or conserve bicarbonate normally produces a hyperchloremic or low anion gap acidosis (see Chapter 71). When the GFR is severely impaired, retention of acid wastes may produce a high anion gap acidosis.

Abnormal Salt and Water Metabolism

Although most fluids administered to patients are hypotonic, plasma osmolality normally remains within tightly fixed limits. The process by which plasma tonicity is preserved depends on the suppression of vasopressin release and the formation of free water in the ascending limb of the loop of Henle. This latter function is impeded whenever GFR is reduced, which results in water retention and hyponatremia. Conversely, some renal disorders are characterized by failure to conserve water. This situation, referred to as *nephrogenic diabetes insipidus*, is most common in tubulointerstitial disease and in partial obstruction of the urinary tract. Patients with these disorders are prone to dehydration and hypernatremia. The subject is covered in more detail in Chapter 72.

Abnormal Calcium and Phosphorus Metabolism

The ability of the kidney to excrete phosphorus normally is impaired when the GFR falls to approximately one third of normal. High serum phosphorus levels lead to formation of insoluble calcium phosphate salts, which may precipitate in soft tissue. If the product of the serum calcium and phosphorus concentrations exceeds 70, precipitation in soft tissues becomes more likely. For this reason, administration of calcium to patients with AKI should be reserved for emergent situations, such as the appearance of tetany, seizures, or refractory hypotension. The tendency toward hypocalcemia with AKI may be additionally aggravated by the injured kidneys' failure to form 1,25-dihydroxycholecalciferol, although vitamin D therapy is rarely required in cases of AKI.

Hyperphosphatemia is common in patients with AKI, particularly in patients with rhabdomyolysis or tumor lysis syndrome. Phosphate binders are typically initiated when phosphate levels rise to more than 6.0 mg per dL. The main phosphate binders available include aluminum hydroxide, calcium salts (calcium acetate and calcium carbonate), sevelamer, and lanthanum hydroxide. Unless the patient is hypercalcemic, calcium carbonate can be administered (1.0 to 1.5 g with meals) as the phosphate-binding agent. Although potent, aluminum-based binders are limited to short-term use because of concerns with aluminum intoxication.

Uremia

Accumulation of endogenous toxins in the body eventually results in uremia. The uremic syndrome is a multisystemic symptom complex. The exact identities of the so-called uremic toxins are not known, although many possibilities have been suggested. Urea and creatinine are not uremic toxins but rather are markers of renal excretory capacity. One cannot deduce on the basis of urea nitrogen and creatinine levels exactly when a patient will become uremic. In general, the syndrome manifests itself at a GFR of less than 10 mL per minute.

Although uremia is considered an indication to initiate dialytic therapy, the syndrome may be insidious in onset and produce only vague symptoms. Lethargy, anorexia, nausea, and malaise, all of which may herald uremia, may well be attributed to extrarenal disease in the patient with AKI. Other, less subjective uremic manifestations constitute stronger indications for prompt initiation of dialysis, including bleeding diathesis, seizures, coma, and the appearance of a pericardial rub.

Dialysis

The use of renal replacement therapy in AKI is discussed in depth in Chapter 75. Briefly, the decision of when to initiate dialysis is historically controversial. Patients with intractable volume overload, hyperkalemia, metabolic acidosis, or frank uremia clearly meet criteria for dialysis. However, many patients with significant AKI do not meet one of these criteria. This has led to a discussion regarding the merits of early or even "prophylactic" dialysis. The rationale for forestalling dialysis includes the invasive nature of the procedure as well as concern that renal replacement therapy can exacerbate hemodynamic instability that might prolong the course of AKI. There is also significant labor and cost associated with performing the procedure in the ICU. Nevertheless, several observational studies appear to show decreased morbidity and mortality in patients initiated early on dialysis. It has been argued that early dialysis results in improved volume control as well as the clearance of a variety of cytokines and/or toxins that may be harmful. Unfortunately, at this time, there is still not adequate data to establish the optimal time to initiate dialysis. This issue is discussed in detail in Chapter 75.

Prognosis and Outcome of Acute Kidney Injury

Overall, the mortality from AKI ranges from 25% [14] to 64% [188]. The large disparity in mortality no doubt reflects the varied intensities of illness and case mixes in the reports. A large retrospective study by McMurray et al. [48] demonstrated 14% mortality in patients with nephrotoxic forms of AKI compared with 35% mortality for all other causes. Similarly, in the prospective study by Hou et al. [14], mortality ranged from a low of 6% in radiocontrast-induced nephropathy to 80% in cases of HRS. Even within the group of patients with AKI due to renal hypoperfusion, mortality varied between 9% in patients with volume depletion and 100% in patients with cardiogenic shock. An analysis of 618 critically ill patients with ATN found the following characteristics associated with mortality: age (odds ratio [OR], 1.13 per decade), sepsis (OR, 1.50), adult respiratory distress syndrome (OR, 1.79), liver failure (OR, 1.62), and creatinine of less than 2.0 mg per dL (OR, 1.99) [189]. Despite medical advances, mortality in AKI has not improved during the past 50 years [190].

Although patients with AKI clearly have increased mortality, there has been some debate about whether this is related to comorbid conditions versus AKI as an independent risk factor. A study by Hoa et al. looked at 843 patients' post–cardiac surgery of which 145 developed AKI. After completing a multivariate analysis, AKI was found to be an independent risk factor for mortality with a hazard ratio of 7.8. It is not entirely clear how AKI impacts the risk of death, but it is known that patients with significant AKI have compromised immune system and platelet function placing them at higher risk for complications. Indeed, in the series reported by Kleinknecht et al. [50], most deaths were the result of sepsis, gastrointestinal hemorrhage, or cardiac causes.

At least half of all cases of AKI are nonoliguric [191]. Nonoliguria is associated with an improved likelihood of recovery of renal function and approximately half the mortality (26%) of oliguric AKI (50%) [191]. AKI is more likely to have developed in nonoliguric patients as a result of exposure to a nephrotoxin than in oliguric patients [191]. Most of these individuals do not have multiorgan failure, and their improved survival may be the result of a less severe primary illness than those for oliguric patients.

The long-term prognosis of patients with AKI is impacted by several factors including the severity of the initial injury as well as baseline patient characteristics. Patients with a brief ischemic event, as may occur with suprarenal clamping of the aorta, typically develop a mild form of AKI that resolves within 72 hours [192]. Patients with prolonged episodes of ischemia or injury may have variable degrees of recovery. A study by Spurney at al. in ICU patients with AKI requiring dialysis found that the majority of the patients were left with some degree of CKD with the average creatinine remaining 1 to 2 mg per dL above their prior baselines [193]. In other studies, elderly individuals as well as patients with baseline CKD have been found to reduced probability of full recovery [194,195].

Delayed recovery can be anticipated in those patients with poor cardiac output [196] or in those with hypovolemia. Therefore, it is imperative that ECF volume be assessed, particularly in patients on hemodialysis or peritoneal dialysis in whom volume depletion may occur. Nevertheless, more than 80% of the patients who survive AKI will recover renal function and remain dialysis free [197].

CHAPTER 74 ■ DRUG DOSING IN RENAL AND HEPATIC FAILURE: A PHARMACOKINETIC APPROACH TO THE CRITICALLY ILL PATIENT

SONIA LIN, KEITH J. FOSTER, RONALD J. DEBELLIS AND BRIAN S. SMITH

Estimates of the incidence of preventable adverse drug events in the intensive care unit (ICU) range from 10 up to 40 per 1,000 patient-days [1,2]. Patients in an ICU are approximately twice as likely to experience an adverse drug event when compared with patients in a general medicine unit. This increased risk is likely a result of the greater number of medical problems faced by patients in the ICU plus their wider range of drug exposures. Critically ill patients are also at increased risk for developing renal dysfunction, with acute kidney injury (AKI) occurring in 7% to 25% of all patients admitted to the ICU. AKI in the ICU is associated with a severalfold increase in mortality [3,4]. Renal injury is also a risk factor for adverse drug events. As many as 45% of patients with an estimated creatinine clearance less than 40 mL per minute receive medications that are dosed as much as 2.5 times higher than the maximum recommended dose [5]. In addition, adverse drug reactions occur in approximately 9% of patients with blood urea nitrogen less than 20 mg per dL versus 24% of patients with blood urea nitrogen greater than 40 mg per dL [6]. Adverse drug events not only place patients at increased risk for morbidity and mortality but also have a tremendous impact financially. It has been estimated that each adverse drug event increases hospital costs by $2,000 to $4,600 [7–9]. For all of these reasons, appropriate drug dosing in critically ill patients with kidney or liver injury is essential. The following review uses pharmacokinetic principles to discuss key concepts of drug dosing in critically ill patients with renal and hepatic dysfunction and provides drug dosage tables to assist clinicians with dosage adjustments in the setting of renal or hepatic disease (Tables 74.1 and 74.2).

PHARMACOKINETIC AND PHARMACODYNAMIC PRINCIPLES

To design an effective and safe medication regimen, a clinician must have a general understanding of a drug's pharmacokinetic and pharmacodynamic characteristics and be able to adjust for changes in the drug's disposition that occur with critical illness, AKI, and hepatic dysfunction. *Pharmacokinetics* relates to the principles of drug absorption, distribution, metabolism, and excretion, whereas *pharmacodynamics* describes the pharmacologic response resulting from the drug at the site of action (receptor). Clinical pharmacokinetics is the application of knowledge of drug absorption, distribution, metabolism, and excretion to design patient-specific drug regimens with the goal of maximizing therapeutic outcomes and minimizing toxicity (Fig. 74.1).

Most drugs used in critically ill patients are metabolized with linear, or first-order, pharmacokinetics. This means that the drug is eliminated from plasma at a constant rate. As the plasma concentration increases or decreases, the amount of drug eliminated increases or decreases in a directly proportional relationship. Clinically, if a drug dose is increased, the plasma concentration increases proportionally, as does the amount eliminated (Fig. 74.2). If a drug's plasma concentration is plotted versus time using a logarithmic scale, two different slopes are evident (Fig. 74.3): The upper portion is known as the *alpha* (or *distribution*) *phase*, which represents the process

TABLE 74.1

GUIDELINES FOR DRUG DOSING IN CRITICALLY ILL PATIENTS WITH RENAL FAILURE

Drug	Normal dose	Creatinine clearance			Extracorporeal drug removal		Notes
		30–50 mL/min	10–30 mL/min	<10 mL/min	HD	CVVHD, CVVHDF	
Acyclovir [10,11]	5–10 mg/kg IV q8h (higher doses are used in CNS infections and immunocompromised patients) [12,13]	5–10 mg/kg IV q12h	5–10 mg/kg IV q24h	2.5–5.0 mg/kg IV q24h	2.5–5.0 mg/kg IV q24h; administer after HD	5–10 mg/kg IV q24h	To help avoid nephrotoxicity after IV acyclovir, it is recommended that the patient have 1 mL of urine for each 1.3 mg of acyclovir administered [14]
Amantadine [15,16]	100 mg PO q12h	100 mg PO q24h	100 mg PO q48h	200 mg q7 d	200 mg q7 d	100 mg PO q48h	
Amikacin [11,17,18]	7.5 mg/kg IV q12h	7.5 mg/kg IV q18–24h	7.5 mg/kg IV q24–48h	7.5 mg/kg IV q48h	7.5 mg/kg IV based on serum levels, re-dose with levels <5 μg/mL	7.5 mg/kg IV q24–48h	Trough levels should be <10 μg/mL
Amphotericin B (conventional) [17,19]	0.3–1.0 mg/kg IV q24h (maximum dose: 1.5 mg/kg)	0.3–1.0 mg/kg IV q24h	0.3–1.0 mg/kg IV q24h	0.3–1.0 mg/kg IV q48h	0.3–1.0 mg/kg IV q48h	0.3–1.0 mg/kg IV q24h	—
Amphotericin B (liposomal) [11,20,21]	3–5 mg/kg IV q24h (higher doses of 15 mg/kg/d have been used) [22]	3–5 mg/kg IV q24h	3–5 mg/kg IV q24h	3–5 mg/kg IV q48h	3–5 mg/kg IV q48h	3–5 mg/kg IV q24h	—
Ampicillin [23]	1–2 g IV q4–6h	1–2 g IV q6–8h	1–2 g IV q8–12h	1–2 g IV q12h	1–2 g IV q12h; supplemental doses are not needed if maintenance doses are scheduled after HD	1–2 g IV q8–12h	
Ampicillin/ sulbactam [11,23,24]	1.5–3.0 g IV q6h	1.5–3.0 g IV q8h	1.5–3.0 g IV q12h	1.5–3.0 g IV q24h	1.5–3.0 g IV q12–24h administered at the end of HD	CVVH: 1.5–3.0 g IV q8–12h CVVHD, CVVHDF: 1.5–3.0 g IV q6–8h	
Aztreonam [23,25]	1–2 g IV q6–8h	1–2 g IV q6–8h	Loading dose 1–2 g, then 1 g IV q6–8h	Loading dose 1–2 g, then 0.5 g IV q6–8h	Loading dose 1–2 g, then 0.5 g IV q6–8h; administer dose after HD	Loading dose 1–2 g, then 1–2 g IV q8–12h	Note that the dosing interval remains constant, and there is a reduction in dose with worsening renal function

Bivalirudin [26]	Coronary angioplasty: 0.75 mg/kg bolus, then 1.75 mg/kg/h × 4 h [27]; myocardial infarction undergoing PCI: 0.75 mg/kg/h, then 1.75 mg/kg/h during procedure [28]	No change	1 mg/kg/h; no bolus needed	1 mg/kg/h; no bolus needed	0.25 mg/kg/h, no bolus needed	—	Metabolic clearance may be the predominant route of elimination [29]
Capreomycin [10,30,31]	1 g/d (maximum: 20 mg/kg/d) for 60–120 d, followed by 1 g 2–3 times/wk **or** 15 mg/kg/d (maximum: 1 g/dose) for 2–4 mo, followed by 15 mg/kg (maximum: 1 g/dose) 2–3 times/wk	No change	12–15 mg/kg (maximum: 1 g/dose) 2–3 d/wk (**NOT** daily)	12–15 mg/kg (maximum: 1 g/dose) 2–3 d/wk (**NOT** daily)	12–15 mg/kg (maximum: 1 g/dose) 2–3 d/wk (**NOT** daily)	5 mg/kg IV q24h	
Cefazolin [11]	1–2 g IV q8h	1–2 g IV q8h	1–2 g IV q12h	1–2 g IV q24h	1–2 g IV q24h administered at the end of HD	CCVHD: 1–2 g IV q12h CVVHDF: 2 g IV q12h	—
Cefepime [11,32,33]	1–2 g IV q8–12h	1–2 g IV q12–24h	1–2 g IV q24h	0.5–1.0 g IV q24h	0.5–1.0 g IV q24h administered at the end of HD	CCVHD: 1–2 g IV q12h CVVHDF: 2 g IV q12h	Covers *Pseudomonas aeruginosa* as well as some Gram-positive organisms
Cefotaxime [11]	1–2 g IV q8h	1–2 g IV q8h	1–2 g IV q12h	1–2 g IV q24h	1–2 g IV q24h administered at the end of HD	CCVHD: 1–2 g IV q12h CVVHDF: 2 g IV q12h	—
Cefotetan [34]	1–2 g IV q12h	1–2 g IV q12h	1–2 g IV q24h	1–2 g IV q48h	1–2 g IV q48h administered at the end of HD	1–2 g IV q12h	—
Cefoxitin [35]	1–2 g IV q6–8h	1–2 g IV q8h	1–2 g IV q12h	1–2 g IV q24h	1–2 g IV q24h administered after HD	1–2 g IV q12h	
Ceftazidime [11,36,37]	2 g IV q8h	2 g IV q12h	Loading dose 2 g IV, then 0.5–1.0 g IV q24h	Loading dose 2 g IV, then 1 g IV q48h	Loading dose 2 g IV, then 1 g IV q48h administered at the end of HD	Loading dose 2 g IV, then 1–2 g IV q12h	Covers *P. aeruginosa*; has limited, if any, Gram-positive coverage
Ceftobiprole [38]	500 mg every 8–12 h	500 mg every 12 h	250 mg every 12 h	—	—	—	
Cefuroxime [10]	0.75–1.5 g IV q8h	0.75–1.5 g IV q8h	0.75–1.5 g IV q12h	0.75–1.5 g IV q24h	0.75–1.5 g IV q24h administered at the end of HD	0.75–1.5 g IV q12h	—
Chloramphenicol [10]	50–100 mg/kg/d IV in divided doses q6h (max: 4 g/d)	—	—	—	—	—	Use with caution in renal failure

(*continued*)

TABLE 74.1

CONTINUED

Drug	Normal dose	Creatinine clearance			Extracorporeal drug removal		Notes
		30–50 mL/min	10–30 mL/min	<10 mL/min	HD	CVVHD, CVVHDF	
Cidofovir [39]	Induction: 5 mg/kg IV once weekly; Maintenance: 5 mg/kg q2 wk	Contraindicated	Contraindicated	Contraindicated	Contraindicated	Contraindicated	Administer probenecid and IV hydration with normal saline with each dose; if Scr increases by 0.3–0.4 mg/dL, decrease dose to 3 mg/kg; discontinue if Scr increases by >0.5 mg/dL
Ciprofloxacin [11,23,40,41]	400 mg IV q12h	400 mg IV q12h	400 mg IV q24h	250–500 mg PO q24h or 400 mg IV q24h	400 mg IV q24h administered at the end of HD	200–400 mg IV q12–24h	—
Clarithromycin [42]	250–500 mg PO q12h	No change	250–500 mg PO q24h	250–500 mg PO q24h	—	—	
Colistimethate [11,43]	2.5–5 mg/kg/d in 2–4 divided doses; 3–8 mg/kg/d in 3 divided doses for cystic fibrosis	Scr 1.3–1.5 mg/dL 2.5–3.8 mg/kg/d divided q12h	Scr 1.6–2.5 mg/d: 2.5 mg/kg/d divided q12–24h	Scr 2.6–4.0 mg/dL: 1.5 mg/kg/d divided q36h	1.5 mg/kg IV q24–48h	2.5 mg/kg IV q48h	CRRT dosing may be as frequent as q12h. [44]
Cycloserine [45,46]	250–500 mg PO q12h	250–500 mg PO q12h	250–500 mg PO q24h	250–500 mg PO q24h	—	—	
Daptomycin [11]	4–6 mg/kg IV q24h	4–6 mg/kg IV q24h	4–6 mg/kg IV q48h	4–6 mg/kg IV q48h	4–6 mg/kg IV q48h administered after HD	4–6 mg/kg IV q48h	
Demeclocycline [47]	150 mg PO q6h	Not recommended	Not recommended	Not recommended	Not recommended	Not recommended	
Diazepam	2–10 mg IV/IM q2–4h p.r.n.; 2–10 mg PO q6–12h p.r.n	No change	No change	No change	No change	No change	Active metabolites may accumulate in RF; doses should be titrated to patient response
Digoxin	IV 0.4–1.0 mg/d loading dose, 0.125–0.375 mg/d maintenance dose; PO 0.75–1.25 mg/d loading dose, 0.125–0.375 mg/d maintenance dose	Same loading dose IV/PO; maintenance dose 0.125–0.375 mg q24h	0.625 mg loading dose; IV/PO maintenance dose 0.125–0.375 mg q24–48h	0.625 mg loading dose; IV/PO maintenance dose 0.125–0.375 mg q48h	No supplement for HD	Normal loading dose, IV/PO maintenance dose 0.125–0.375 mg q36h	The volume of distribution of digoxin can decrease by up to 50% in patients with RF, necessitating dose adjustment

Dofetilide	500 μg PO b.i.d.; IV dose for atrial fibrillation/flutter: 2.5–4.0 μg/kg bolus, repeat doses given 15 min later if conversion did not occur [48]	250 μg PO b.i.d. with CrCl from 40–60 mL/min	125 μg PO b.i.d. with CrCl from 20–40 mL/min	Contraindicated when CrCl <20 mL/min	Contraindicated when CrCl <20 mL/min	Contraindicated when CrCl <20 mL/min	Patients should be off amiodarone for at least 3 mo before using dofetilide; >50% of dose is excreted in urine, leading to an increased half-life in RF [49]
Doripenem [50]	500 mg IV q8h	250 mg IV q8h	250 mg IV 12 h	—	—	—	
Enoxaparin [51,52]	Prophylaxis: 30 mg SC q12h or 40 mg SC q24h; treatment: 1 mg/kg SC q12h or 1.5 mg/kg SC q24h	No change, use caution	Prophylaxis: 30 mg SC q24h; treatment: 1 mg/kg SC q24h	Prophylaxis: 30 mg SC q24h; treatment: 1 mg/kg SC q24h	No guidelines determined	No guidelines determined	Patients with renal failure are at increased risk for bleeding
Ertapenem	1 g IV q24h	1 g IV q24h	500 mg IV q24h	500 mg IV q24h	500 mg IV q24h		
Erythromycin [53]	0.5–1 g IV q6h	No change	No change	0.25–0.5 g IV q6h	0.25–0.5 g IV q6h		
Famotidine [54]	20–40 mg IV q12h	20 mg IV q12h	20 mg IV q12h	20 mg IV q24h or 40 mg IV q48h	20 mg IV q24h at the end of HD	20 mg IV q12h	—
Fluconazole [11,23,55,56]	400–800 mg IV/PO q24h	Loading dose 400–800 mg IV/PO, then 200–400 mg IV/PO q24h	Loading dose 400–800 mg IV/PO, then 100–200 mg IV/PO q24h	Loading dose 400–800 mg IV/PO, then 100–200 mg IV/PO q24h	100–400 mg IV/PO after each HD only	Loading dose 400–800 mg IV/PO, then 400–800 mg IV/PO q24h	—
Fondaparinux	DVT prophylaxis: 2.5 mg SC q24h	No change, use caution (clearance estimated to be reduced by 40%)	Contraindicated (clearance estimated to be reduced by 55%)	Contraindicated	No guidelines determined	No guidelines determined	Treatment dose not recommended for use in patients with CrCl <30 mL/min. Use of 2.5 mg SC after hemodialysis on dialysis days, with anti-Xa monitoring has been reported [57]
Foscarnet [58]	40–80 mg/kg/dose IV q8h	CrCL (mL/min/kg): >1–1.4: 30–45 mg IV q8h >0.8–1: 35–50 mg IV q12h >0.6–0.8: 25–40 mg IV q12h >0.5–0.6: 40–60 mg IV q24h >0.4–0.5: 35–50 mg IV q24h	Not recommended	Not recommended	45–60 mg/kg after each HD session	—

TABLE 74.1

CONTINUED

Drug	Normal dose	Creatinine clearance			Extracorporeal drug removal		Notes
		30–50 mL/min	10–30 mL/min	<10 mL/min	HD	CVVHD, CVVHDF	
Ganciclovir [59]	Induction: 5 mg/kg IV q12h; maintenance: 5 mg/kg IV q24h	Induction: 2.5 mg/kg IV q24h; maintenance: 1.25 mg/kg IV q24h	Induction: 1.25 mg/kg IV q24h; maintenance: 0.625 mg/kg IV q24h	Induction: 1.25 mg IV 3 × wk; maintenance: 0.625 mg/kg IV 3 × wk	Induction: 1.25 mg IV 3 × wk; maintenance: 0.625 mg/kg IV 3 × wk	Induction: 1.25 mg/kg IV q24h; maintenance: 0.625 mg/kg IV q24h	Accumulation of ganciclovir occurs in renal tissue [60]
Gentamicin	Varied, depends on traditional versus large dose-extended interval dosing regimens; consult institution-specific guidelines	—	—	2 mg/kg based on lean body weight; follow levels once daily and re-dose when trough level is <2.0 μg/mL	2 mg/kg after each HD treatment	Dose based on CrCl of 25 mL/min	Trough aminoglycoside levels post-HD should be drawn 4 h after HD has stopped to allow for equilibrium
Imipenem and cilastatin [11,23,61]	500 mg IV q6h for ≥70 kg; subsequent dose adjustments are based on a total of 2 g/d (considered to be an average ICU dose); 500 mg IV q8h, 60–70 kg; 250 mg IV q6h, 50–60 kg; 250 mg IV q6h, 40–50 kg	500 mg IV q8h for ≥70 kg; 250 mg IV q6h, 60–70 kg; 250 mg IV q6h, 50–60 kg; 250 mg IV q8h, 40–50 kg	250 mg IV q6h for ≥70 kg; 250 mg IV q8h, 60–70 kg; 250 mg IV q8h, 50–60 kg; 250 mg IV q12h, 40–50 kg	250 mg IV q12h for all weights from 40 to ≥70 kg	500 mg IV q12h; administer dose after HD	500 mg IV q6–8h	Use cautiously in patients with renal impairment; adjusting dose may not be adequate to prevent seizure [62]; average time to seizure is 7 d
Lepirudin [63,64]	HIT: 0.4 mg/kg bolus, infuse at 0.15 mg/kg/h	0.2 mg/kg bolus, infuse at 0.045–0.075 mg/kg/h	0.2 mg/kg bolus, infuse at 0.0225 mg/kg/h	0.08–0.1 mg/kg bolus, monitor aPTT and rebolus when aPTT falls to 1.5 × standard	0.08–0.10 mg/kg bolus, monitor aPTT and rebolus when aPTT falls to 1.5 × standard	0.08–0.1 mg/kg bolus, follow aPTT and re-dose when aPTT falls to 1.5 × standard	Monitor aPTT closely, especially in patients with renal impairment; therapeutic range: aPTT 1.5–2.5 × normal
Levofloxacin [23,41]	500–750 mg IV/PO q24h	Loading dose 500–750 mg IV/PO × 1, then 250–500 mg IV/PO q24h	Loading dose 500–750 mg IV/PO × 1, then 250–500 mg IV/PO q48h	Loading dose 500–750 mg IV/PO × 1, then 250–500 mg IV/PO q48h	Loading dose 500–750 mg IV/PO × 1, then 250–500 mg IV/PO q48h administered at end of HD	Loading dose 500–750 mg IV/PO × 1, then 250–750 mg IV/PO q24–48h	—
Linezolid [11,23,65]	600 mg IV/PO q12h	No change	No change	No change	No change, time dose to occur after HD	No change	Metabolites may accumulate in renal failure but clinical significance is unknown [66,67]

Lorazepam	1–10 mg IV/IM q2–4h p.r.n.; 0.5–10 mg PO q4–6h p.r.n.	No change	No change	No change	No change	No change	Doses should be titrated to patient response. Use IV lorazepam with caution in patients with RF due to propylene glycol toxicity [68]
Mannitol	0.25–2 g/kg IV q4–6h	0.25 g/kg IV q6–12h	0.25 g/kg IV q8–12h	Avoid use	Avoid use	Avoid use	Maintain serum osmolarity of 290–310
Meperidine [69]	50–100 mg IV q3–4h, titrate for pain control	37.5–75 mg IV q3–4h, titrate for pain control	37.5–75 mg IV q3–4h, titrate for pain control	25–50 mg IV q3–4h, titrate for pain control	Avoid	37.5–75 mg IV q3–4h, titrate for pain control	Normeperidine, a toxic metabolite, affects the central nervous system and can lead to seizure when meperidine is used in patients with RF
Meropenem [11,23,70,71]	1 g IV q8h	1 g IV q12h	500 mg IV q12h	500 mg IV q24h	500 mg IV q24h; administer dose after HD	0.5–1 g IV q8–12h	Seizures have occurred only in patients with preexisting seizure disorder [72]
Metoclopramide	10–20 mg IV q6h	7.5–15 mg IV q6h	7.5–15 mg IV q6h	5–10 mg IV q6h	5–10 mg IV q6h, administered at the end of HD	7.5–15 mg IV q6h	—
Metronidazole [73]	250–500 mg IV/PO q8h	No change	No change	250 mg IV/PO q8h	Administer dose after HD	No change	Treatment for *Clostridium difficile* diarrhea; causes dark urine
Midazolam [17]	0.01–0.05 mg/kg (0.5–4 mg) IV load over 2–5 min, then 0.02–0.1 mg/kg/h titrated to response	No change	No change	0.5–4 mg/kg load over 2–5 min, then 0.01–0.05 mg/kg/h titrated to response	Guidelines not determined	Guidelines not determined	Prolonged infusions, especially in patients with RF, may result in prolonged sedation due to the accumulation of metabolites; doses should be titrated to patient response [74]
Milrinone [75]	50–75 μg/kg load over 10 min; 0.375–0.75 μg/kg/min infusion based on clinical response	Same load, 0.38–0.43 μg/kg/min infusion based on clinical response	Same load, 0.28–0.33 μg/kg/min infusion based on clinical response	25–50 μg/kg load over 10 min; 0.2–0.23 μg/kg/min infusion based on clinical response	No data	Use normal dose	85% of dose eliminated unchanged in urine within 24 h

(*continued*)

TABLE 74.1

CONTINUED

Drug	Normal dose	Creatinine clearance			Extracorporeal drug removal		Notes
		30–50 mL/min	10–30 mL/min	<10 mL/min	HD	CVVHD, CVVHDF	
Morphine [76]	2–15 mg IV q2–4h, titrate for pain control	1.5–12 mg IV q2–4h, titrate for pain control	1.5–12 mg IV q2–4h, titrate for pain control	1–8 mg IV q2–4h, titrate for pain control	1–8 mg IV q2–4h, titrate for pain control	1.5–12 mg IV q2–4h, titrate for pain control	Although morphine is hepatically metabolized, dose adjustment in renal insufficiency is recommended to avoid accumulation of morphine-6-glucuronide, which may have narcotic activity [77,78]
Nadolol	40–320 mg PO qd in single or divided doses	20–160 mg PO daily in single or divided doses, or use normal dose and change interval to q24–36h	20–160 mg PO daily in single or divided doses, or use normal dose and change interval to q24–48h	10–80 mg PO daily in single or divided doses, or use normal dose and change interval to q48h	Supplement 40 mg after HD	20–160 mg q24h in single or divided doses, or use normal dose and change interval to q24–48h	Alteration of the interval instead of dose is an option [79]
Nesiritide	IV bolus of 2 μg/kg followed by a continuous infusion at a dose of 0.01 μg/kg/min; maximum dose 0.03 μg/kg/min	No change	No change	No change	No guidelines established	No guidelines established	Use if nesiritide in patients with renal insufficiency has been associated with elevations of Scr [80]
Nitroprusside [17]	0.25–10 μg/kg/min; titrate for BP control	No change	No change	No change	No change	No change	Thiocyanate, a toxic metabolite, accumulates in RF, causing seizure and coma; thiocyanate is removed via HD [81]
Norfloxacin [17]	400 mg PO q12h	No change	400 mg PO q24h	400 mg PO q24h	400 mg PO q24h	—	
Ofloxacin [82,83]	300 mg PO q12h	300 mg PO q24h	150–300 mg PO q24h	150 mg PO q24h		300 mg PO q24h	
Oseltamivir [84,85]	75–150 mg PO q12h	No change	75–150 mg PO q24h	—	30 mg after every other HD	—	Higher doses are recommended for treatment of H1N1 influenza infection [86]

Pancuronium	0.04–0.10 mg/kg load, then 0.01–0.06 mg/kg as needed to maintain paralysis	0.02–0.05 mg/kg load, then 0.01–0.03 mg/kg as needed to maintain paralysis	0.02–0.05 mg/kg load, then 0.01–0.03 mg/kg as needed to maintain paralysis	Avoid use	Guidelines not determined	Guidelines not determined	—
Penicillin G [17,23]	1–4 million units IV q4–6h; 1–2 million units for most uses, 4 million units in meningitis	0.75–3 million units IV q4–6h	0.75–3 million units IV q4–6h	0.5–2 million units IV q4–6h	0.5–2 million units IV q4–6h; supplemental doses are not needed if maintenance doses are scheduled after HD	2–4 million U IV q4–6h	—
Pentamidine [10,13]	3–4 mg/kg IV q24h	No change	No change	3–4 mg/kg IV q24–36h	3–4 mg IV q24–36h		No adjustment in renal failure has been reported [87]
Pentostatin [88]	4 mg/m^2 every 2 wk	2–3 mg/m^2 every 2 wk	2 mg/m^2 every 2 wk	Not recommended	—	—	
Phenobarbital	Status epilepticus: 10–20 mg/kg IV; 60–250 mg PO q24h	No change	No change	60–100 mg PO q24h	No change, dose after dialysis	—	Monitor levels closely; therapeutic range: 10–40 μg/mL
Phenytoin [89]	15 mg/kg IV load, then 200–400 mg PO/IV daily divided q8–12h	No change	No change	No change	No change	No change	Monitor levels closely. Phenytoin binding is altered in uremic patients and patients with low albumin; serum levels should be monitored accordingly
Piperacillin [90]	3–4 g IV q4–6h	3–4 g IV q6–8h	3–4 g IV q6–8h	3–4 g IV q8h	3–4 g IV q8h administered at the end of HD	3–4 g IV q6–8h	—
Piperacillin/ tazobactam [11,23,90,91]	Nosocomial pneumonia: 4.5 g IV q6h; moderate-to-severe infections: 3.375 g IV q6h	CrCl 20–40 mL/min: Nosocomial pneumonia: 3.375 g IV q6h; moderate-to-severe infections: 2.25 g IV q6h	CrCl <20 mL/min: Nosocomial pneumonia: 2.25 g IV q6h; moderate-to-severe infections: 2.25 g IV q8h	See CrCl <20 mL/min	Nosocomial pneumonia: 2.25 g IV q8h; moderate-to-severe infections: 2.25 g IV q12h	2.25–3.375 g IV q6–8h	Because HD removes 30%–40% of piperacillin/ tazobactam, give a supplementary dose of 0.75 g intravenously after dialysis
Polymyxin B [92]	15,000–25,000 units/kg/d IV divided q12h	11,250–18,750 units/kg/d IV divided q12h	7,500–12,500 units/kg/d IV divided q12h	2,250–3,750 units/kg/d divided q12h	2,250–3,750 units/kg/d divided q12h	—	
Posaconazole [93,94]	200–400 mg PO q12h	No change	No change	No change	No change	—	Monitor breakthrough fungal infections due to variability in drug exposure

(*continued*)

TABLE 74.1

CONTINUED

Drug	Normal dose	Creatinine clearance			Extracorporeal drug removal		Notes
		30–50 mL/min	10–30 mL/min	<10 mL/min	HD	CVVHD, CVVHDF	
Procainamide [17,95]	50–100 mg/min IV until arrhythmia is suppressed or dose reaches 500–1,000 mg, then infuse at 2–6 mg/min; oral: 500–1,000 mg PO q4–6h	500 mg PO q6h	500 mg PO q12h	500 mg PO q12–24h	500 mg PO q24h after dialysis	—	Monitor electrocardiogram, procainamide, and NAPA levels closely in renal dysfunction. Procainamide: 4–12 μg/mL; NAPA: 5–15 μg/mL [96]
Ranitidine [97]	50 mg IV q8h or 6.25 mg/h continuous infusion	50 mg IV q12–24h	50 mg IV q12–24h	50 mg IV q24h	50 mg IV q24h, administered at end of HD	50 mg IV q12h	—
Rifabutin [98,99]	300 mg PO q24h	No change	150 mg PO q24h	150 mg PO q24h	150–300 mg PO q24h	—	
Rifampin [13,77]	600 mg PO/IV q24h	300–600 mg PO/IV q24h	300–600 mg PO/IV q24h	300 mg PO/IV q24h	300–600 mg PO q24h	300–600 mg PO q24–48h	—
Sotalol [100]	80–320 mg PO q12h; start with 80 mg PO q12h	Lengthen dosing interval to q24h	Lengthen dosing interval to q36–48h, based on clinical response	Dose according to clinical response	Supplement 80 mg after HD	Lengthen dosing interval to q36–48h based on clinical response	Data suggest that HD patients need a decrease in dose and increase in interval [101]
Spironolactone [77]	25–200 mg PO q24h	12.5–100 mg PO q24h	12.5–100 mg PO q24h	Not effective	Not effective	Not effective	Use should be avoided in patients with GFRs <10 mL/min; monitor for hyperkalemia
Streptomycin [77]	1 g IM q12–24h	1 g IM q24–48h	1 g IM q48–72h	1 g IM q72–96h	1 g IM q72–96h, administer after HD	—	
Sulfamethoxazole and trimethoprim [102,103]	8–20 mg/kg/d; when IV, divided into q6h; when PO, divided q6–12h	No change	4–10 mg/kg/d; when IV or PO, divided q12h	4–10 mg/kg/d; when IV or PO, divided q12h	4–10 mg/kg/d; when IV or PO, divided q12h, administer dose after HD	4–10 mg/kg/d when IV or PO, divided q12h	Dosing values are based on the trimethoprim component
Ticarcillin/ clavulanate potassium [11,23]	3.1 g IV q4–6h	2 g IV q4h	2 g IV q8h	2 g IV q12h	2 g IV q12h, administered at the end of HD	2–3.1 g IV q6–8h	Patients with CrCl <10 mL/min with hepatic dysfunction should receive 2 g IV q24h

Tinzaparin [51]	Deep venous thrombosis therapy: 175 anti-Xa IU/kg SC qd × 6 d or adequate warfarin anticoagulation is in place; deep venous thrombosis prophylaxis: 3,500 anti-Xa IU SC qd	Use with caution	Use with caution	—	—	—	Not recommended for use in patients with CrCl <30 mL/min unless monitoring anti-Xa levels [104]
Tobramycin	See gentamicin	—	—	—	—	—	—
Valacyclovir [105]	1 g PO q8h	1 g PO q12h	1 g PO q24h	500 mg PO q24h	500 mg PO q24h, administered after HD	—	—
Valganciclovir [13,59,106]	Induction: 900 mg PO q12; Maintenance: 900 mg PO q24h	I: 450 mg PO q12–24h M: 450 mg PO q24–48h	I: 450 mg PO q24–48h M: 450 mg PO q48h to 2×/wk	Not recommended	Not recommended	M: 450 mg PO q48h [107]	—
Valproic acid	10–15 mg/kg/d	No change	No change	May requite dosage adjustment; see comments	No change	No change	Do not infuse faster than 20 mg/min. With renal impairment, may see increase in free levels. Measurement of total concentration can therefore be misleading
Vancomycin [11,108,109]	Refer to institution-specific guidelines	—	—	—	1 g IV every wk, measure random vancomycin level on 4th day after dose to ensure blood levels, dose for level <10 μg/mL	7.5–15 mg/kg q12–48h	—
Voriconazole [110]	6 mg/kg IV q12h × 2 doses; follow with 4 mg/kg IV q12h	IV not recommended	IV not recommended	IV not recommended	IV not recommended	IV not recommended	IV formulation not recommended in CrCL <50 mL/min; accumulation of the intravenous vehicle (cyclodextrin) can occur
Ziprasidone [111]	40–80 mg PO q12h; 10 mg IM q24h	No change for PO. Caution with IM use	No change for PO. Caution with IM use	No change for PO. Caution with IM use	—	—	Injection form contains cyclodextrin sodium that is renally eliminated. Caution recommended with IM use in renal impairment

aPTT, activated partial thromboplastin time; b.i.d., twice daily; CrCl, creatine clearance; CVVDH, continuous venovenous hemodialysis; CVVHDF, continuous venovenous hemodiafiltration; DVT, deep vein thrombosis; ESRD, end-stage renal disease; GFR, glomerular filtration rate; HD, hemodialysis; ICU, intensive care unit; IM, intramuscularly; IV, intravenous; NAPA, *N*-acetyl procainamide; PO, by mouth; p.r.n., as needed; q, every, t.i.d., three times a day; RF, renal failure; SC, subcutaneously; Scr, serum creatinine.

TABLE 74.2

GUIDELINES FOR DRUG DOSING IN CRITICALLY ILL PATIENTS WITH HEPATIC FAILURE

Drug	Normal dose	Child-Pugh score A (mild)	Child-Pugh score B (moderate)	Child-Pugh score C (severe)	Special circumstances/notes
Abacavir [112]	300 mg PO q12h OR 600 mg PO q24h	200 mg PO q12h	Use is contraindicated	Use is contraindicated	
Alprazolam [113]	0.25–1 mg PO 2–3 times a d Max: 4 mg/d				Hepatic impairment: reduce dose by 50%–60%; avoid in cirrhosis
Amlodipine [114,115]	Usual dose: 5–10 mg PO q24h				Hypertension: initial dose 2.5 mg PO q24h; angina: initial dose 5 mg PO q24h
Argatroban [116]	HIT/HITTS: initial dose: 2 μg/kg/min; PCI: initial dose: 25 μg/kg/min and administer bolus dose of 350 μg/kg; Cerebral thrombus: 60 mg/d by continuous infusion for 2 d, followed by 10 mg IV twice daily for 5 d. Myocardial infarction: 100 μg/kg IV bolus followed by 2–3 μg/kg/min infusion for 6–72 h.		HIT/HITTS: initial dose: 0.5 mcg/kg/min		During PCI, avoid use in patients with elevations of ALT/AST (>3 times ULN); the use of argatroban in these patients has not been evaluated.
Aspirin [117,118]	81–325 mg PO q24h			Avoid use	
Carvedilol [119,120]	Hypertension: 6.25–25 mg PO q12h; heart failure: 3.125–50 mg PO q12h			Use is contraindicated	Extended release is contraindicated in hepatic impairment; liver impairment with cirrhosis: reduce dose by 20%
Caspofungin [121]	Candidiasis, Aspergillosis (invasive): initial dose: 70 mg IV on day 1; subsequent dosing: 50 mg IV q24h	No adjustment necessary	Initial: 70 mg IV loading dose, then 35 mg IV q24h	No clinical experience	
Colchicine [122]	Acute attacks: PO: 0.5–1.2 mg, followed by 0.6 mg PO every 1–2 h to a max of 6 mg; IV: 1–2 mg then 0.5 mg every 6 h to a max of 4 mg				Dosage adjustment should be considered in severe hepatic impairment. Treatment course should not be repeated more than once in a 2-wk period.
Cyclobenzaprine [123]	5–10 mg PO q8h	Initial: 5 mg PO; use with caution and consider less frequent dosing	Use not recommended	Use not recommended	Mild-severe impairment: not recommended for extended release formulation
Cytarabine [124–126]	Remission induction: *IV:* 100–200 mg/m^2/d for 5–10 d or 100 mg/m^2/d for 7 d or 100 mg/m^2/dose every 12 h for 7 d; *IT:* 5–75 mg/m^2 q2–7 d until CNS findings normalize; Remission maintenance: *IV:* 70–200 mg/m^2/d for 2–5 d at monthly intervals; *IM, SubQ:* 1–1.5 mg/kg single dose for maintenance at 1- to 4-wk intervals				AST/ALT (any elevation): administer 50% of dose; TBili >2 mg/dL: administer 50% of dose

Daunorubicin [124,127]	Range: 30–60 mg/m^2/d for 3 d, repeat dose in 3–4 wk; ALL combination therapy: 45 mg/m^2/d for 3 d; AML combination therapy (induction): adults <60 y: induction: 45 mg/m^2/d for 3 d of the first course of induction therapy; subsequent courses: 45 mg/m^2/d for 2 d				TBili 1.2–3 mg/dL: administer 75% of dose; serum TBili >3 mg/dL: administer 50% of dose; serum TBili >5 mg/dL: avoid use.
Diazepam [128,129]	2.5–10 mg PO 2–4 times a day ICU sedation: 0.05–0.1 mg/kg IV every 30 min to 6 h; Status epilepticus: IV 5–10 mg every 5–10 min, max of 30 mg				Patients with cirrhosis: reduce dose by 50%
Docetaxel [124,130]	Breast cancer: *locally advanced or metastatic:* 60–100 mg/m^2 every 3 wk; *operable, node-positive:* 75 mg/m^2 every 3 wk for 6 courses; non-small cell lung cancer: 75 mg/m^2 every 3 wk; prostate cancer: 75 mg/m^2 every 3 wk; Gastric adenocarcinoma: 75 mg/m^2 every 3 wk; head and neck cancer: 75 mg/m^2 every 3 wk for 3 or 4 cycles				TBili >ULN, or AST and/or ALT >1.5 times ULN concomitant with ALK >2.5 times ULN: should not be administered; hepatic impairment dosing adjustment specific for gastric adenocarcinoma: *AST/ALT >2.5 to ≤5 times ULN and alkaline phosphatase ≤2.5 times ULN:* administer 80% of dose *AST/ALT >1.5 to ≤5 times ULN and alkaline phosphatase >2.5 to ≤5 times ULN:* administer 80% of dose *AST/ALT >5 times ULN and/or alkaline phosphatase >5 times ULN:* discontinue docetaxel; AST/ALT 1.6–6 times ULN: administer 75% of dose; AST/ALT >6 times ULN: use clinical judgment
Doxorubicin [124,131]	60–75 mg/m^2/dose q21 d or 60 mg/m^2/dose q2 wk or 40–60 mg/m^2/dose q3–4 wk or 20–30 mg/m^2/d for 2–3 d every 4 wk or 20 mg/m^2/dose once weekly				TBili 1.2–3 mg/dL: administer 50% of dose; 3.1–5 mg/dL: administer 25% of dose; severe hepatic impairment: use is contraindicated; AST/ALT 2–3 times ULN: administer 75% of dose; AST/ALT >3 times ULN or TBili 1.2–3 mg/dL: administer 50% of dose; TBili 3.1–5 mg/dL: administer 25% of dose; TBili >5 mg/dL: do not administer
Epirubicin [132,133]	Breast cancer: *CEF-120:* 60 mg/m^2 on days 1 and 8 q28 d for 6 cycles; *FEC-100:* 100 mg/m^2 on day 1 q21 d for 6 cycles				TBili 1.2–3 mg/dL or AST 2–4 times the ULN: administer 50% of recommended starting dose; TBili >3 mg/dL or AST >4 times the ULN: administer 25% of recommended starting dose; severe hepatic impairment: use is contraindicated
Esomeprazole [134,135]	20–40 mg PO/IV 1–2 times a day	No adjustment necessary	No adjustment necessary	Do not exceed 20 mg IV/PO q24h	

(*continued*)

TABLE 74.2

CONTINUED

Drug	Normal dose	Child-Pugh score A (mild)	Child-Pugh score B (moderate)	Child-Pugh score C (severe)	Special circumstances/notes
Etoposide [124,125, 136,137]	Small cell lung cancer: IV: 35 mg/m^2/d for 4 d or 50 mg/m^2/d for 5 d every 3–4 wk; IVPB: 60–100 mg/m^2/d for 3 d; CIV: 500 mg/m^2 over 24 h every 3 wk; Testicular cancer: IVPB: 50–100 mg/m^2/d for 5 d repeated every 3–4 wk; IV: 100 mg/m^2 every other day for 3 doses repeated every 3–4 wk; BMT/relapsed leukemia: IV: 2.4–3.5 g/m^2 or 25–70 mg/kg administered over 4–36 h				TBili 1.5–3 mg/dL or AST >3 times ULN: administer 50% of dose; TBili 1.5–3 mg/dL or ALT or AST >180 units/L: administer 50% of dose; TBili 1.5–3 mg/dL or AST 60–180 units/L: administer 50% of dose; TBili >3 mg/dL or AST >180 units/L: avoid use
Ezetimibe [138]	10 mg PO q24h	No adjustments necessary	Not recommended	Not recommended	
Fluorouracil [124,125]	*IV bolus:* 500–600 mg/m^2 every 3–4 wk or 425 mg/m^2 on days 1–5 every 4 wk; *continuous IV infusion:* 1,000 mg/m^2/d for 4–5 d every 3–4 wk or 2,300–2,600 mg/m^2 on day 1 every wk or 300–400 mg/m^2/d or 225 mg/m^2/d for 5–8 wk				TBili >5 mg/dL: avoid use; TBili <5 mg/dL: administer 100% of dose
Glipizide [139]	*Immediate release:* 2.5–20 mg PO 1–2 times a day; *Extended release:* 5–20 mg PO q24h				Initial: 2.5 mg PO q24h
Glyburide [140]	*Immediate release:* 1.25–20 mg PO 1–2 times a day. Max 20 mg/day; *Micronized tablets*: 0.75–12 mg PO q24h	No adjustments necessary	No adjustment necessary	Avoid use	
Idarubicin [141,142]	Leukemia: *IV:* induction: 12 mg/m^2/d for 3 d consolidation: 10–12 mg/m^2/d for 2 d; stem cell transplantation: *IV:* 20 mg/m^2/24 h continuous IV infusion or 21 mg/m^2/24 h continuous infusion for 48 h				TBili >5 mg/dL: should not be administered
Ifosfamide [124,143]	Antineoplastic: testicular cancer: 1,200 mg/m^2/d for 5 d every 3 wk; Dose ranges used in other cancers: 4,000–5,000 mg/m^2/d for 1 d every 14–28 d or 1,000–3,000 mg/m^2/d for 2–5 d every 21–28 d				TBili >3 mg/dL: administer 25% of dose
Imatinib [144,145]	400–800 mg PO daily	No adjustments necessary	No adjustments necessary	Reduce dose by 25%	TBili >3 times ULN or AST/ALT >5 times ULN occur, withhold treatment until TBili <1.5 times ULN and AST/ALT <2.5 times ULN: resume treatment at a reduced dose as follows: Adults: if current dose 400 mg, reduce dose to 300 mg; if current dose 600 mg, reduce dose to 400 mg; if current dose 800 mg, reduce dose to 600 mg

Lamotrigine [146]	25–375 mg PO daily in 2 divided doses	No adjustment necessary	Without ascites: initial, escalation and maintenance: decrease by 25%; With ascites: initial, escalation and maintenance: decrease by 50%		
Losartan [147]	25–100 mg PO q24h				Reduce initial dose to 25 mg PO q24h
Methadone [148]	2.5–40 mg PO/IV q24h	No adjustment necessary	No adjustment necessary	Avoid use	
Naltrexone [149]	25–50 mg PO q24h	No adjustment necessary	No adjustment necessary	Use with caution	
Nicardipine [150]	*IV*: initial: 5 mg/h increased by 2.5 mg/h every 15 min to a maximum of 15 mg/h; consider reduction to 3 mg/h after response is achieved; *immediate release*: 20–40 PO q8h; *sustained release*: 30–60 mg PO q12h				*Immediate release:* starting dose: 20 mg PO q12h with titration; *sustained release:* no initial dose adjustment necessary
Nimodipine [151]	60 mg PO every 4 h				Liver failure: reduce dosage to 30 mg PO every 4 h.
Paclitaxel [152]	Ovarian carcinoma: *IV*: 135–175 mg/m^2 over 3 h every 3 wk or 135 mg/m^2 over 24 h every 3 wk or 50–80 mg/m^2 over 1–3 h weekly or 1.4–4 mg/m^2/d continuous infusion for 14 d every 4 wk; *intraperitoneal:* 60 mg/m^2 on d 8 of a 21-d treatment cycle for 6 cycles; metastatic breast cancer: 175–250 mg/m^2 over 3 h every 3 wk or 50–80 mg/m^2 weekly or 1.4–4 mg/m^2/d continuous infusion for 14 d every 4 wk; non-small cell lung carcinoma: 135 mg/m^2 over 24 h every 3 wk; AIDS-related Kaposi's sarcoma: 135 mg/m^2 over 3 h every 3 wk or 100 mg/m^2 over 3 h every 2 wk				24-h infusion: *AST/ALT <2 times ULN and TBili level ≤1.5 mg/dL:* 135 mg/m^2 *AST/ALT 2 to <10 times ULN and TBili level ≤1.5 mg/dL:* 100 mg/m^2 *AST/ALT <10 times ULN and TBili level 1.6–7.5 mg/dL:* 50 mg/m^2 *AST/ALT ≥10 times ULN or TBili level >7.5 mg/dL:* avoid use; 3-h infusion: *AST/ALT <10 times ULN and TBili level ≤1.25 times ULN:* 175 mg/m^2 *AST/ALT <10 times ULN and TBili level 1.26–2 times ULN:* 135 mg/m^2 *AST/ALT <10 times ULN and TBili level 2.01–5 times ULN:* 90 mg/m^2 *AST/ALT ≥10 times ULN or TBili level >5 times ULN:* avoid use
Paroxetine [153–156]	10–60 mg PO q24h				*Paxil®, Pexeva®:* initial: 10 mg PO q24h; maximum dose: 40 mg/day; *Paxil CR®:* initial: 12.5 mg PO q24h; maximum dose: 50 mg/d

(*continued*)

TABLE 74.2

CONTINUED

Drug	Normal dose	Child-Pugh score A (mild)	Child-Pugh score B (moderate)	Child-Pugh score C (severe)	Special circumstances/notes
Procainamide [157]	*Immediate release formulation:* 250–500 mg/dose PO every 3–6 h; *extended release formulation:* 500 mg to 1 g PO every 6 h; *Procanbid®:* 1,000–2,500 mg PO every 12 h; *IV*: loading dose: 15–18 mg/kg administered as slow infusion over 25–30 min or 100–200 mg/dose repeated every 5 min as needed to a total dose of 1 g. Maintenance dose: 1–4 mg/min by continuous infusion				Liver impairment: reduce dose by 50%
Quetiapine [158,159]	*Immediate release:* 25–50 mg PO 2–3 times a day. Max dose of 800 mg/d; *extended release*: 50–300 mg PO q24h. Max dose 800 mg/d				*Immediate release*: initial: 25 mg PO q24h; *extended release:* initial: 50 mg PO q24h
Risperidone [160]	1–6 mg PO q24h; 12.5–50 mg IM every 2 wk				Initial dose of 0.5 mg PO q12h; initial dose of 12.5 mg IM
Sirolimus [161,162]	Low-to-moderate immunologic risk renal transplant patients: *Oral:* <40 kg: loading dose: 3 mg/m^2 on day 1, followed by maintenance dosing of 1 mg/m^2 once daily ≥40 kg: loading dose: 6 mg on day 1; maintenance: 2 mg once daily; high immunologic risk renal transplant patients: *Oral:* loading dose: up to 15 mg on day 1; maintenance: 5 mg/d; obtain trough concentration between days 5 and 7 and adjust accordingly	Reduce dose by 33%	Reduce dose by 33%	Reduce dose by 50%	
Tigecycline [163]	Load: 100 mg IV followed by 50 mg IV every 12 h	No adjustment necessary	No adjustment necessary	Load: 100 mg IV followed by 25 mg IV every 12 h	
Tramadol [164,165]	*Immediate release formulation:* 50–100 mg PO every 4–6 h (not to exceed 400 mg/d) *Ultram® ER:* patients not currently on immediate release: 100 mg PO q24h (maximum: 300 mg/d)			*Extended release:* should not be administered	Hepatic impairment with cirrhosis: *Immediate release:* Recommended dose: 50 mg PO q12h; *Ryzolt*™ should not be used in any degree of hepatic impairment
Triazolam [166]	0.125–0.5 mg PO at bedtime	No adjustment necessary	No adjustment necessary	0.125 mg PO at bedtime	Avoid use in cirrhosis

Vinblastine [124,167]	Antineoplastic (typical dosages): *IV:* initial: 3.7 mg/m^2; adjust dose every 7 d up to 5.5 mg/m^2 (second dose); 7.4 mg/m^2 (third dose); 9.25 mg/m^2 (fourth dose); and 11.1 mg/m^2 (fifth dose). Usual range: 5.5–7.4 mg/m^2 every 7 d; maximum dose: 18.5 mg/m^2; Hodgkin's disease: usual dose: 6 mg/m^2 every 2 wk; testicular cancer: usual dose: 0.11 mg/kg daily for 2 d every 3 wk or 6 mg/m^2/d for 2 d every 3–4 wk; Bladder cancer: 3 mg/m^2 every 7 d for 3 out of 4 wk or 3 mg/m^2 days 2, 15, and 22 of a 28-d treatment cycle; melanoma: 2 mg/m^2 days 1–4 and 22–25 of a 6-wk treatment cycle; non-small cell lung cancer: 4 mg/m^2 d 1, 8, 15, 22, and 29, then every 2 wk; ovarian cancer: 0.11 mg/kg daily for 2 d every 3 wk; prostate cancer: 4 mg/m^2 every wk for 6 wk of an 8-wk treatment cycle				TBili >3 mg/dL: administer 50% of dose; TBili >3.1 or AST/ALT >3 times ULN: avoid use; TBili 1.5–3 mg/dL or AST 60–180 units: administer 50% of dose; TBili 3–5 mg/dL: administer 25% of dose; TBili >5 mg/dL or AST >180 units: avoid use
Vinorelbine [168]	Non-small cell lung cancer: Single-agent therapy: 30 mg/m^2/dose every 7 d Combination therapy with cisplatin: 25–30 mg/m^2/dose every 7 d; breast cancer: 25 mg/m^2/dose every 7 d; cervical cancer: 30 mg/m^2/dose days 1 and 8 of a 21-d treatment cycle; Ovarian cancer: 25 mg/m^2/dose every 7 d or 30 mg/m^2/dose days 1 and 8 of a 21-d treatment cycle				TBili ≤2 mg/dL: administer 100% of dose; TBili 2.1–3 mg/dL: administer 50% of dose; TBili >3 mg/dL: administer 25% of dose
Voriconazole [110]	100–200 mg PO every 12 h IV: Load: 6 mg/kg every 12 h for 2 doses followed by 3–4 mg/kg every 12 h	Reduce dose by 50%	Reduce dose by 50%	Should only use if benefits outweighs risks	
Zolpidem [169]	*Ambien®:* 10 mg PO immediately before bedtime; maximum dose: 10 mg; *Ambien CR®:* 12.5 mg PO immediately before bedtime				Hepatic impairment: Ambien®: 5 mg PO at bedtime; Ambien CR®: 6.25 mg PO at bedtime

b.i.d., twice daily; HIT, heparin-induced thrombocytopenia; HITTS, heparin-induced thrombotic thrombocytopenia syndrome; IM, intramuscularly; IV, intravenous; PCI, percutaneous coronary intervention; PO, by mouth; q, every; SC, subcutaneously; TBili, total bilirubin; t.i.d., three times a day; ULN, upper limits of normal.

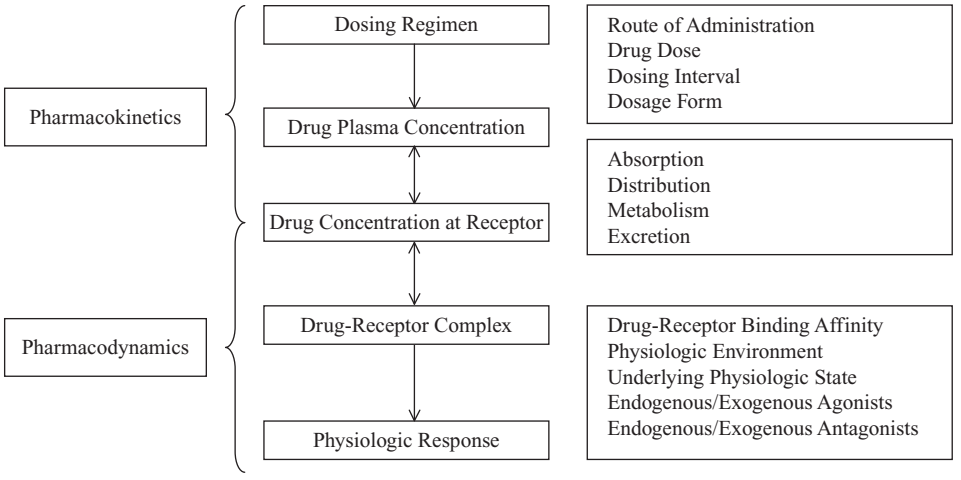

FIGURE 74.1. The relationship between pharmacokinetics and pharmacodynamics. [Adapted from Chernow B (ed): *Critical Care Pharmacotherapy*. Baltimore, MD, Williams & Wilkins, 1995, p 4.]

of achieving equilibrium between the central and peripheral compartments. When monitoring serum drug concentrations, it is important to sample after the distribution phase is complete to avoid making decisions based on falsely elevated drug levels. The *beta* (or *elimination*) *phase* describes the section of the graph once distribution is completed. This phase represents drug elimination from the central compartment. The elimination rate constant (K_{el}) is obtained by calculating the slope of the line during the elimination phase, and it can be used to calculate a drug's half-life ($t_{1/2}$).

Some drugs, such as phenytoin, follow zero-order or nonlinear kinetics. *Zero-order*, or *Michaelis-Menten pharmacokinetics*, refers to removal of a constant quantity of drug per unit of time. As the plasma concentration of the drug decreases or increases, the amount eliminated remains the same. This is the result of metabolism by a saturated enzyme system capable of eliminating drug only at a constant rate, regardless of the serum concentration. Clinically, this means small increases in the drug's dose can lead to large increases in the plasma concentration; hence, the term *nonlinear pharmacokinetics* (Fig. 74.2).

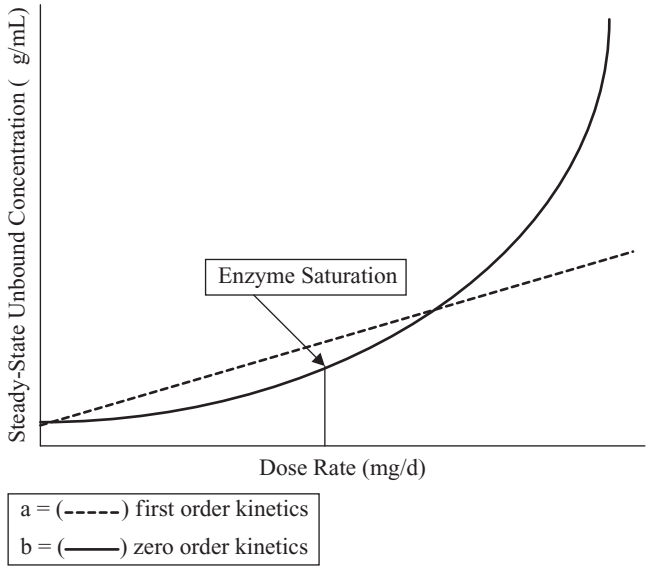

FIGURE 74.2. The effect of increasing daily dose on average steady-state drug concentrations for drugs undergoing nonlinear or zero-order pharmacokinetic modeling is shown in this figure by the *solid line*. The effect of increasing daily dose on average steady-state drug concentrations for drugs undergoing linear or first-order pharmacokinetic modeling is shown by the *dotted line*.

PHARMACOKINETIC TERMINOLOGY

The half-life of a medication is defined as the amount of time required for the concentration of the drug to decrease by 50% and is a function of drug metabolism and elimination. The half-life of a specific drug remains constant provided that the metabolizing and eliminating processes remain constant. If a patient's renal or hepatic function declines, the half-life of the drug can be significantly prolonged.

The half-life of a medication can be used to determine the time required for a drug to reach steady state. Steady state is achieved when the amount of drug entering the body equals the amount eliminated, so plasma drug levels no longer increase. Steady-state conditions are achieved at a time approximately equal to four half-lives. A clinician should generally wait for steady state to be achieved before obtaining a drug serum

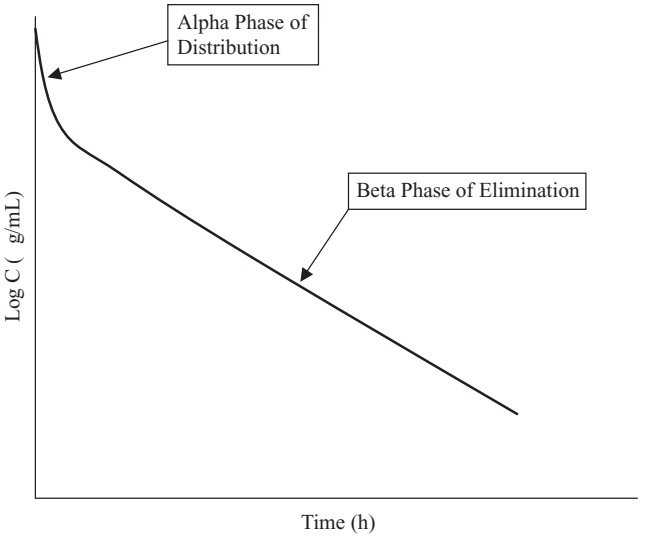

FIGURE 74.3. Logarithm of plasma concentration (Cp) versus time plot for a drug after rapid intravenous injection, delineating the alpha distribution and beta elimination phases.

concentration or changing medication dose. Knowledge of a drug's half-life may help estimate how long it should take for a pharmacologic or toxic effect to wear off. It is also important to be aware, however, that certain drugs (e.g., azithromycin) may be pharmacologically active longer than would be predicted from serum concentrations.

The rate of drug elimination from the body is described as the K_{el}. With first-order elimination, a constant percentage of drug is removed from the plasma per unit of time and is often expressed as minutes^{-1} or hours^{-1}. The K_{el} is also inversely proportional to the drug's half-life. A drug's K_{el} and half-life are constants and do not change unless the metabolizing or eliminating processes (or both) change.

Volume of distribution is not a physiologic volume but rather a theoretical volume that relates the plasma concentration to the administered dose. It is easiest to explain the concept of volume of distribution by providing an example. If a 700-mg dose of a drug administered as an intravenous bolus to 70-kg patient results in a calculated maximum plasma concentration of 7 mg per L, it appears as if the drug is dissolved in 100 L of fluid. The volume of distribution would be 100 L or 1.429 L per kg. Under normal physiologic conditions, however, a 70-kg adult does not have 100 L of body fluid. A large volume of distribution means that the amount of drug available to be measured in the plasma is reduced due to distribution among peripheral compartments or binding to plasma proteins. Medications that are hydrophilic and remain in the central (vascular) compartment, and without high affinity for plasma protein binding, tend to have a lower volume of distribution with a value that is closer to the intravascular volume. Drugs that are highly lipophilic and distribute to peripheral tissues, or are highly plasma protein bound, tend to have a very large volume of distribution.

Clearance describes the volume of fluid cleared of drug over time. Clearance through an organ is determined by the product of blood flow to the organ and the extraction ratio for the organ. The *extraction ratio* is the percentage of medication removed from the blood as it passes through the eliminating organ: It depends not only on the blood flow rate but also on the free fraction of drug and the intrinsic ability of the organ to eliminate drug.

Changes in blood flow to the organ responsible for clearing the drug or any factor altering the extraction ratio of a drug can alter a drug's clearance. For example, a patient experiencing septic or cardiogenic shock may have impaired blood flow to the liver or kidneys, hampering the clearance of a particular drug. In addition, if a pharmacologic vasopressor is added to the therapy, blood flow to the gastrointestinal tract may be compromised, resulting in a decreased absorption and transport of drug to the site of action.

RENAL DRUG EXCRETION

The primary organ of drug and drug metabolite clearance is the kidney. There are three major processes involved in renal drug clearance: glomerular filtration, tubular secretion, and tubular reabsorption. Both critical illness and renal dysfunction can alter any of these pathways individually or in combination. Studies evaluating the effect of renal impairment on drug elimination typically examine changes in total body clearance or serum concentration, since it is difficult to determine the specific impact on each pathway individually if multiple clearance routes are affected simultaneously.

Glomerular filtration is the most common pathway of renal medication excretion. The glomerular filtration rate (GFR) for an average healthy adult is between 100 and 125 mL per minute and represents approximately 20% of total plasma flow to the kidneys. Many physiologic factors affect glomerular filtration, including hydrostatic pressure and osmotic gradients. For drugs whose primary route of elimination is glomerular filtration, excretion occurs at a rate that is directly proportional to GFR (first-order process). The degree of plasma protein binding also affects filtration because only unbound drug is sufficiently small in size to be filtered across the glomerular capillaries. To estimate the possible impact of decreased filtration, it is important for the clinician to be aware of the fraction of renal drug elimination, in addition to the excretion method for any active or toxic metabolite.

Tubular secretion refers to the active process of drug transport from the interstitial fluid surrounding the proximal tubule into the tubule's lumen. The secretion rate depends on the intrinsic activity of the transporter, proximal tubule blood flow, and the percent of free or unbound drug. Tubular secretion can be an extremely efficient process with drug clearance rates exceeding filtration clearance [170]. Impaired renal function impacts tubular secretion because endogenous and exogenous organic acids and bases accumulate and compete for the transporters required for active secretion. It is difficult to predict if secretion will be increased or diminished, which may ultimately lead to drug toxicity or reduced efficacy [171].

Tubular reabsorption of drugs can be active or passive. Most of the ultrafiltrate passing through the nephron is reabsorbed. As the volume of fluid in the tubule decreases with this massive reabsorption, there can be a dramatic increase in drug concentration in the tubule, which promotes passive diffusion from inside the tubule into the plasma. Manipulation of urine pH can be used to decrease drug reabsorption and, therefore, increase excretion. Urine alkalization enhances the elimination of weak acids (e.g., barbiturates) by increasing the fraction of ionized drug.

PHARMACOKINETIC CHANGES IN CRITICALLY ILL PATIENTS WITH RENAL DYSFUNCTION

The pharmacokinetics of drugs used in critically ill patients can be altered as a function of the many dynamic physiologic changes that occur. Studies examining the pharmacokinetics of drugs used in the critically ill patient population are limited; most are performed in healthy volunteers or in relatively stable patients with a specific disease state. Patients with chronic kidney disease take multiple medications, and thus have an inherently increased risk of drug interactions, particularly in the context of altered pharmacokinetics associated with worsening renal dysfunction and critical illness. The next section of this chapter addresses some of the known pharmacokinetic changes and drug interactions that may occur in critically ill patients with renal impairment.

Absorption

Drug absorption in patients with renal dysfunction may be altered for many reasons. Gastrointestinal edema, nausea and vomiting due to uremia, and delayed gastric emptying all affect drug absorption in this patient population. In addition, patients may have comorbidities that contribute to changes in drug absorption, such as diabetic gastroparesis, diarrhea, and cardiovascular failure. Patients with chronic kidney disease and diabetic gastroparesis often are prescribed prokinetic agents (e.g., metoclopramide or erythromycin). The use of these agents may decrease enteral absorption of medications due to decreased gastric transit time, leading to decreased therapeutic effect or delayed onset of action [172]. Patients requiring phosphate-binding medications or antacids (aluminum or

calcium salts) are at risk for having these medications chelate or bind to other medications and decrease their absorption. To minimize chelation, certain medications administered enterally, such as ciprofloxacin, need to be spaced around the dosing of antacid/phosphate binders by at least 2 hours [173]. Changes in gastric pH from antacids or other acid-suppressing medications may impair the dissolution process of other enteral medications, leading to incomplete drug absorption. Bioavailability studies are lacking in critically ill patients, as most are conducted in healthy adults. In a majority of medications, however, the bioavailability in patients with impaired renal function is unchanged or increased [174].

Distribution

The distribution of drugs with high affinity for plasma protein binding can be significantly altered in critically ill patients with renal failure. Highly protein-bound drugs exist in a state of equilibrium between unbound (free) and bound drug (not free). Only the unbound drug is pharmacologically active. This means that if binding decreases, the amount of free drug available to exert a pharmacologic and toxic effect increases. Drug–drug interactions can occur when two highly plasma protein–bound drugs (>90% bound to plasma proteins) compete for the same plasma protein. If drugs such as warfarin, phenytoin, valproic acid, and salicylates (all highly bound to albumin) are administered together, displacement-mediated drug interactions may occur [175]. Drug-binding interactions also occur in patients with poor renal function due to changes in the configuration of albumin [176,177]. For example, the pharmacodynamic effects of phenytoin and warfarin are increased in patients with renal failure due to changes in albumin.

Critically ill patients often have reduced albumin levels due to malnutrition or the metabolic stress of acute illness (or both), and this can lead to higher free fractions of drugs and potentially increase the risk of toxicity. If a patient taking warfarin rapidly develops hypoalbuminemia due to critical illness, the result is an increased availability of free drug, resulting in an elevated international normalized ratio and potential risk for bleeding.

The volume of distribution for drugs administered to critically ill patients with renal failure can fluctuate considerably as fluid status changes. This can affect the clearance of drugs, and also protein binding, by altering the amount of free drug available to be metabolized, eliminated, or both. Although it is very difficult, if not impossible, to predict these changes in drug distribution, it is important for the clinician to be aware of the risks and monitor for the signs of efficacy and toxicity so that the interactions are recognized and corrected.

Metabolism

The kidneys also actively metabolize medications, and impaired renal function can affect both renal and hepatic drug metabolism. Therefore, clinicians must potentially adjust drug dosages to account for diminished renal metabolism as well as decreased renal elimination [178,179]. Drugs that are oxidized by the cytochrome P450 2D6 isoenzyme are more likely affected than those metabolized by other isoenzymes [180]. The clinical significance of these effects in critically ill patients with renal disease remains to be determined and the true relevance is difficult to define, since critically ill patients often have impaired metabolic function from nonrenal causes, including hepatic damage, diminished hepatic blood flow (shock, elderly), and use of medications that act as enzyme inhibitors or inducers.

Elimination

Determining drug elimination in the critically ill patient population is challenging for many reasons. First, the majority of the studies to determine drug pharmacology and clearance are performed in critically ill patients undergoing anesthesia or in patients with chronic diseases limited to a single organ system. It is difficult to apply these data to a critically ill patient with unstable, multiple organ dysfunction. In addition, critically ill patients each have a unique combination of factors (i.e., liver failure, hemodynamic instability, malnutrition) that can affect renal drug clearance.

AKI is often accompanied by metabolic acidosis and respiratory alkalosis, which may affect the ionization of drug molecules and, therefore, affect tissue redistribution and clearance. A low serum albumin is often associated with AKI and can lead to an increase in filtration of free drug and increased clearance of drugs that are normally highly plasma protein bound.

Dysfunction of other organ systems can significantly alter renal drug clearance through various mechanisms. For example, low cardiac output from a cardiomyopathy or acute myocardial infarction or shunting of blood away from the kidney to the heart, brain, and muscle secondary to increased sympathetic nerve activity can lower renal perfusion. Both of these mechanisms decrease drug delivery to the glomeruli, thus reducing the clearance of drugs that are eliminated primarily by glomerular filtration. Retention of fluid may increase a drug's volume of distribution and further reduce drug clearance. States of profound vasodilation, such as sepsis, systemic inflammatory response syndrome, pancreatitis, and liver failure, may impair renal drug elimination by decreasing GFR. Patients with mechanical ventilation may have reduced cardiac output (due to increased mean intrathoracic pressure), volume of distribution changes, and acid–base imbalance, which can affect renal drug disposition.

ASSESSING RENAL FUNCTION

Assessment of kidney function in a critically ill patient is challenging but essential for appropriately dosing renally eliminated medications. There are many equations available to clinicians to estimate GFR. The Cockroft-Gault equation is the most commonly used in the clinical and research settings. The Cockroft-Gault equation generally overestimates the true GFR, thus appropriate clinical judgment should be exercised. The Modification of Diet in Renal Disease (MDRD) study equation is an alternative method and is the preferred equation for patients with chronic kidney disease [181]. Depending on the equation used to estimate GFR, discordance rates of between 12% and 36% of dose adjustment recommendations can be observed [182–184]. The clinician should be aware of the potential limitations of the currently available methods of GFR estimation and use clinical judgment to assess the level of renal function to use the medication dosage guidelines in Table 74.1 appropriately. A more detailed discussion regarding the assessment of renal function can be found in Chapter 73.

DIALYSIS

The clinician must often make decisions on medication dose adjustments for patients on renal replacement therapy despite a paucity of available information. It is therefore important to

consider the dialysis system and drug characteristics that affect drug clearance, in addition to the degree, if any, of residual renal function. Detailed information regarding the many individual factors that must be considered to estimate dialysis drug clearance is discussed elsewhere [185,186]. Postdialysis replacement doses are usually necessary if clearance is particularly efficient, or residual renal function is significant. In Table 74.1, dosing information for hemodialysis, continuous venovenous hemofiltration, and continuous venovenous hemodiafiltration is provided. Drug dosing in peritoneal dialysis is not included because it is not commonly used in critically ill patients. Drug dosing recommendations with newer forms of dialysis such as slow low-efficiency dialysis, sustained low-efficiency daily dialysis, and extended daily dialysis are not included due to the limited availability of data.

Drug level monitoring may be useful for medications with established correlation between serum levels and drug efficacy or toxicity. Peak levels are usually drawn 1 to 2 hours after oral drug administration and approximately 30 minutes after parenteral administration to allow an appropriate period of time for tissue redistribution (alpha phase). Peak levels are usually monitored 4 hours postdialysis for drugs with a high volume of distribution (e.g., digoxin) because tissue penetration of these medications is more extensive and therefore less of these drugs are available in the blood to be cleared by dialysis. As a result, the intercompartmental re-equilibration postdialysis takes longer, so measurement of the level must be delayed to ensure an accurate result. Additional information regarding dialysis can be found in Chapter 75.

PHARMACOKINETIC CHANGES IN CRITICALLY ILL PATIENTS WITH HEPATIC FAILURE

Similar to renal disease, liver disease has the potential to significantly alter the pharmacokinetics of many drugs used in critically ill patients. Again, like renal dysfunction, liver dysfunction may alter the absorption, distribution, metabolism, and elimination of a drug. Unfortunately, there are limited data to help clinicians assess the impact of liver dysfunction on drug metabolism and facilitate appropriate dosage adjustments. For this reason, it is imperative for clinicians practicing in an ICU have an understanding of a drug's pharmacokinetic profile, understand potential mechanisms by which liver disease and critical illness may affect the kinetics and dynamics of drugs, and use the pharmacology of the drug to appropriately monitor for efficacy and toxicity.

Absorption

Drugs administered via the enteral route are absorbed through the gastrointestinal lining, enter the portal circulation, and pass through the liver before entering the systemic circulation. Some drugs are immediately metabolized during this initial transit through the liver, a phenomenon often called *first-pass metabolism* or the *first-pass effect*. Critically ill patients with hepatic dysfunction may have a reduced capacity to metabolize drugs which may limit the extent of first-pass metabolism. This will effectively increase the bioavailability of an enterally administered medication, resulting in higher serum levels of the drug. Medications such as morphine, midazolam, and labetalol all undergo significant first-pass metabolism and all may have increased bioavailability when given orally to patients with liver disease [187–189].

Distribution

Liver disease and critical illness may increase a medication's volume of distribution. This is often a result of a reduction in plasma proteins, development of ascites or edema, or a combination of these factors. The effects of reduced plasma protein binding on volume of distribution have been discussed earlier in this chapter. The role of plasma protein binding on hepatic metabolism and elimination will be discussed later in this chapter.

Metabolism and Elimination

Liver failure may directly alter the pharmacokinetics of a drug by a reduction in metabolism and elimination. There are many factors involved in the hepatic metabolism and eliminations of drugs. Three major factors include cellular metabolism, hepatic blood flow, and protein binding.

The two primary pathways for cellular hepatic metabolism of medications involve phase I and/or phase II metabolism. Phase I metabolism often involves the cytochrome P450 enzyme system, whereas phase II metabolism generally consists of conjugation reactions. It is important to note that liver dysfunction tends to reduce phase I metabolic pathways more than phase II metabolic pathways [190,191]. An example of this effect can be seen with midazolam and lorazepam. Midazolam undergoes phase I metabolism via CYP450 3A4 and lorazepam undergoes phase II metabolism via glucuronidation. Liver failure significantly reduces the metabolic clearance (phase I) of midazolam but does not have a significant effect on the metabolic clearance (phase II) of lorazepam [192]. Critical illness has the potential to alter both phase I and phase II metabolic activity. Data are limited, but there is some evidence to suggest the hepatic metabolism of phenytoin may be increased after severe head injury [193]. Clinicians must also be aware of changes that may influence CYP450 activity. Some patients may have genetic polymorphisms, which will result in increased or decreased drug metabolism, or patients may receive other drugs that inhibit or induce CYP450 activity. Detailed discussion of the CYP450 system and drug–drug interactions is beyond the scope of this chapter.

Hepatic Blood Flow

The clearance of drugs by the liver is determined primarily by the extraction ratio and hepatic blood flow. The hepatic extraction ratio is the fraction of drug removed after passing through the liver. The rate of hepatic metabolism of drugs with high extraction ratios (>0.7) tends to depend on hepatic blood flow and depend less on cellular metabolism. Drugs with high extraction ratios include morphine and fentanyl. For example, if a critically ill patient is receiving intravenous morphine and has a reduction in hepatic blood flow from septic shock, one might anticipate a reduction in morphine metabolism secondary to the reduction in hepatic blood flow. The rate of hepatic metabolism of drugs with a low extraction ratio (<0.3) tends to depend on cellular metabolism and depend less on hepatic blood flow. Medications with low extraction ratios include lorazepam, diazepam, and methadone [194,195].

Protein Binding

Plasma protein binding can be classified as nonrestrictive or restrictive. Medications that bind in a nonrestrictive fashion are easily dissociated from plasma proteins so that free drug

is available for hepatic metabolism. Changes in protein binding for drugs exhibiting nonrestrictive binding have minimal impact on hepatic metabolism because free drug is readily available for metabolism. Drugs that display restrictive protein binding will have less free drug available for metabolism. If there is a reduction in plasma proteins during critical illness, there will be an increase in free drug available for metabolism and there may be a resulting increase in the extraction ratio.

Estimating Hepatic Drug Metabolism

Although creatinine clearance can be a useful estimate for renal function in critically ill patients, currently there are no readily available, accurate, inexpensive methods for a clinician to quantify hepatic drug metabolism. Some studies have used scoring systems such as the Child's Score or Child's Score with Pugh Modification. These scoring systems have been useful in assessing the severity of hepatic disease and predicting mortality, but they do not accurately quantify the ability of the liver to metabolize medications and should be used cautiously. To appropriately assess hepatic function as it relates to drug metabolism, a clinician must consider many factors including laboratory data (bilirubin, albumin, prothrombin time), clinical features (hepatic blood flow, protein binding, ascites), other medications (drug–drug interactions), a medication's pharmacokinetic profile (absorption, distribution, metabolism, elimination), and the pharmacologic properties of the medication (efficacy and toxicity). In Table 74.1, dosing guidelines for varying levels of hepatic function as assessed by the Child-Pugh Score or serum bilirubin level are summarized. It is important for the clinician to use judgment when applying these dosing recommendations in clinical practice so that drug efficacy and patient safety may be optimized.

CHAPTER 75 ■ RENAL REPLACEMENT THERAPY IN THE INTENSIVE CARE UNIT

GLENN KERSHAW, MATTHEW J. TRAINOR AND PANG-YEN FAN

INTRODUCTION

Rapid deterioration of kidney function in acutely ill patients is common and potentially catastrophic. Acute kidney injury (AKI) occurs in up to 70% of patients admitted to the intensive care unit (ICU) and is associated with a twofold increase in the already high mortality rate for this population. Medical therapy is often inadequate for management of the metabolic disturbances and fluid overload that complicate AKI. In this setting, renal replacement therapy (RRT) is essential to the survival of the patient. In addition, patients with end-stage renal disease (ESRD) have high rates of hospitalization, particularly for cardiovascular disease and infection. These patients often require ICU care including RRT.

We are now entering the fifth decade of providing dialysis support to ICU patients with AKI. Despite many technical advances, mortality remains alarmingly high (40% to 60%). The high death rate is largely due to the severity and the array of nonrenal organ system dysfunction, as mortality for patients with AKI is now primarily due to multiorgan system failure (MOSF). Accumulating evidence suggests that the acutely injured kidney may in turn injure distant organs and that some forms of RRT may prevent MOSF [1].

The objectives of modern day RRT now extend beyond correction of metabolic disturbances and volume overload to include facilitation of nutritional support and drug therapy, optimization of volume status, and even promotion of nonrenal organ system recovery. Treatment strategies have shifted from reactive to proactive approaches, leading to a trend toward earlier initiation of dialysis. For example, with growing recognition that fluid overload increases mortality and that volume control can improve outcomes [2–4], RRT is applied more aggressively to prevent volume overload. An important principle of renal support strategies is that of "capacity (supply) and demand mismatch." Critically ill patients have increased "demand" for renal function. Such patients often generate increased solute from their hypercatabolic metabolism and intensive nutritional support. In addition, they receive enormous amounts of fluid because of medications, blood products, enteral and parenteral nutrition, and volume resuscitation. The stress of high solute and fluid loads may overwhelm the capacity of even a minimally injured kidney. Furthermore, the limited "supply" of renal function from kidneys already compromised by AKI is further reduced by tenuous hemodynamics and endogenous/exogenous renal pressor activity. RRT expands the limited capacity of the injured kidney to match the high fluid and solute demand, thereby restoring balance [5].

PRINCIPLES OF SOLUTE CLEARANCE AND FLUID REMOVAL BY DIALYTIC TECHNIQUES

Dialysis therapies involve the movement of solute and plasma water across a semipermeable membrane separating a blood compartment and a dialysate compartment. For intermittent hemodialysis (IHD) and continuous renal replacement therapies (CRRT), this process occurs within a cartridge called a hemofilter or hemodialyzer as shown in Figure 75.1. For peritoneal dialysis (PD), the peritoneum serves as the semipermeable membrane separating blood in the mesenteric vasculature from the dialysate in the peritoneal cavity. Characteristics such as membrane thickness and pore dimensions determine the size and transfer rate of molecules that move between the blood and dialysate.

Removal of solute and water in RRT may occur by diffusion or convection. Diffusion involves movement of solute down a concentration gradient, that is, from areas of high concentration to low concentration. Conversely, water will move from an area of low osmolality to an area of high osmolality. Solute molecules have kinetic energy and move in solution. They collide with one another and with water molecules resulting in an even dispersion throughout the solution. Dialysis is diffusion across a semipermeable membrane. When solute in

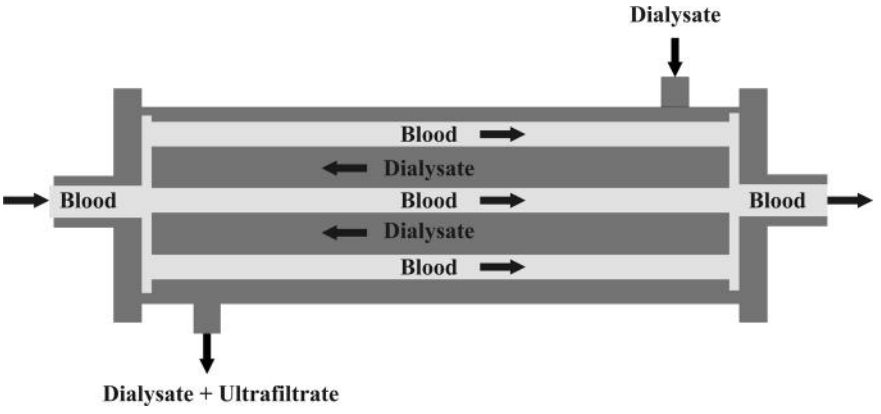

FIGURE 75.1. Schematic diagram of a hollow fiber dialyzer. Blood enters the hemofilter, passes through hollow fibers, and exits at the opposite end. Dialysate enters through the side port, flows around the blood-filled fibers in the opposite direction as the blood, combines with ultrafiltrate, and exits via the side port near the blood entry port.

motion encounters a membrane pore of sufficient dimensions, it moves through the membrane into the adjacent compartment. Small molecules with greater molecular velocity are more readily cleared than are larger molecules even if both fit through the membrane pore. A high concentration of solute in a given compartment favors a high frequency of membrane collisions and passage through the pore. Water will also pass easily through the membrane to the compartment with higher osmolality. Large shifts of water may pull some solute through the membrane, a phenomenon known as solvent drag. In a static system, net transfer (dialysis) ceases when solute concentrations equilibrate in the compartments. For RRT, blood and dialysate are continuously replenished to maintain the high concentration gradients favoring maximum transfer of solute and water.

Convection involves the transfer of solute across a semipermeable membrane driven by a hydrostatic pressure gradient. Those solutes small enough to pass through pores are swept along with water by solvent drag. The membrane acts as a sieve, retaining molecules that exceed the pore size. All filtered solutes below the membrane pore size are removed at rates proportionate to their concentration. The convective removal of fluid in this manner is termed *hemofiltration* or sometimes *ultrafiltration*. This technique does not change the plasma concentration of small solutes (blood urea nitrogen [BUN], creatinine, electrolytes, glucose), since water is removed in proportion to solute. In contrast, the concentration of larger molecules (albumin) and formed elements (hematocrit) increase as they are sieved off by the smaller membrane pores. Thus, the chemical composition of the filtrate (often referred to as ultrafiltrate) is almost identical to that of the plasma except for the absence of large molecules such as albumin. Some thought leaders opt for convection-based RRT because of greater clearance of medium-sized and large molecules than with diffusion-based techniques.

OVERVIEW OF DIALYSIS MODALITIES

The general features of different dialysis modalities are summarized in Table 75.1.

TABLE 75.1

DIALYSIS MODALITIES

Technique	Dialyzer	Physical principle
Hemodialysis		
IHD	Hemodialyzer	Concurrent diffusion (solute clearance) and convection (fluid removal)
UF	Hemodialyzer	Convection (fluid removal, limited solute clearance)
CRRT		
SCUF	Hemofilter	Convection (fluid removal, limited solute clearance)
CAVH	Hemofilter	Convection (solute clearance and fluid removal)
CAVHD	Hemofilter	Principally diffusion with some convection
CAVHDF	Hemofilter	Concurrent diffusion and convection
CVVH	Hemofilter	Convection (solute clearance and fluid removal)
CVVHD	Hemofilter	Principally diffusion with some convection
CVVHDF	Hemofilter	Concurrent diffusion and convection
Peritoneal dialysis		
CAPD	None	Principally diffusion with some convection
CCPD	None	Principally diffusion with some convection

CAPD, continuous ambulatory peritoneal dialysis; CAVH, continuous arteriovenous hemofiltration; CAVHD, continuous arteriovenous hemodialysis; CAVHDF, continuous arteriovenous hemodiafiltration; CCPD, continuous cycling peritoneal dialysis; CRRT, continuous renal replacement therapies; CVVH, continuous venovenous hemofiltration; CVVHD, continuous venovenous hemodialysis; CVVHDF, continuous venovenous hemodiafiltration; IHD, intermittent hemodialysis; SCUF, slow continuous ultrafiltration; UF, ultrafiltration.

Intermittent Hemodialysis

Intermittent hemodialysis is the standard form of RRT for the majority of stable ESRD patients in the United States. In IHD, blood is circulated through a dialysis machine and hemodialysis cartridge and then returned to the patient. Utilizing diffusion (principally for solute clearance) and convection (principally for ultrafiltration), this highly efficient modality provides rapid solute and volume removal but requires both specialized equipment and trained staff. Both blood and dialysate are pumped through the hemofilter at high flow rates. The dialysate flow is countercurrent to blood flow to maximize concentration gradients throughout the course of the filter (Fig. 75.1). Diffusion of solute across the filter is bidirectional. Urea, creatinine, and potassium move from plasma to dialysate, whereas bicarbonate and usually calcium diffuse in an opposite path (Fig. 75.2).

Standard dialysis machines can also perform isolated ultrafiltration which results in fluid removal but does not significantly alter the chemical composition of plasma. During ultrafiltration, the dialysis machine pumps only blood, but not dialysate through the hemofilter. This process generates a hydrostatic pressure gradient across the hemofilter membrane, resulting in convective fluid removal. However, no dialysate is used, so there is no diffusive solute clearance. Isolated ultrafiltration is typically used when volume overload is the sole concern.

Solute clearance can be adjusted changing the dialyzer size and membrane, blood and dialysate flow, and dialysis time as detailed later in this chapter. Fluid removal can be adjusted by changing the hydrostatic pressure gradient between the blood and dialysate compartments within the hemofilter, an automated process performed by the dialysis machine. Although this technique is commonly used in the ICU setting, the rapid shifts in solute and fluid can precipitate hemodynamic instability and may therefore be less suitable for critically ill patients. IHD treatments are typically performed for several hours three to four times per week. However, since the technique is labor and resource intensive, more frequent treatments may be limited by staffing and cost.

Peritoneal Dialysis

Peritoneal dialysis is the main form of RRT for approximately 5% to 10% of ESRD patients in the United States. In PD, dialysate is instilled into the peritoneal cavity. Through diffusion, solute and volume enter the dialysate, which is periodically drained and replaced with fresh dialysate. Solute clearance is adjusted by altering the volume of dialysate or varying the duration of each "dwell" (the interval between dialysate exchanges). More frequent exchanges will enhance solute removal, provided there is sufficient time between dialysate instillation and drainage to permit diffusion across the peritoneum. Volume is removed by maintaining a high dialysate osmolality through a high concentration of dextrose. This osmolar gradient results in the movement of water into the peritoneal cavity and also contributes to solute clearance through solvent drag. Fluid removal is adjusted by altering the dialysate dextrose content.

PD can be performed as a series of manual dialysate exchanges done during the day (chronic ambulatory peritoneal dialysis or CAPD) or through automated exchanges utilizing a PD machine (cycler) typically done at night (continuous cycled peritoneal dialysis or CCPD). For CAPD, dialysate is changed every 4 to 6 hours with a longer overnight "dwell." For CCPD, the exchanges are typically done every 2 to 3 hours through the night, and the abdomen is often left empty or with only a small volume of dialysate (sometimes called a "cushion") during the day. PD is much less efficient than IHD but is better tolerated hemodynamically, since solute and fluid shifts occur gradually. In the ICU setting, PD is generally reserved for ESRD patients who are already maintained on this modality. PD is generally not used for AKI because of technical difficulty in establishing dialysis access (discussed later in this chapter) as well as the

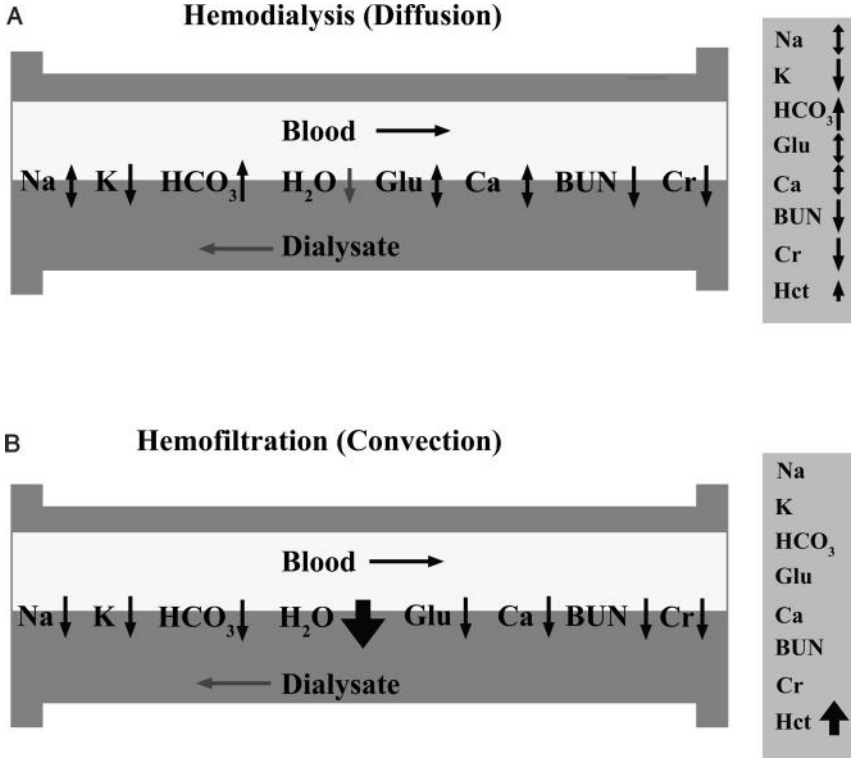

FIGURE 75.2. Solute and water movement across the dialyzer membrane in hemodialysis and hemofiltration. Net effect on serum chemistries and hematocrit shown in box at right. **A:** Significant flux in solute with relatively small shift in water in hemodialysis. Postdialyzer chemistries significantly altered with small increase in hematocrit. **B:** Significant removal of water with concomitant removal of solute in hemofiltration. Posthemofilter chemistries unchanged, since solute is removed in proportion to plasma concentration; however, hematocrit is significantly increased due to high filtration fraction. See text for more detail.

low efficiency of solute clearance. Furthermore, instillation of 1 to 2 L of dialysate into the peritoneal cavity can impair ventilation in patients with compromised oxygenation, particularly in the setting of abdominal distention or ileus.

Continuous Renal Replacement Therapies

The continuous renal replacement therapies encompass a family of dialytic modalities that vary in their mode of solute removal and duration of treatment, but share the characteristic of slow solute and volume removal maintained over an extended period of time rather than high clearances over 3 to 4 hours as with IHD. Although less efficient than IHD, CRRT provides much higher clearances than PD. Like PD, these techniques are better tolerated hemodynamically than IHD, since solute and volume are removed gradually. These modalities require intensive monitoring and necessitate ICU admission. They are widely used in the critical care setting. CRRT can be performed by a number of methods detailed later in the chapter. The operating parameters of different CRRT systems are summarized in Table 75.2. A schematic of the circuitry of the different techniques is presented in Figure 75.3.

Continuous Arteriovenous Hemofiltration, Hemodialysis, and Hemodiafiltration

Arteriovenous (AV) systems were used at the dawn of CRRT. AV systems relied on the pressure gradient between the arterial and venous circulation to drive ultrafiltration across the hemofilter membrane. However, variations in arterial pressure led to inconsistent rates of ultrafiltration and solute clearance. AV systems also required the placement and long-term maintenance of large bore arterial catheters at the femoral site. With the development of reliable double-lumen venous catheters and advanced pump-driven venovenous systems, these modalities have largely fallen out of favor.

Continuous Venovenous Hemofiltration, Hemodialysis, and Hemodiafiltration

In CRRT, solute removal is achieved by convection, diffusion, or a combination of these methods. Continuous venovenous hemofiltration (CVVH) is a purely convective technique in which a pump system drives blood through the hemofilter and generates ultrafiltration rates of 1 to 4 L per hour. Blood flow rate is generally lower than with IHD and dialysate is not used. Solute clearance is achieved by replacing these large volumes of ultrafiltrate with fluid that does not contain the solutes targeted for removal (e.g., urea and potassium). Solute clearance and volume removal are adjusted by altering the ultrafiltration rate and the rate of infusion of replacement fluid (RF). The administration of RF maintains fluid balance and lowers the plasma concentration of solute by dilution. RF can be infused before or after the filter along the course of the dialyzer circuit (Fig. 75.3).

In diffusion-based techniques such as continuous venovenous hemodialysis (CVVHD), a dual pump system drives both blood and dialysate through the hemofilter. Dialysate flow and blood flow rates are typically much lower than with IHD. The technique creates less ultrafiltrate (2 to 5 L per day) than CVVH, since the infusion of dialysate lowers the pressure gradient across the hemofilter membrane. As with IHD, diffusion of solute across the filter is bidirectional (Fig. 75.2). No RF is administered. In CVVHD, the flow of dialysate through the filter is countercurrent to the flow of blood, but the dialysate flow rate is significantly slower (1 to 2 L per hour = 17 to 34 mL per minute) than the blood flow rate (100 to 200 mL per minute). This disparity permits full equilibration of plasma urea across the membrane and complete saturation of dialysate.

For all forms of CRRT, the effluent volume (Qef) relates directly to solute clearance and is a therapeutic target to assure dosing adequacy. The effluent volume is the product of the filtration process. It comprises the ultrafiltrate in CVVH, the "spent" (equilibrated) dialysate in CVVHD, and the combination of ultrafiltrate and spent dialysate in continuous venovenous hemodiafiltration (CVVHDF). Since urea is freely filtered in CVVH, its concentration in the ultrafiltrate is identical to that of plasma. Thus, 48 L of ultrafiltrate (effluent) represents 48 L of plasma fully cleared of urea. Similarly, in CVVHD, the effluent (spent dialysate) is fully saturated with urea. Each liter of spent dialysate reflects a liter of plasma fully cleared of urea. In diffusive systems, blood flow has little impact on clearance at low dialysate flow (1 to 2 L per hour) but increasing impact as dialysate flow increases.

CVVHDF combines diffusion and convection into a single procedure. Dialysate is infused at 1 to 2 L per hour to boost the convective clearance generated by high (1 to 2 L per hour) ultrafiltration rates. RF is needed to offset the high rate of ultrafiltration. Historically, CVVHDF was developed to overcome clearance limitations posed by the older generation of CRRT equipment which limited both dialyzer blood and dialysate flow. However, current CRRT equipment delivers blood flow at 400 mL per minute and dialysate flow at up to 10 L per hour. Large bore (13 French) catheters are increasingly used to support high flow systems. These advances allow high volume ultrafiltrate generation with less complex CVVH or CVVHD systems and have called the role of CVVHDF into question.

TABLE 75.2

COMPARISON OF RRT MODALITIES

	IHD	SLED	SCUF	CVVH[a]	CVVHD[a]	CVVHDF[a]
Blood flow *(mL/min)*	250–400	100–200	<100	200–400	100–200	100–200
Dialysate flow *(mL/min)*	500–800	100	0	0	17–34	17–34
Filtrate *(L/d)*	0–4	0–4	0–4	48–96	0	24–48
Replacement fluid *(L/d)*	0	0	0	46–94	0	23–44
Effluent saturation *(%)*	15–40	60–70	100	100	85–100	85–100
Solute clearance	Diffusion	Diffusion	Convection	Convection	Diffusion	Both
Duration *(h)*	3–5	8–12	Variable	>24	>24	>24

[a]In the absence of a blood pump, arteriovenous circuits can be used to provide continuous therapy (CAVH, CAVHD, CAVHDF).
IHD, intermittent hemodialysis; CVVH, continuous venovenous hemofiltration; CVVHD, continuous venovenous hemodialysis; CVVHDF, continuous venovenous hemodiafiltration; RRT, renal replacement therapy; SCUF, slow continuous ultrafiltration; SLED, sustained low efficiency dialysis.

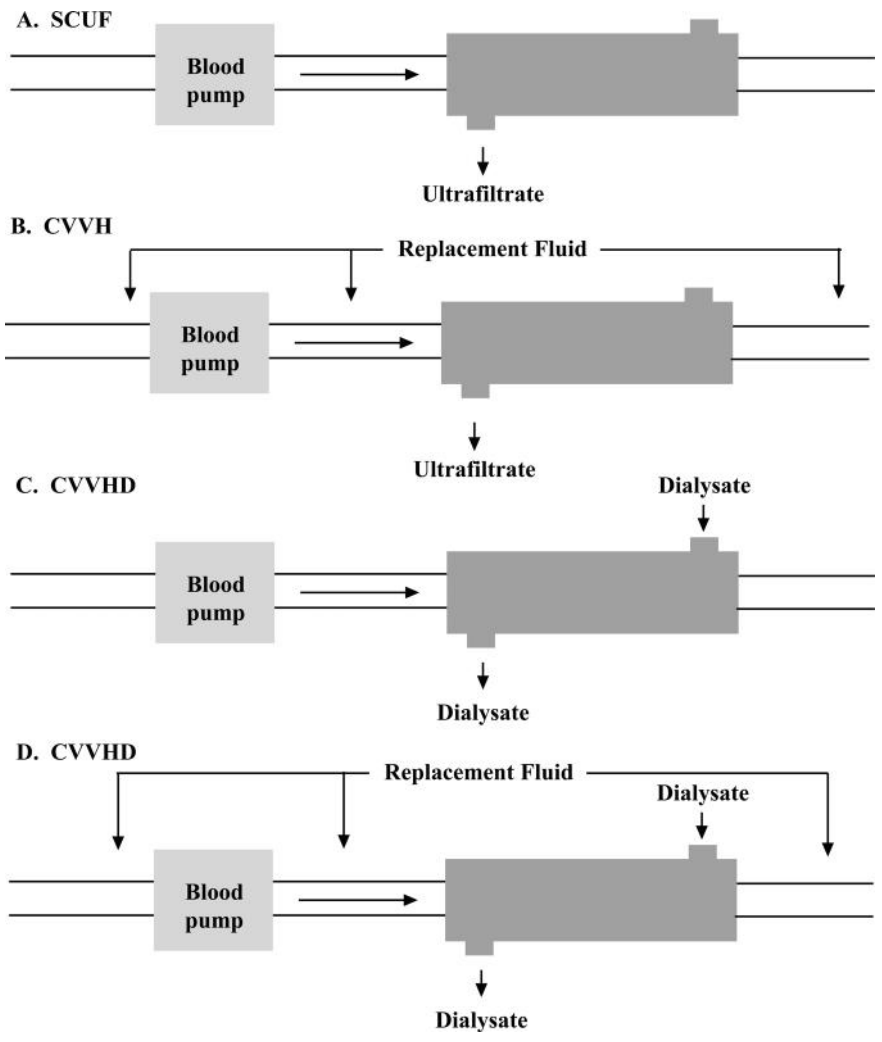

FIGURE 75.3. Schematic diagram of various CRRT configurations. **A:** SCUF (slow continuous ultrafiltration). Ultrafiltrate is generated by the transmembrane pressure gradient produced by the blood pump. **B:** CVVH (continuous venovenous hemofiltration). Large volume ultrafiltrate is generated and replacement fluid is infused preblood pump, prehemofilter, or posthemofilter. **C:** CVVHD (continuous venovenous hemofiltration). Dialysate is pumped through the filter to generate diffusive solute clearance. **D:** CVVHD (continuous venovenous hemodiafiltration). The system utilizes high ultrafiltration with replacement fluid as well as dialysate.

Slow Continuous Ultrafiltration

In slow continuous ultrafiltration (SCUF), a pump system maintains low blood flow (usually no more than 100 mL per minute) through a hemofilter and generates low rates of ultrafiltration (typically 100 to 300 mL per hour). This modality provides volume removal but does not alter the chemistry of plasma, since water is removed in proportion to solute. Compared with other CRRT modalities, SCUF is a low intensity nursing procedure. The procedure is often used in settings of severe volume overload with acceptable chemistries. At our institution, SCUF is often employed as an adjunct to IHD in the hemodynamically stable, volume overloaded patient.

Sustained Low Efficiency Dialysis

Hybrid therapies apply the CRRT principle of low solute clearance over an extended, but not continuous, period of time. Sustained low efficiency dialysis (SLED) is better tolerated hemodynamically than IHD and can be performed with either standard hemodialysis machines or with CRRT equipment. Lower blood flow (100 to 200 mL per minute) and dialysate flow (100 mL per minute) rates achieve adequate diffusive solute clearance and convective volume removal over a typical 8- to 12-hour session. SLED done with standard hemodialysis machines expands the clinical utility of these devices, but generally requires the presence of a trained dialysis nurse. However, this modality can be done with a CRRT machine by an ICU nurse. There are no data comparing SLED outcomes with either IHD or CRRT.

TECHNICAL CONSIDERATIONS FOR RENAL REPLACEMENT THERAPY

Anticoagulation

Hemofilter fibers are prone to thrombosis, as removal of fluid through ultrafiltration leads to hemoconcentration at the distal end of the dialyzer. As the filtration fraction (FF), that is, the proportion of plasma flow that is filtered, increases, the risk of filter thrombosis also rises. The FF can be calculated as follows:

$$\begin{aligned} FF &= \text{ultrafiltration rate plasma flow rate} \\ &= \text{ultrafiltration rate}/[\text{blood flow rate} \times (100\text{-Hct})] \end{aligned}$$

Thus, higher rates of ultrafiltration, especially if coupled with low blood flows, predispose to hemofilter thrombosis. Poor filter performance and filter clotting increases sharply at FF greater than 20%. Higher blood flow rates permit greater rates of fluid removal, since hemoconcentration within the filter is limited by the short transit time of blood through the dialysis cartridge.

Hemodialysis can generally be performed without anticoagulation. The high blood flows used with this technique permit adequate solute clearance and ultrafiltration with limited risk of dialyzer thrombosis [6]. However, IHD without anticoagulation also necessitates frequent saline flushes through the hemodialyzer to help maintain fiber patency and therefore is more labor intensive than standard IHD. In addition, packed red blood cell transfusions cannot be infused through the arterial line of the dialyzer circuit, since the resulting increase in hematocrit will lead to hemofilter clotting.

However, with CCRT, blood flow rates are typically low and ultrafiltration rates high, especially for CVVH, and filter thrombosis is a significant barrier to effective implementation of these therapies. One approach called *predilutional hemofiltration* involves infusion of RF into the CRRT circuit at a point before the filter, thus lowering the hematocrit through dilution. As a result, a higher ultrafiltration rate may be achieved without compromising filter life. However, prefilter RF also dilutes the solute concentration of blood entering the filter and reduces effective clearance. With this approach, the target effluent volume should be increased by 25% to compensate for the dilutional effect. Other CRRT parameters such as blood and ultrafiltration rate must be adjusted to compensate for this inefficiency.

Anticoagulation, typically with unfractionated heparin, is generally necessary to maintain hemofilter patency with CRRT, especially for principally convective modalities such as CVVH. After an initial bolus of 1,000 to 2,000 units, a continuous infusion of approximately 10 units per kg per hour is adjusted to maintain the partial thromboplastin time in the venous line of the blood circuit at 1.5 to 2 times control. However, heparin infusions do result in some systemic anticoagulation and may be contraindicated in patients with active hemorrhage or heparin-induced thrombocytopenia (HIT).

Despite theoretical advantages, low-molecular-weight heparins do not appear to offer any significant advantages in efficacy or safety over unfractionated heparin for RRT [7]. In addition, these agents are more costly and their anticoagulant effects more difficult to monitor.

For patients with active hemorrhage, regional anticoagulation limited to the CRRT blood circuit is preferred. Citrate regional anticoagulation is widely used and has become the primary mode of anticoagulation in many centers. Citrate infused in the arterial limb of the CRRT circuit prevents hemofilter thrombosis by chelating calcium, a critical component of the clotting cascade. Calcium chloride infused into the venous line of the system restores normal systemic calcium levels. This approach appears to reduce the risk of hemorrhage and extend hemofilter patency [8]. In addition, citrate can be used for patient with HIT.

Serum and ionized calcium levels must be carefully monitored, especially in patients with significant liver dysfunction, and the calcium infusion appropriately adjusted. Citrate is hepatically metabolized into bicarbonate and can cause metabolic alkalosis. In the setting of hepatic failure, citrate accumulation results in elevated serum but low ionized calcium levels, reflecting increased circulating calcium bound to citrate. Trisodium citrate solution, typically used in this form of anticoagulation, may also cause hypernatremia.

Other methods of regional anticoagulation such as prostacyclin infusion or heparin reversal with protamine have been less successful. Prostacyclin, an arachidonic acid metabolite, has a half-life of only 3 to 5 minutes and inhibits platelet aggregation. However, it induces vasodilatation and is associated with hypotension and it is costly. Protamine binds and neutralizes heparin, but infusions are technically complex and may be associated with rebound bleeding.

Anticoagulation is unnecessary for PD. However, intraperitoneal fibrin can occlude the dialysis catheter. If fibrin clots are noted in the dialysate, heparin (1,000 units) should be added to each PD exchange for several days. Intraperitoneal heparin is not absorbed and will not cause systemic anticoagulation.

Blood Flow Rate

Maximal urea clearances with standard dialyzers require blood flows of approximately 400 mL per minute through the hemofilter. However, when dialysis is initiated for ESRD, blood flow rates begin at 200 to 250 mL per minute and are increased incrementally over several sessions. The low blood flow limits the efficiency of the dialysis and prevents rapid solute and water shifts that can precipitate complications including delirium, seizures, and dyspnea, collectively known as the dysequilibrium syndrome. With AKI, high blood flow rates (400 mL per minute) may be used immediately unless the BUN has been markedly elevated for a prolonged period (e.g., >100 mg per dL for >3 days). Blood flow rates for CRRT can vary from 100 to 400 mL per minute, but dysequilibrium syndrome is not a concern because solute and fluid removal are much less efficient than with IHD. For diffusive CRRT modalities such as CVVHD, dialysate flows are so low that solute concentrations fully equilibrate between the blood and dialysate compartments of the hemofilter. Therefore, increases in blood flow do not appreciably enhance solute clearance for these forms of RRT.

Dialysate Flow Rate

The dialysate flow rate is typically fixed or has very limited variability (500 to 800 mL per minute) in most hemodialysis machines. These rates are sufficiently high so that changes in dialysate flow have relatively little impact on IHD clearances. However, since dialysate flow rates are much lower with CRRT, increases in dialysate flow can significantly enhance solute removal. Thus, change in dialysate flow rate is an important adjustment to achieve adequate clearances with these modalities. With PD, clearances can also be increased by increasing total dialysate volumes, either by instilling more dialysate with each exchange or by increasing the frequency of exchanges. The maximal of volume per exchange is limited by abdominal discomfort and/or respiratory compromise, and high exchange volumes can predispose to leakage of dialysate from the catheter tunnel. Exchanges done more often than every 2 hours provide little additional solute clearance, as shorter dwell time limits diffusion across the peritoneum.

Dialyzer Membrane

Most hemodialyzers and hemofilters are constructed as cylinders containing hollow fibers composed of a semipermeable membrane (Fig. 75.1). The surface area of the membrane depends on the number and length of these fibers. Membrane surface area affects solute clearance and ultrafiltration. Membrane size or surface area varies with the specific model of hemodialyzer or hemofilter. Bigger dialysis cartridges are used for large patients or those needing high solute clearances. Children usually require specially downsized hemofilters.

The hemofilter membrane may consist of nonorganic, synthetic compounds (e.g., polysulfone, polyacryl nitrate) or cellulose-derived materials (cellulosic membranes). In vitro exposure of blood to cellulosic membranes leads to complement activation and leukocyte adherence and these membranes are categorized as bioincompatible. Synthetic membranes are inert and are termed *biocompatible*. A seminal randomized trial reported better survival and higher rates of recovery

from AKI among patients dialyzed on biocompatible membranes [9]. This outcome advantage was challenged in subsequent trials and meta-analyses [10]. Modern day cellulosic membranes claim biocompatibility, since the offending, complement-activating moiety (hydroxyl group) is now buried deep within the membrane. Regardless, we recommend exclusive use of synthetic (biocompatible) dialyzers in patients with AKI. The cost differential between synthetic and cellulosic membranes is minimal.

Pore dimensions determine the size selectivity of molecular flux across the membrane. Low flux (small pore) membranes clear small molecules (urea, potassium, and creatinine) but do not clear the larger "middle molecules" which may act as toxins. High flux membranes (large pore) clear middle molecules, such as β_2 microglobulin and perhaps inflammatory cytokines generated by AKI and MOSF. This theoretic advantage of high flux membranes may be compromised in settings of low water quality. Large pore size would permit backflow (dialysate to blood) into the patient of endotoxin fragments and other harmful water-borne molecules, such as heavy metals. In settings with high-quality water systems (generally available in the United States), we recommend the use of high flux, large surface area, biocompatible membranes.

Dialysate Composition

Dialysate solutions are composed of specific concentrations of sodium, potassium, bicarbonate, calcium, chloride, glucose, and magnesium. The range and standard concentrations of contents of dialysates for both IHD and PD are summarized in Table 75.3. For IHD, chloride, glucose, and magnesium concentrations are generally fixed. The usual dialysate sodium concentration is 140 mEq per L, but higher concentrations (148 to 150 mEq per L) are often used early in an IHD session to prevent hypotension. Dialysis against a high sodium concentration (148 to 150 mEq per L) results in diffusion of sodium into plasma. This maintains plasma osmolality at a time when urea and other small solutes are being rapidly cleared across the membrane, thus preventing acute intracellular shifts of water that can precipitously lower plasma volume. Later in the dialysis procedure, when urea mobilization is proceeding at a slower pace, dialysate (serum) sodium concentration is returned to normal (140 mEq per L) to prevent hypernatremia. This process of sodium profiling (or sodium modeling) is one of the major strategies employed to prevent hypotension in the AKI patient managed with IHD. Modern dialysis machines offer a variety of sodium modeling profiles. This technique is not needed for CRRT, since solute and volume removal occurs slowly.

The dialysate potassium concentration generally ranges from 2.0 to 4.0 mEq per L. It is adjusted to normalize the serum potassium after the postdialysis equilibration period and for the next 24 hours. A rapid rate of rise of serum potassium is best treated with daily IHD or CRRT rather than alternate day IHD using low potassium (1.0 mEq per L) dialysate because of the risk of arrhythmias precipitated by intradialytic hypokalemia. Low potassium dialysate is reserved for patients with life-threatening hyperkalemia. In this setting, intradialytic potassium levels should be monitored hourly and the dialysate potassium increased as soon as the potassium is lowered to below the life-threatening range (<6 to 6.5 mEq per L). The dialysate potassium concentration is adjusted based on the predialysis serum potassium:

serum K^+ <4.0	dialysate K^+ 4.0
serum K^+ 4.0–5.5	dialysate K^+ 3.0–3.5
serum K^+ 5.6–7.5	dialysate K^+ 2.0
serum K^+ >7.5	dialysate K^+ 1.0

The buffer used in dialysate is now uniformly bicarbonate. The concentration of bicarbonate in dialysate usually varies from 33 to 35 mEq per L. Higher bicarbonate concentrations (40 mEq per L) are used in severe acidosis or to offset elevations of carbon dioxide resulting from the permissive hypercapnia that attends low tidal volume ventilation.

Dialysate calcium concentration in maintenance hemodialysis is 2.5 mEq per L of diffusible calcium. Since 50% of total calcium is protein bound, this value approximates the diffusible or ionized calcium in plasma at a total serum calcium concentration of 10 mg per dL (10 mg per dL total calcium = 5 mg per dL ionized calcium = 2.5 mEq per L ionized calcium). Since hypocalcemia is common in AKI and correction of acidosis may further depress ionized calcium, some experts advocate higher dialysate calcium concentration (3.0 to 3.5 mEq per L) in patients with AKI. High calcium dialysate may be used to correct hypocalcemia but should be used with caution. Calcium loading in animal models of sepsis increases mortality [11].

For CRRT, a wide variety of dialysate and RFs may be used. These may be custom compounded by hospital pharmacies, by regional pharmacies or may be purchased as commercially prepared solutions. The composition of dialysate employed in CVVHD may be identical to that of RF employed in CVVH. Potassium and calcium concentrations are selected to meet patient needs. Base composition may be bicarbonate, lactate, or citrate. The latter two buffers are metabolized to bicarbonate and effectively address acidosis in most patients with adequate hepatic function.

A decade ago, commercially prepared lactate buffered solutions were widely used because of their stability and extended shelf life. Bicarbonate-based solutions were unstable and available only if compounded on site. Now a number of commercially prepared bicarbonate-based solutions are available. Prolonged shelf life is achieved by a partition in the infusion bag that separates bicarbonate from the remaining solution. Breaking the partition just before use mixes the two compartments. Bicarbonate provides better hemodynamic stability than does lactate and is the buffer of choice in hepatic failure. Citrate-based RF has also been used successfully in CVVH systems.

In contrast to IHD, the composition of peritoneal dialysate is relatively constant. These commercially produced solutions are available in 2- and 5-L bags and vary only in dextrose

TABLE 75.3

DIALYSATE FORMULATION FOR HEMODIALYSIS AND PERITONEAL DIALYSIS

Solute	Range (usual concentration)
Intermittent hemodialysis	
Na^+	138–145 mEq/L (140)
K^+	0–4 mEq/L (2)
Cl^-	100–110 mEq/L (106)
HCO_3^-	35–45 mEq/L (35)
Ca^+	1.0–3.5 mEq/L (2.5)
Mg^+	1.5 mEq/L (1.5)
Glucose	0–200 mg/dL (200)
Peritoneal dialysis	
Na^+	132 mEq/L
K^+	0
Cl^-	96 mEq/L
Lactate	35 mEq/L
Ca^+	2.5 or 3.5 mEq/L
Mg^+	0.5 or 1.5 mEq/L
Glucose	1.5%, 2.5%, or 4.25% g/dL

content (1.5%, 2.5%, and 4.25% concentrations). Icodextrin, a glucose polymer which is absorbed more slowly than dextrose, has been used for selected patients with poor ultrafiltration [12]. If necessary, potassium, insulin, or even certain antibiotics can be added to the dialysate.

Dialysis Access

Establishing and maintaining adequate access is paramount to the delivery of all types of RRT. Access is best considered in two distinct settings: the ESRD patient with permanent access and the AKI patient requiring temporary access.

Arteriovenous Fistula and Graft

For the ESRD patient maintained with IHD, permanent dialysis access options include an arteriovenous fistula (AVF), arteriovenous graft (AVG), or, rarely, a tunneled central venous catheter (discussed later in the chapter). Created by connecting an artery directly to a vein, typically in the upper extremity, an AVF must "mature," a process during which high blood flow causes gradual dilatation and thickening or "arterialization" of the veins proximal to the AV anastomosis. Once mature, the AVF can be repetitively cannulated with large bore needles several times a week for IHD. Consider the optimal access for hemodialysis, AVF provides high blood flow (>500 mL per minute), durable long-term vascular access, relatively low thrombosis rates, and low infection rates. However, AVFs require long maturation time (typically several months), making them unsuitable for patients with AKI. In addition, AVFs cannot withstand prolonged cannulation, precluding their use for CRRT.

For an AVG, a synthetic graft, usually composed of material such as polytetrafluoroethylene, is used to connect the artery and vein. AVGs are used when the native veins are deemed of insufficient size or quality and unlikely to mature into a functional AVF. Although maturation time is only a few weeks, AVGs cannot be used for AKI. AVGs are not as durable as AVFs because the graft material deteriorates with multiple cannulations. In addition, AVGs have much higher rates of thrombosis and infection and they also cannot be used for CRRT.

To preserve the patency of AVFs and AVGs, measurement of blood pressure, venipuncture, and constricting dressings or tourniquets should be avoided in the access extremity. Acute thrombosis may also occur in the setting of hypotension or severe volume depletion, two conditions commonly seen in critically ill patients.

Peritoneal Dialysis Catheters

Unlike IHD and CRRT, patients on PD do not require vascular access. Instead, PD catheters allow for infusion and drainage of dialysate from the peritoneal cavity. There are several different catheters used for ESRD, but none have established superiority over the others. Most are made of silicone and have two synthetic cuffs, one placed beneath the skin and one beneath the abdominal fascia, which prevent displacement and infection of the catheter. The connectors between these catheters and dialysate fluid bags vary with each manufacturer, necessitating the use of adapters to join equipment or dialysate solutions from different companies. These catheters are typically not used for 1 or 2 weeks after placement to permit healing of the insertion site and catheter tunnel. Premature use increases the risk of dialysate leak and infection. In urgent situations, early use of permanent catheters can be attempted with low volume exchanges and the patient supine.

Although very rarely used, when access is required for AKI, a noncuffed catheter can be placed at the bedside and used immediately. This procedure should be reserved for unique situations and be performed by a skilled operator because of the risks of bowel perforation or organ puncture. Acute catheters can only be used for 3 days before the risk of peritonitis rises dramatically. At that point, the catheter must be removed and a new catheter placed at a different insertion site.

Catheters

For most patients with AKI, dialysis access is achieved by placement of a temporary central venous catheter. These devices fall into two different categories, acute noncuffed, nontunneled lines or long-term cuffed, tunneled catheters, but all are large diameter (12 to 15 French) and of dual lumen design. The acute catheters are typically constructed of materials such as polyurethane and are relatively stiff at room temperature, but become pliable at body temperature. For patients with urgent or emergent need of dialysis, acute catheters provide rapid access for IHD and CRRT and are typically inserted at the bedside into the internal jugular or femoral veins. The subclavian site is generally avoided due to the risk of developing venous stenosis after placement of relatively stiff acute dialysis catheters. Subclavian vein stenosis can preclude future placement of an AVF or AVG graft in the ipsilateral arm by restricting venous flow. Other complications of these catheters include infection, thrombosis, and vascular perforation and are discussed below.

Cuffed, tunneled catheters are placed when the expected duration of dialytic support exceeds 2 weeks. Composed of soft material such as silicone, they are usually inserted under fluoroscopic guidance into the internal jugular, external jugular, subclavian, or femoral vein and exit through a subcutaneous tunnel. These devices are available in different configurations and may have a single or dual lumen. For appropriate function, the catheters are placed so that the tips extend into the right atrium, thus permitting higher blood flows. Unlike the stiffer acute noncuffed dialysis lines, the softer cuffed catheters do not pose a significant risk for perforation. The subcutaneous cuff and insertion tunnel serve to anchor the catheter and also inhibit infection such that these lines may remain in place for several months or longer. Given the duration of use, these devices should not be placed in patients with bacteremia. Complications are similar to those with uncuffed catheters and will also be discussed below.

INDICATIONS FOR AND TIMING OF INITIATION OF RENAL REPLACEMENT THERAPY

Remarkably, there is no consensus on the absolute indications for initiation of RRT in AKI. The absence of rigorous or quantitatively defined clinical or biochemical findings that warrant dialytic support have resulted in wide variation in clinical practice. Even the limits of medical therapy and diuretic therapy are poorly defined. Conventional indications are as follows:

- Volume overload refractory to or inadequately controlled with diuretic therapy
- Hyperkalemia or metabolic acidosis refractory to medical management
- Concomitant intoxication with a dialyzable drug or toxin
- Overt uremic signs or symptoms
  - encephalopathy
  - pericarditis
  - uremic bleeding diathesis
- Progressive and advanced asymptomatic azotemia

Reserving RRT for patients who meet one of these criteria may have little impact on the high mortality of AKI, particularly in the setting of MOSF. A management strategy that merely

prevents uremic complications follows the old paradigm for AKI: these patients die *with*, but not *of*, their renal dysfunction. The modern paradigm recognizes that AKI is an independent risk factor for death [13–15] and that the aggressive management of RRT may affect outcomes and reduce mortality [16–18]. However, no consensus guideline exists which defines the optimal time to initiate RRT. No threshold of azotemia or duration of oliguria has been identified beyond which dialysis support is indicated.

Early Versus Late Initiation of RRT

The evidence for early initiation of RRT in AKI is summarized in Table 75.4. Prior to 1999, all studies employed IHD. Results were often conflicting and difficult to interpret, since both timing of RRT initiation and intensity of RRT varied. Three retrospective studies from the 1960s and 1970s reported a survival advantage with early dialysis [19–21]. It is noteworthy that BUN values that defined "early dialysis" (<93 to 150 vs. >160 to 200 mg per dL) are rather high by today's standards. A small prospective trial conducted on a US Navy Hospital Ship during the Viet Nam War reported better survival with early initiation [22]. The early dialysis group also received more intensive dialysis. Ten years later, the same investigator prospectively studied early and intensive dialysis in a population with nontraumatic AKI [23]. The target BUN in the early/intensive group was 60 mg per dL, whereas the target BUN in the late/less intensive group was 100 mg per dL. No survival advantage was observed in the early/intensive group. This small underpowered study led to the general view that in the absence of life-threatening complications or uremic symptoms, HD need not be initiated until the BUN exceeded 100 mg per dL.

Studies on early initiation over the last 10 years involve primarily CRRT. A retrospective review of 100 trauma patients with AKI [24] reported a distinct survival advantage (39% vs. 20%) of "early starters" (BUN <60) over "late starters" (BUN >60). The early group started CRRT on hospital day 10 with a mean BUN of 43 and late starters on hospital day 19 with a mean BUN of 93. Late starters had more MOSF. One interpretation of this observation is that early CRRT improves survival by preventing MOSF.

A single modern-day, prospective, randomized trial has been published on early initiation of RRT [25]. Dutch investigators randomized 106 oliguric patients to early high volume CVVHD, early low volume CVVHD, and late low volume CVVHD. The criterion for early starters was oliguria more than 6 hours after optimizing hemodynamics or creatinine clearance less than 20 mL per minute on a 3-hour collection. Late starters initiated CVVHD at a BUN more than 112, K more than 6.5 or for pulmonary edema. Survival at 28 days was no different in the three groups. We suggest caution when interpreting this negative study. It is likely underpowered for the primary outcome (death). The overall mortality (27%) was much lower than the typical patient with AKI requiring CRRT support (>60%).

A survival advantage to early CRRT is reported in two retrospective studies of AKI following cardiac surgery [26,27]. Both studies report better survival when the indication for CRRT was set as diuretic resistant oliguria (urine output <100 mL per 8 hours) rather than traditional laboratory parameters. CRRT was initiated less than 24 hours postoperatively in early starters and 2.5 days postoperatively in the late starter group.

A recent large ($n = 243$) multicenter, observational study reported a survival advantage with early initiation [28]. Early and late starts were defined by an initiation BUN less than 76 mg per dL (low azotemia) and greater than 76 mg per dL (high azotemia), respectively. After adjusting for comorbid variables and for propensity for initiation of RRT, the relative risk of death at 60 days in the high azotemia group was nearly twofold.

A recent meta-analysis on the timing of initiation of RRT analyzed 18 (retrospective) cohort studies involving more than 2,000 patients [29]. A 28% risk reduction in mortality was observed with early dialysis. Publication bias, variations in technology over the 50-year span of cited studies, and heterogeneity of the definitions of early and late therapy preclude definitive conclusions.

A major methodological limitation of all observational studies is the omission of patients who never receive RRT from the analysis. Less than 15% of patients who meet RIFLE criteria (threefold increase in creatinine) receive RRT during their hospitalization. Some patients with AKI recover renal function and survive while others may expire before initiating RRT. Yet, neither outcome is integrated into a retrospective analysis. Among AKI patients managed with RRT, patients destined to recover and survive may enrich early start groups, whereas patients destined to die of MOSF after an extended ICU course may be overrepresented in late start groups. Future studies on early RRT versus late RRT, whether prospective or observational, must integrate a "No RRT" arm into the study design [30].

The best attempt to provide quantitative sample guidelines for RRT was formulated by the Acute Kidney Injury Network (AKIN) in 2008 [31]. This expert panel of critical care nephrologists references key outcome studies in justifying specific parameters to trigger RRT and are summarized in Table 75.5.

Several points are emphasized as follows:

Indications for and timing of RRT are viewed within the context of the patient's entire clinical condition. A specific indication may be absolute or relative. An absolute indication represents a stand-alone condition that makes RRT mandatory. A relative indication requires a concomitant condition without which RRT is not mandatory but could be recommended. The presence of an indication in a relatively stable patient with oliguric AKI as single organ system failure would be viewed differently from the same parameter existing in a critically ill patient with MOSF.

Trends and trajectories of illness may be more important than absolute parameters. The strength of an indication for RRT depends on whether the patient's clinical condition is improving, deteriorating, or static.

Comorbid severity scores were discussed but never formulated into the guideline.

The AKIN panel underscores a growing body of evidence that volume overload in AKI carries high morbidity and mortality [2]. Early and meticulous control of volume with CRRT can improve outcomes especially in the pediatric population with AKI and following cardiac surgery [3,4].

The panel makes no particular comment on sepsis-related AKI. The intriguing concept of cytokine clearance by convective CRRT systems in septic shock remains unproven [32–34]. Metabolic or oliguric thresholds for initiating CRRT often exist early in the course of sepsis. We advocate early CRRT in the oliguric, hypotensive septic patient even when specific metabolic indications have not been met.

Dialysis Dose

There is no benchmark for the dose or intensity of RRT used to treat AKI. Many experts suggest that IHD in this setting should at least achieve the urea clearance recommended for patients with ESRD, although there are no data validating this approach. Urea clearance can be quantitated through the Kt/V or urea reduction ratio (URR). The Kt/V is a dimensionless

TABLE 75.4

SUMMARY OF STUDIES EVALUATING TIMING OF INITIATION OF RENAL REPLACEMENT THERAPY

Study	RRT modality	Study design	Patients	Criteria for early RRT	Criteria for late RRT	Survival (%), early RRT	Survival (%), late RRT	Comment
Parsons et al. [19]	IHD	Retrospective	33	BUN 120–150	BUN >200	75	12	Historical control
Fischer et al. [20]	IHD	Retrospective	162	BUN ~150	BUN >200	43	26	Historical control
Kleinknecht et al. [21]	IHD	Retrospective	500	BUN <93	BUN >163	73	58	Historical control
Conger [22]	IHD	RCT	18	BUN <70 or Creat <5	BUN ~150 Creat ~10	64	20	Posttrauma, Navy ship Tests intensity + timing

INDICATIONS FOR RENAL REPLACEMENT THERAPY IN PATIENTS WITH ACUTE KIDNEY INJURY

Indication	Characteristics	Absolute/Relative
Metabolic abnormality	BUN >76 mg/dL	Relative
	BUN >100 mg/dL	Absolute
	Hyperkalemia >6 mEq/L	Relative
	Hyperkalemia >6 mEq/L with ECG changes	Absolute
	Dysnatremia	Relative
Acidosis	pH >7.15	Relative
	PH <7.15	Absolute
	Lactic acidosis related to metformin use	Absolute
Anuria/oliguria	<0.5 mL/kg/h × 6 h	Relative
	<0.5 mL/kg/ h × 12 h	Relative
	<0.3 mL/kg/h × 24 h or anuria × 12 h	Relative
Fluid overload	Diuretic sensitive	Relative
	Diuretic resistant	Absolute

index of dialysis dose for which K is the urea clearance of the dialyzer, t is the duration of dialysis, and V is the volume of distribution of urea; the Kt/V is thought to be a measure of time-averaged urea clearance and is determined by applying predialysis and postdialysis urea and volume data to a published formula. The Kt/V for each IHD should exceed 1.2, assuming single pool urea kinetics. Alternatively, some programs target a URR of more than 65% or 70%. The URR is calculated from the following formula:

$$\text{URR} = (\text{predialysis BUN} - \text{postdialysis BUN})/\text{predialysis BUN}$$

Finally, RRT can be used simply to maintain the BUN below a target level such as less than 80 to 100 mg per dL.

Methods of increasing urea clearance include maintaining high dialysis blood flows, often necessitating the use of large bore catheters and high gauge needles, using larger dialyzers, and extending dialysis time or frequency. It is important to note that adequate urea clearance does not ensure that ultrafiltration needs are met and additional RRT may be required to address volume overload.

There is little data regarding the dosage or intensity of PD for patients with AKI. Guidelines for stable ESRD patients on this form of RRT remain incompletely validated, even for commonly used techniques such as CCPD. When employed in the ICU setting, the patient's maintenance outpatient regimen is typically continued. However, adjustments such as increased exchange frequency, altered dialysate dextrose concentration, and, rarely, increased dialysate volume can be used to enhance solute and volume removal as clinically indicated.

Guidelines for the intensity of renal support in critically ill patients with AKI, particularly those on CRRT, are based primarily on the Acute Renal Failure Trial Network (ATN Trial) published in 2008 [35]. Prior to this, several single-center studies suggested that more dialysis leads to better outcomes. One study compared daily to alternate day IHD and reported lower mortality (28% vs. 46%) and shorter duration of AKI (9 vs. 16 days) in the daily IHD group [36]. Of note, the dose of dialysis delivered to the alternate day IHD group was very low (Kt/V_{urea}, 0.94). In addition, this study has been criticized for several methodologic irregularities. A seminal study by Ronco et al. reported improved survival with high-volume CVVH [37]. Four hundred and twenty-five patients were randomized to CVVH at variable ultrafiltration rates: 20, 35, and 45 mL per kg per hour. Survival was 41%, 57%, and 58%, respectively. This study set a standard minimum ultrafiltration rate of 35 mL per kg per hour for patients with AKI undergoing CRRT. This standard of care was reinforced by a latter prospective trial that compared CVVH at 25 mL per kg per hour to an augmented dose delivered by CVVHDF [38]. In the later group, the addition of dialysate at 18 mL per kg per hour to an ultrafiltration rate of 24 mL per kg per hour improved 28-day survival from 39% to 59%.

A large multicenter US trial, the ATN trial, tested the hypothesis that more intensive RRT in critically ill patients would decrease mortality and promote recovery of renal function [35]. A total of 1,124 patients at 27 centers were randomized to intensive therapy (IT) and less intensive therapy (LIT). An integrated treatment strategy was used. Hemodynamically stable patients were managed by IHD, whereas unstable patients were managed with CVVHD or SLED. Patients were permitted to move from one modality to another as their hemodynamic status changed. In the IT group, IHD and SLED were performed six times per week and CVVHDF provided an effluent flow rate of 35 mL per kg per hour. In the LIT group, IHD and SLED was performed three times per week and CVVHDF provided an effluent flow of 20 mL per kg per hour. The 60-day mortality was no different (53.6% in IT and 51.5% in LIT). There was no difference between the two groups in duration of RRT, rate of recovery of renal function, or recovery from nonrenal organ failure. Another multicenter, randomized trial conducted in Australia and New Zealand compared the effect of CRRT at two levels of intensity [39]. Higher intensity therapy did not reduce mortality at 90 days.

The results of the ATN trial do not imply that the dose of RRT is unimportant in managing AKI. Patients in the LIT group were better dialyzed than patients receiving usual care in typical clinical practice. Dialysis treatment (IHD, SLED) in the LIT group delivered a mean single pool Kt/V_{urea} of 1.30 that generated a mean predialysis BUN of 70. Among patients managed CVVHDF, the median time of treatment was 21 hours per day, substantially longer than times achieved in clinical practice. We support the dosing recommendation of the ATN investigators:

- IHD or SLED
  - Provide hemodialysis three times per week (alternate days).
  - Monitor the delivered dose to ensure delivery of a single pool Kt/V of 1.20 or more.

- CRRT
  - Employ large caliber catheters and systems of anticoagulation to maximize filter life.
  - Ensure effluent flow rate (hemofiltration rate + dialysate flow rate) of 20 mL or more per kg per hour.
  - In convective systems which employ RF, add 25% to the prescribed effluent flow rate (RF rate) to adjust for dilutional effects if prefilter RF is used.

MODALITY SELECTION

In the United States, the hemodynamically stable patient with AKI is generally managed with IHD. The technique provides rapid solute clearance and volume removal, but it is of limited utility in the setting of hypotension. Unstable patients are more often managed by one of the CRRTs. Patients may move from one modality to another with changes in hemodynamic status. Dialysis sessions are delivered at a minimum of three times per week. More frequent sessions are often required to achieve specific volume and metabolic targets. The average ICU patient with AKI receives 3.5 L of fluid daily. It is challenging if not impossible to mobilize this volume (24 L per week) over three IHD sessions alone. IHD may be supplemented with additional ultrafiltration sessions to meet volume needs.

The principal RRT options are IHD and CRRTs. PD management of AKI has declined markedly over the past 30 years, though it remains an important ICU modality in developing countries. SLED is used in a minority of programs, often in response to resource considerations.

IHD Versus CRRT

Modality selection in AKI is highly variable and appears to be changing in favor of CRRT. Ten years ago, most patients in the United States were treated with IHD. However, a recent survey of VA and US Academic Medical Centers reports a mix of IHD and CRRT modalities [40]. In the United Kingdom and Australia, CRRT is used as initial support in the vast majority of patients with AKI [41]. The shift toward CRRT is driven by a number of important practical as well some theoretical advantages for CRRT over IHD:

- CRRT induces less hypotension and is better tolerated by the patient with unstable hemodynamics.
- CRRT permits removal of large fluid volumes without inducing or exacerbating hypotension.
- Since CRRT induces less hypotension, it may promote renal recovery from AKI
- CRRT provides greater solute clearance than alternate day IHD.
- Since CRRT minimizes/limits hypotension and disequilibrium, it may better preserve cerebral perfusion in acute brain injury and in hepatic failure.
- The convective clearance of CRRT, particularly CVVH, may remove harmful immunomodulatory substances in sepsis.

The major trials comparing IHD with CRRT are summarized in Table 75.6. Retrospective studies from the 1990s show no survival advantage of modality selection in AKI [49,50]. Most report higher unadjusted mortality among the CRRT treated patients, but this difference is lost after adjusting for severity of illness. A modern day multicenter, observational series reported *increased* mortality with CRRT even after adjusting for study site, age, hepatic failure, and sepsis [48]. Incomplete adjustment for severity of illness may have confounded these findings. Nevertheless, the authors raise the possibility that aspects of care associated with CRRT (anticoagulation, medical errors, and removal of nutrients or drugs) may induce harm.

However, several prospective randomized trials have compared the effect of modality selection on outcomes in AKI (Table 75.6). In a small ($n = 30$) study of septic patients with AKI [51], CVVH preserved systemic hemodynamics better than

TABLE 75.6

MAJOR TRIALS COMPARING IHD AND CRRT

Study	Design	*N*	Mortality (IHD)	Mortality (CRRT)	Odds of death in IHD (95% CI)	RR,[a] CRRT vs. IHD	Comments
Mehta et al. [42]	RCT	166	48	66	0.63 (0.30–1.10)	35% vs. 33%	More liver failure, more MOSF in CRRT group
Augustine et al. [43]	RCT	80	70	68	1.12 (0.40–3.20)	No difference	More fluid removal, less hypotension in CRRT

did IHD over the first 24 hours, but long-term ICU mortality was 70% in both groups. In a larger single-center study of 80 patients [46], CVVHD induced less hypotension and better-controlled volume, but these factors did not improve survival, preservation of urine flow, or recovery of renal function. A potential benefit of CVVHD may have been lost in an attempt to control dialysis dose among modalities. Average dialysis times in IHD patients were 5 to 6 hours. In CVVHD patients, dialysate flow rates were often reduced to less than 1 L per hour. A US multicenter trial reported higher mortality among patients randomized to CRRT, but the randomization process was flawed [42]. Patients assigned to CRRT had more liver failure, higher APACHE scores, and a greater number of failed organ systems than did their IHD counterparts. After covariate adjustment, there was no mortality difference attributable to modality of RRT.

The French conducted the largest and most rigorous prospective multicenter trial to date [45]. In the Hemodiafe study, 359 patients from 21 medical centers were randomized to IHD or CVVHDF. Severity of illness was similar among groups. Pressor support was common at randomization (86% and 89%, IHD and CVVHD) as was sepsis (69% and 56%). Crossover from the IHD group to CVVHDF was low (3.3%) and both groups used the same dialyzer membranes. Sixty-day survival and recovery of renal function were identical between the groups. Unlike other prospective studies, Hemodiafe reported similar rates of hypotension. Hemodynamic stability among IHD patients was meticulously promoted by routine use of cool dialysate (35°C), very high dialysate sodium concentration (150 mmol), isovolemic connections, progressive ultrafiltration, and extended dialysis time (>5 hours). This study stands as evidence that all patients could be managed with IHD irrespective of hemodynamics.

Three recent meta-analysis and systematic reviews also conclude that no specific modality of renal support provides a survival advantage in AKI [52–54]. Similarly, none of the meta-analyses reported an advantage of CRRT in preserving renal function. However, two observational studies excluded from these analyses suggest some differences between IHD and CRRT. In one analysis of 1,281 patients with AKI, independence from dialysis at discharge was more common in patients treated with CRRT (85% vs. 66%), but CRRT patients had lower survival (36% vs. 52%) [46]. Multivariate adjustment identified CRRT as predictive of dialysis independence but not predictive of survival. A second analysis of 2,200 patients, managed in 32 ICUs throughout Sweden, reported twofold higher rates of dialysis dependency (16% vs. 8%) among 90-day AKI survivors managed with IHD [47]. However, mortality was higher (50.6% vs. 45.7%) among the CRRT group.

In summary, no evidence exists to support a survival advantage of specific modality support in AKI. Some prospective trials suggest improved hemodynamic stability with CRRT, and some retrospective analyses suggest enhanced recovery of renal function. In many circumstances, modality selection is guided by medical and nursing expertise and by availability of equipment or nursing support. When both modalities are available, selection should be individualized according to clinical status. Most US tertiary care centers opt for CRRT in settings of hemodynamic instability. The French experience suggests IHD can be used successfully in hemodynamically unstable patients, provided ultrafiltration rates are reduced by increasing the frequency and duration of treatment. Acute hemodialysis programs may be insufficiently staffed to perform high frequency (five to six times per week) and/or extended (>5 hours) dialysis. The same staffing limitations have lead many US programs to extend the indications for CRRT to the patient with stable hemodynamics but with severe volume overload and large obligate fluid intake.

Recommendations

We support the practice of most US centers and recommend CRRT over IHD for the management of AKI in the following clinical settings:

- Hypotension requiring pressor support
- Massive volume overload with high obligate fluid intake
- Highly catabolic patients who have failed to reduce BUN less than 80 mg per dL over three IHD sessions
- AKI in the setting of severe liver failure

Technical recommendations:

- We favor pump-driven venovenous systems over arteriovenous systems.
- We practice CVVH because of its simplicity and theoretic advantage of clearing middle molecules and harmful immunomodulatory cytokines. There is no evidence that CVVH is associated with better outcomes than CVVHD or CVVHDF.
- Regardless of the CRRT modality, the prescribed effluent volume should be 20 to 25 mL per kg per hour.
- When RF is administered in the predilution (prefilter) mode, increase target effluent volume by 25%.

Discontinuation of Therapy

Recovery of renal function is traditionally defined by the reversal of oliguria and progressive decline in serum creatinine. Increased urine volume may not be apparent in the nonoliguric patient. If the CRRT patient is intensively treated, the serum creatinine may be normal, making it impossible to detect a spontaneous decline. We define recovery of renal function according to the criteria used in the ATN study [35]:

- Urine volume exceeding 30 mL per hour (720 mL per day)
- 6-hour timed urine collection to compute creatinine clearance:

$$C_{creat} = U_{creat} \times \text{volume}/P_{creat} \div 360$$

<12 mL per minute	continue CRRT
12–20 mL per minute	individualize ongoing CRRT
20 mL per minute	discontinue CRRT

COMPLICATIONS OF RRT

A comprehensive discussion of RRT complications is beyond the scope of this chapter. For example, complications of central venous catheter placement are discussed in Chapter 2. However, we will review selected complications of dialytic support that are common in the ICU setting.

Infection

Infection is a common complication of all RRT modalities. For IHD and CRRT, infection is usually associated with hemodialysis catheter use and may result in interruption of RRT and increased mortality. Early studies showed higher infection rates with femoral versus subclavian and internal jugular vein cannulation [55,56]. However, the largest prospective randomized study comparing internal jugular and femoral catheters showed no difference in the risk of infection after 5 days [57]. This trial randomly assigned 750 patients to receive either jugular or femoral vein catheterization. The rate of catheter-related sepsis was the same for both groups (1.5 vs. 2.3 per 1,000 catheter days for femoral and jugular venous catheterization,

respectively). Hematomas were significantly more common for jugular compared with femoral cannulation (3.6 vs. 1.1%).

Peritonitis is a common infectious complication of PD and is the leading cause of catheter removal and modality conversion. It typically results from bacterial contamination during the exchange procedure or migration along the catheter tunnel. Symptoms and signs include fever, abdominal pain and tenderness, and cloudy dialysate effluent. The peritoneal fluid white blood cell count of greater than 100 cells per mL with at least 50% neutrophils indicates bacterial infection; however, a lymphocyte-predominate cell count may accompany fungal or mycobacterium infections. When peritonitis is suspected, cultures should be done prior to antibiotic therapy. *Staphylococcus aureus* and *Staphylococcus epidermidis* account for less than 50% of cases; however, polymicrobial and fungal infections should receive special consideration in the ICU. Patients with suspected peritonitis should receive empiric antibiotics to cover both Gram-positive and Gram-negative organism, pending culture results.

Electrolyte and Acid–Base Disorders

All forms of RRT can cause a variety of electrolyte and acid–base disturbances. These are most common with CVVH, as convective losses of large volumes of plasma can easily lead to hypocalcemia, hypomagnesemia, hypophosphatemia, hypokalemia, and metabolic acidosis if RF and solute supplementation are not carefully adjusted. Measurements of serum electrolytes are needed at least daily and may be required more frequently in many clinical situations. With IHD and CVVHD, metabolic disturbances are less frequent, since the dialysate composition is adjusted to avoid excessive potassium removal and usually maintains calcium and magnesium levels while supplementing bicarbonate. Hypophosphatemia is uncommon with intermittent and continuous dialysis modalities because phosphorus clearance is much lower for diffusion-based RRT when compared with convective RRT.

Access Thrombosis

Thrombosis of vascular access is a frequent complication of RRT. For patients with dialysis catheters, thrombus can form around the catheter. Clinically, patients will often present with dramatic edema of the ipsilateral extremity. In some cases, the only sign is impaired blood flow through the catheter. The diagnosis can be established with venous duplex studies or venography, though the latter approach necessitates radiocontrast exposure. If the catheter remains functional, the patient can usually be anticoagulated and the line left in place and safely used for dialysis.

Dialysis catheters may also develop impaired blood flow due to the formation of a thin layer of thrombus, also known as a fibrin sheath, along the outer surface of the line. In such cases, radiologic evaluation and procedures such as removal of the thrombus with a wire (catheter stripping) or localized infusion of thrombolytics may be needed to restore function. In severe cases, the catheter must be replaced.

For patients with ESRD, thrombosis of the AVF or AVG often occurs in the setting of hypotension or severe volume depletion, particularly if there is stenosis of the venous system proximal to the access. AVGs are much more prone to thrombosis than AVFs. The diagnosis is usually obvious, as the access will no longer have a palpable thrill or audible bruit. In cases of incomplete or impending thrombosis, cannulation of the access may reveal the presence of clots. Rarely, duplex of the access is needed to confirm thrombosis. If possible, the access patency should be reestablished by either surgical thrombectomy or mechanical or chemical thrombolysis. The decision to repair or revise the AVF or AVG, as well as the approach used, will depend on the patient's clinical status and the expertise and equipment available.

Hypotension

Hypotension often complicates volume removal by IHD. Severe reductions in blood pressure during dialysis limit ultrafiltration, perpetuate renal injury, and compromise perfusion to other vital organs. The pathophysiology of intradialytic hypotension involves left ventricular (LV) underfilling and inadequate reactive (pressor) response to decreasing volume. The rate of ultrafiltration, the magnitude of fluid shifts between the extracellular and intracellular compartments, and the plasma refill rate (as fluid moves from the interstitium to plasma) determine LV filling pressure. The risk of hypotension during IHD can be reduced by several methods:

- Reduce ultrafiltration rate by extending the duration of treatment
- Reduce ultrafiltration rate by increasing frequency of treatment
- Minimize intracellular fluid shifts by employing sodium modeling
- Potentiate vasoconstrictor tone by cooling the dialysate to 35°C

Effective strategies employed less frequently are as follows:

- Enhance plasma refill rate by infusions of albumin
- Promote vasoconstrictor tone with high concentration of calcium in dialysate
- Promote vasoconstrictor tone with oral midodrine prior to dialysis
- Promote vasoconstrictor tone with infusion of norepinephrine or vasopressin

Noninvasive monitoring tools are available to titrate volume removal to specific targets. Techniques involve bioimpedance analysis, pulse contour analysis, and echocardiography. The utility of these technologies in preventing intradialytic hypotension is still unproven.

RICHARD T. ELLISON, III

CHAPTER 76 ■ APPROACH TO FEVER IN THE ICU PATIENT

RAUL E. DAVARO AND RICHARD H. GLEW

Humanity has but three great enemies: fever, famine and war; of these by far the greatest, by far the most terrible, is fever [1].

Sir William Osler

APPROACH TO THE FEBRILE PATIENT

Fever is identified as the body's host defense mechanism and although it is commonly associated with infections, the relationship between infection and elevation of body's temperature is poorly understood [2]. The incidence of fever in the intensive care unit (ICU) ranges from 28% to 70% [3].

Pathophysiology

The normal core body temperature of approximately 37°C is well conserved in vertebrates with minimal changes [2]. Core temperature typically exhibits diurnal rhythmicity, with a nadir of about 36.2°C in the morning and a peak of approximately 37.7°C in the afternoon [4]. Temperature elevates to 39°C to 40°C in febrile response to infection or other stress [2].

The febrile response is a complex physiologic reaction to disease involving cytokine-mediated rise in core temperature, generation of acute-phase reactants, and activation of numerous physiologic endocrinologic and immunologic systems [5]. In contrast, simple heat illness or malignant hyperthermia is an unregulated rise in body temperature caused by inability to eliminate heat adequately [4]. Physiologically, fever begins with the production of one or more proinflammatory cytokines in response to exogenous pyrogenic substances (such as microorganisms, toxic agents) or immunologic mediators. Interleukin-1 (IL-1) was the first purified protein with demonstrated pyrogenic properties; subsequently, other cytokines such as tumor necrosis factor (TNF), lymphotoxin, interferons (IFNs), and interleukin (IL–6) were documented to induce fever independently. Cytokines interact with receptors located at the organum vasculosum of the lamina terminalis causing synthesis and release of prostaglandins, chiefly prostaglandin E_2, which raise body temperature by initiating local cAMP production, which resets the thermoregulatory set point of the hypothalamus, and by coordinating other adaptive responses such as shivering and peripheral vasoconstriction [5,6]. Fever induces the production of heat shock proteins (HSPs), a class of proteins critical for cellular survival during stress. HSPs that act as molecular chaperones may have an anti-inflammatory role and indirectly decrease the level of proinflammatory cytokines [2].

Measurement

No single normal body temperature exists, and temperatures measured at different times of day and sites may vary. The Society of Critical Care Medicine and the Infectious Disease Society of America issued a consensus statement recommending that core temperature of higher than 38.3°C (101°F) be considered fever [7].

All ICU patients should be monitored with regular reliable temperature determinations. Rectal temperature is about 0.3° to 0.4°C higher than simultaneous oral temperature. Electronic thermometers operate in a predictive manner and complete a temperature reading before thermal equilibrium is reached, thereby providing rapid accurate reading. However, in a tachypneic patient, oral temperature, even obtained with an electronic thermometer, may be misleadingly low. Infrared detection tympanic thermometers appear equivalent to rectal probes when placed properly in the external auditory canal.

In general, axillary measurements and skin temperature recordings and chemical dot thermometers are unreliable and should not be used in the ICU [7]. Fever patterns are not helpful in suggesting or establishing specific diagnosis [8].

ETIOLOGY OF FEVER IN THE INTENSIVE CARE PATIENT

Approximately one third of medical inpatients will develop fever during their hospitalization and nowhere is this more common than in the ICU [9].

Noninfectious Causes of Fever

Although acute bacterial infections are among the most common and serious causes of fever in the ICU patients, fever may result from noninfectious illnesses as well (Table 76.1) [7,10]. Pseudosepsis is a clinical picture of noninfectious etiology characterized by fever, leukocytosis and hemodynamic parameters consistent with sepsis, that can occur in critically ill patients with large hematomas, acute vasculitis, subarachnoid hemorrhage, dissection of an aortic aneurysm, mesenteric ischemia, heat stroke, pancreatitis, or hyperthyroidism [11]. Fever may appear in the patient in whom the stress of surgery unmasks adrenal insufficiency or in the patient in whom malignant hyperpyrexia develops during surgery or in association with administration of nonanesthetic agents such as phenothiazines [12]. Bilateral adrenal hemorrhage, noted to occur in patients with a history of thromboembolic disease, recent surgery, and/or anticoagulant therapy, can present with fever,

TABLE 76.1

NONINFECTIOUS SOURCES OF FEVER IN THE ICU PATIENT

  2. Malignant hyperthermia secondary to anesthesia or medications
  3. Hyperthyroidism
  4. Adrenal insufficiency/hemorrhage
  5. Alcohol withdrawal
  6. Seizures
  7. Neuroleptic malignant syndrome
D. Neoplasia
  1. Lymphoma
  2. Renal cell carcinoma
  3. Hepatocellular carcinoma
  4. Malignancy metastatic to liver
  5. Colon carcinoma

ICU, intensive care unit; CNS, central nervous system.

hypotension, and abdominal or flank pain [13]. Fever is a cardinal manifestation of delirium tremens in patients with acute alcohol withdrawal, although it is necessary to exclude other complications of alcohol abuse such as pneumonia or spontaneous bacterial peritonitis [14]. Likewise, fever associated with seizures must be differentiated from possible underlying causes of seizure, such as meningitis, encephalitis, brain abscess, or stroke [4].

Fever and hyperthermia can be the sole manifestation of an adverse drug reaction in 3% to 5% of cases. Drug fever can occur several days after initiation of the drug and takes few days to subside after cessation of its administration [15].

Particular diagnostic and therapeutic difficulties arise with the appearance of fever in patients with malignancy, because it is important to differentiate between neoplastic fever (especially common with lymphoma, primary and metastatic liver tumors, hypernephroma, and colon carcinoma), fever due to mechanical complications caused by the malignancy (perforation, obstruction, or hemorrhage), and fever due to infection [8].

The patient infected with the human immunodeficiency virus (HIV) who develops fever poses a formidable diagnostic challenge because opportunistic infections may occur on occasion with more than one problem at a time. In addition, HIV-infected patients have a greater incidence of adverse reactions to drugs. Intermittent fevers without discernible etiology also occur in these patients [16].

Conspicuously absent from Table 76.1 is atelectasis. Although this process is widely regarded as a cause of fever, especially in the postoperative patient where atelectasis is common, there is no clear evidence of such [17].

Accurate and timely recognition of noninfectious causes of fever can avoid unnecessary use of antibiotics, reducing the risks of untoward reactions.

Infectious Causes of Fever

Nosocomial infections are an endemic problem in the ICU, in part because of the numerous invasive devices used to monitor and support critically ill patients, and also because of the acute illnesses that predispose critically ill patients to the development of infections. Although hospital-associated infections can arise in many sites, the most common sources of bacterial infection in the ICU are bacteremia, infections associated with intravenous lines, pneumonia, intra-abdominal infection, urinary tract infection, and sinusitis (Table 76.2) [18,19].

Bacteremias

Secondary bacteremia may originate from multiple sources (e.g., lungs, genitourinary tract, abdomen, skin, and soft tissues) or can develop as a consequence of vascular invasion via intravenous and intra-arterial lines and monitors, temporary transvenous pacemakers, and intra-aortic assist devices.

Healthcare-Associated Pneumonia

Ventilator-associated pneumonia (VAP) is the most common infection acquired in the ICU. Necrotizing bacterial and fungal pneumonias occur in patients receiving antibiotics, chemotherapy, and/or corticosteroids, on ventilatory assistance, following abdominal surgery or in the setting of malignancy, neutropenia, or vascular access devices [20].

Intra-Abdominal Infections

The gastrointestinal tract can serve as the source of serious nosocomial infections. Intra-abdominal abscesses must be suspected in patients who develop postoperative fever after abdominal surgery. Acute acalculous cholecystitis complicated by biliary sepsis may occur after surgery or severe trauma [21]. Pseudomembranous colitis caused by *Clostridium difficile* in patients receiving broad-spectrum antibiotics is a common source of fever in the ICU [22].

Urinary Tract Infections

In hospital, ICUs have the highest rate of urinary tract infections, the majority of which are associated with the use of indwelling urine catheters. Partial or total obstruction or local complications (e.g., intrarenal or perinephric abscesses) must be suspected in patients with bacteremic pyelonephritis if fever and bacteremia persist [23].

TABLE 76.2

INFECTIOUS SOURCES OF FEVER IN THE ICU PATIENT

A. Urinary tract
   1. Pyelonephritis
   2. Prostatitis, prostatic abscess
B. Vascular devices

H. Miscellaneous
   1. Pyarthrosis
   2. Osteomyelitis (including vertebral osteodiscitis in adults)
   3. Meningitis

ICU, intensive care unit; CNS, central nervous system.

Nosocomial Sinusitis

Nosocomial sinusitis may develop in patients who require extended periods of intensive care. Nasogastric and nasotracheal tubes, facial fractures, and nasal packing are common predisposing factors. However, sinusitis alone is responsible for fever in only a minority of intubated patients [24].

DIAGNOSTIC CONSIDERATIONS

In some ICUs, the finding of fever triggers an automatic fever workup resulting in many tests that are time consuming, costly, and disruptive to the patient and staff. The American College of Critical Care Medicine and the Infectious Disease Society of America convened a task force to provide guidelines for evaluation of new fever in patients older than 18 years in the ICU setting [7].

History and Physical Examination

If able to communicate, the patient should be interviewed to identify localizing complaints. The patient and hospital chart should be reviewed thoroughly for a history of relevant antecedent problems (e.g., previous infections, cancer, allergic reactions to drugs). If the patient is unable to communicate, the medical record and medical personnel can provide insightful information concerning duration of intravascular accesses, amount and purulence of sputum or wound drainage, changes in skin condition, apparent abdominal or musculoskeletal pain or tenderness, difficulty in handling respiratory secretions and feeding, and changes in ventilator support parameters. Relatives and friends of the patient can provide epidemiologic information related to the patient's exposures and risk factors for infections.

Physical examination of the febrile ICU patient may be difficult to conduct due to limitations imposed by catheters, ventilator tubes, and monitors but nonetheless should be thorough. Skin examination may demonstrate findings suggestive of drug reaction, vasculitis, endocarditis, or soft tissue necrosis. All intravenous and intra-arterial line sites should be inspected; a tender intravenous access site, with or without purulence, can indicate septic thrombophlebitis. Spreading erythema, warmth, and tenderness that appear to indicate cellulitis of an extremity also can be the hallmarks of deep venous thrombophlebitis, pyarthrosis, or gout. After the first 24 hours postoperatively, wounds should be examined; this may require fenestrating or changing a cast to allow examination of a fractured extremity if no other source of fever is found.

Head and neck examination can provide important signs of systemic and localized infection. Funduscopic examination, preferably by an ophthalmologist, can provide clues to systemic fungal or viral infections in the immune compromised [25]. Hospital-associated sinusitis often develops in patients who required extensive period of intensive care and it may have a paucity of associated symptoms. Oral lesions of recrudescent herpetic stomatitis are common in the ICU setting and often obscured by the presence of oral endotracheal tubes or orogastric feeding tubes. These lesions may be extensive, more ulcerated and necrotic, and less vesicular in appearance in a seriously ill patient.

Examination of the lungs can be difficult in the intubated ICU patient and often is unrewardingly nonlocalizing and nonspecific. More sensitive (although nonspecific) indicators of pneumonia include the chest roentgenogram and the occurrence of unexplained deterioration in arterial oxygenation and changes in the color and amount of respiratory secretions [26]. Unfortunately, pulmonary infiltrates and arterial hypoxemia also can be seen with congestive heart failure, atelectasis, aspiration pneumonitis, pulmonary embolism, acute respiratory distress syndrome, and, less commonly, reactions to medications and pulmonary hemorrhage. Cardiac examination may demonstrate a new or changing murmur possibly due to endocarditis.

Abdominal findings can be misleadingly unremarkable in the elderly, in the patient with obtunded sensorium, and in the patient receiving sedatives. Abdominal examination can be confounding in the patient with recent abdominal or thoracic surgery. Abdominal pain and tenderness may be localized (cholecystis, intra-abdominal abscess, diverticulitis) or generalized (diffuse peritonitis, ischemic bowel, antibiotic-associated colitis). Examination of the genitalia and rectum may demonstrate unsuspected epididymitis, prostatitis, prostatic abscess, or perirectal abscess [27].

Unexplained noninfectious fever is common in patients in the neurologic ICU such as in patients with subarachnoid hemorrhage and is associated with the development of symptomatic vasospasm [28].

Diagnostic Studies

Because the information provided by positive blood cultures has important prognostic and therapeutic implications, blood cultures should be obtained in patients with new fever when clinical evaluation suggests an infectious cause. It is recommended to draw three to four blood cultures from separate sites within the first 24 hours of the onset of fever [7]. When urinary tract may be the source of fever, a urine specimen (aspirated from the catheter sampling port) should be obtained and evaluated by microscopy, and quantitative culture [7].

In patients with clinical suspicion for pneumonia, a portable chest radiograph is mandatory, and efforts should be made to obtain secretions for stains and cultures. Sputum samples should be subjected to microscopic examination to document paucity of squamous cells and to assess the approximate number of polymorphonuclear leukocytes and numbers and types of bacteria as a guide for empiric antibiotic decision making and ultimate interpretation of the results of sputum culture. Techniques aimed at obtaining samples of secretions and tissue from the distal respiratory tract include protected and nonprotected bronchoalveolar lavage (BAL), transbronchial biopsy, protected specimen brush, telescoping plugged catheter, video-assisted lung biopsy, and open lung biopsy; respiratory secretions from these sampling methods may use quantitative culture thresholds to improve the diagnostic accuracy. BAL is the preferred diagnostic approach, with a low rate of complications (2%) and a diagnostic yield between 30% and 90% depending on the type of population studied, prior antibiotic treatment, and the definition of pneumonia used [26]. The triggering receptor expressed on myeloid cells (TREM-1) is upregulated by exposure to bacteria and fungi. Measurement soluble TREM-1 in BAL has been proposed in establishing or excluding the diagnosis of bacterial of fungal pneumonia [29].

In general, abnormal fluid collections (pleural effusion, joint effusion, ascites) should be sampled for microscopic, hematologic, and chemical analysis, as well as microbiologic culture. Microbiologic yield from ascites culture has been shown to be greater when ascitic fluid is placed into blood culture or fungal isolator media [30]. Infection, crystal-induced disease, trauma, and a variety of systemic diseases can create a painful, swollen peripheral joint; arthrocentesis is indicated to establish the nature of the effusion [31]. Meningitis is an uncommon nosocomial infection, except in cases of head trauma, CSF leakage, neurosurgery, or high-grade bacteremia with virulent invasive pathogens such as *Staphylococcus aureus* or Gram-negative bacilli. Thus, sampling of cerebrospinal fluid usually should not be considered in the initial workup for nosocomial fever. However, lumbar puncture should be considered in the febrile ICU patient with sudden, unexplained change in mental status and in the febrile patient who has undergone recent neurosurgery or head trauma and whose mental status is difficult to evaluate [32].

Symptomatic complaints or physical findings referable to the abdomen dictate the need for determination of liver chemistries and serum amylase, as well as CT abdominal diagnostic imaging [21].

Examination of fluid from an inflamed, effused joint necessarily includes analysis for crystals (as well as hematological analysis) smears, and cultures. Exacerbations of gout and pseudogout mimic the symptoms, physical examination, and leukocytosis of the septic joint, and coexistence of gout and joint infection, although uncommon, can occur [31,33].

Many patients in the ICU experience diarrhea, and by far the most common enteric cause of fever in the ICU is *C. difficile*, which should be suspected in any patient with fever or leukocytosis who received an antibacterial agent or *chemotherapy* within 60 days before the onset of diarrhea [7].

Serum procalcitonin levels can be employed as an adjunctive diagnostic tool for discriminating infection as the cause of fever [7].

TREATMENT CONSIDERATIONS

Initial Antibiotic Therapy

Compelling evidence suggests that in infected critically ill patients, source control of the pathogen and early and appropriate antibiotic therapy remain the most important intervention that the clinician can implement for such patients [34]. Antimicrobial therapy should be evaluated daily to optimize efficacy, prevent resistance, and avoid toxicity [35]. Positive cultures may permit narrowing of the spectrum of antibiotic coverage or may dictate that additional organisms need to be covered by added antimicrobial therapy. Negative cultures in a patient who is unimproved yet stable on broad therapy indicate that antibiotics should be discontinued and the patient reevaluated. Negative cultures in a febrile patient who is unimproved or worsened may be a clue to disseminated fungal infection, and empiric antifungal therapy should be considered.

Once efforts have been made to determine the most likely site or sites of infection, one can make a reasonable estimate of infecting pathogens. In an ICU patient, one should assume that in addition to the usual expected pathogens at a given site, infection is likely to involve more opportunistic hospital-associated pathogens such as *S. aureus* (including methicillin-resistant *S. aureus* or MRSA), coagulase-negative staphylococci, and multidrug-resistant enteric Gram-negative bacilli and lactose nonfermenting Gram-negative bacilli (e.g., *Pseudomonas aeruginosa*, *Acinetobacter* species) and yeast (*Candida* sp). In light of possible impairment of mechanical and immunologic defenses and the presence of intravascular lines, the febrile ICU patient should be considered to be bacteremic until proven otherwise. Patients with intravascular lines and bacteremia should have their lines removed, if possible [36].

Once the spectrum of potential infecting organisms has been narrowed to one or a few likely candidates, empiric antibiotic therapy should be changed according to generally accepted principles as outlined later in the chapter (Table 76.3). However, such guidelines must be interpreted in light of the types of organisms and patterns of drug resistance prevalent in the specific institution and ICU. Definitive antibiotic therapy is determined by review of the final microbiologic data, with identification of the isolated infecting microorganism and its antibiotic susceptibilities [38].

Dosage and Route of Administration

Critically ill patients with severe sepsis and septic shock possess unique characteristics that affect the choice of antimicrobial therapy [38]. As a rule, the intravenous route is preferred because of possible unreliable absorption from muscle and the gastrointestinal tract due to impaired hemodynamics and/or gastrointestinal function.

Antibiotics such as the penicillins, cephalosporins, macrolides, and fluoroquinolones, which exhibit a high therapeutic/toxic ratio, usually are administered to adults according to a standardized dosage regimen (g per day) independent of the patient's weight. For antibiotics such as the aminoglycosides,

TABLE 76.3

PRESUMPTIVE ANTIBIOTIC THERAPY IN THE ICU OR CCU PATIENT

Site/diagnosis	Potential causes	Initial therapy	Alternative therapy
Vascular/line-associated bacteremia [36]	*Staphylococcus aureus*, GNR, coagulase-negative *staphylococci*	Vancomycin **plus** a third-generation cephalosporin[a]; suspect MRSA.	Linezolid **plus** a fluoroquinolone
Vascular/acute endocarditis [37]	*S. aureus*, *Enterococcus* spp	Vancomycin (modify according to susceptibilities MRSA, MSSA, VRE)	Linezolid or daptomycin; consider adding an aminoglycoside in *Enterococcus* spp is the pathogen
Vascular/bacteremia [36]	GNR	Third-generation cephalosporin[b] or imipenem or piperacillin–tazobactam	Linezolid **plus** fluoroquinolone
Pulmonary/pneumonia [3,21,26–55]	GNR, *Haemophilus influenzae*, *Streptococcus pneumoniae*	Piperacillin–tazobactam or third-generation cephalosporin[b] **plus** metronidazole if anaerobes suspected	Imipenem or meropenem or ertapenem
Pulmonary/pneumonia [3,21,26–55]	*S. aureus*	Vancomycin or linezolid until MRSA excluded	Cefazolin or oxacillin or nafcillin if MSSA
Pulmonary/pneumonia [3,21,26–55]	*Legionella pneumophila*	Azithromycin or fluoroquinolone	Doxycycline or clarithromycin
Urinary tract/ pyelonephritis [56]	GNR, *Enterococcus* spp	Third-generation cephalosporin[b] or fluoroquinolone	Aztreonam or ampicillin or piperacillin–tazobactam (if *Enterococcus* spp suspected)
Abdomen/peritonitis, abscess, pelvic infection [21]	GNR, anaerobes, *Enterococcus* spp	Piperacillin–tazobactam or fluoroquinolone **plus** metronidazole	Vancomycin **plus** metronidazole **plus** aztreonam or imipenem or tigecycline
Abdominal/biliary tract [21]	GNR, enterococcus, anaerobes (less often)	Piperacillin–tazobactam or fluoroquinolone **plus** metronidazole	Vancomycin **plus** metronidazole **plus** aztreonam or imipenem
CNS/meningitis (community acquired) [54]	*Streptococcus pneumoniae*, *Neisseria meningitidis*	Ceftriaxone or cefotaxime **plus** vancomycin	Vancomycin **plus** aztreonam
CNS/meningitis (elderly) [54]	*S. pneumoniae*, *Listeria monocytogenes*, GNR	Ampicillin **plus** third-generation cephalosporin[b] possibly **plus** vancomycin	Vancomycin **plus** third-generation cephalosporin[b] or aztreonam **plus** trimethoprim–sulfamethoxazole if *Listeria* suspected
CNS/meningitis (nosocomial) [32]	GNR, *S. aureus*, coagulase-negative *staphylococci*, *S. pneumoniae*	Vancomycin **plus** ceftazidime	Oxacillin[c] or nafcillin[c] **plus** ceftazidime or aztreonam
CNS/abscess [57]	*S. aureus*, GNR, anaerobes, microaerophilic *Streptococcus* spp	Third-generation cephalosporin[b] **plus** metronidazole **plus** vancomycin if MRSA suspected	Vancomycin **plus** metronidazole **plus** fluoroquinolone[b]
Sepsis syndrome [35]	GNR, *S. aureus*	Piperacillin–tazobactam or ceftazidime **plus** vancomycin	Fluoroquinolone **plus** linezolid

[a] Gentamicin, tobramycin, or amikacin.
[b] Cefotaxime, ceftriaxone, or ceftazidime.
[c] Vancomycin if methicillin-resistant *S. aureus* common.
GNR, Gram-negative rod; MRSA, methicillin-resistant *S. aureus*; MSSA, methicillin-sensitive *S. aureus*; VRE, vancomycin-resistant enterococci.

which exhibit a narrow toxic–therapeutic ratio and with which likelihood of toxicity is proportional to serum and tissue levels, dosing should be based on the patient's estimated lean body weight and renal function. The creatinine clearance can be calculated readily using the modification of diet in renal disease equation (MDRD); see Chapter 73.

Serum creatinine concentrations should be checked frequently, and serum antibiotic concentrations (especially trough) monitored periodically and more often if renal function or hemodynamics are unstable.

Dosing intervals for most antibiotics are selected so that the drugs are administered every three to four serum half-lives ($t_{1/2}$). Because most of the older parenterally administered β-lactam antibiotics have a $t_{1/2}$ of about 1 hour, intravenous penicillins and cephalosporins traditionally were given every 4 hours. However, the $t_{1/2}$ for cefazolin, cefotaxime, ceftazidime

is 1.5 to 2.5 hours, and these agents can be administered less frequently, perhaps ever 6 to 8 hours, even for serious infections; for ceftriaxone, the $t_{1/2}$ is 8 hours and the administration frequency is every 12 to 24 hours. Levofloxacin and the macrolide azithromycin are administered once a day.

Antimicrobial Therapy

Antimicrobial administration within the first hour of documented hypotension is associated with increased survival in adult patients with septic shock [39]. Antimicrobial therapy should be initiated at maximal recommended doses in all patients with suspected life-threatening infections without delay.

Initial Therapy of Life-Threatening Infection

Antimicrobial therapy for both Gram-negative and Gram-positive bacteria is the mainstay in the treatment of critically ill patients with severe sepsis. For example, suspected acute overwhelming infection of unknown or uncertain source in an ICU patient warrants therapy with vancomycin to cover *S. aureus*, including MRSA, plus a third-generation cephalosporin or a fluoroquinolone to treat Gram-negative bacilli. If hospital-acquired, ventilator-associated, or healthcare-associated pneumonia is likely, a fluoroquinolone such as levofloxacin or gatifloxacin along with piperacillin–tazobactam and vancomycin provides optimal coverage for Gram-negative enteric bacilli; atypical bacterial pathogens, such as *Legionella*, *Chlamydia trachomatis*, and *Mycoplasma*; and MRSA [26]. In patients with febrile neutropenia, an antipseudomonal penicillin (piperacillin/tazobactam) or cephalosporin (ceftazidime) or carbapenem (imipenem) is recommended [40]: vancomycin is added for clinical or bacteriological evidence of MRSA, such as severe mucositis, catheter-related sepsis, and hypotension [40,41]. It is important when choosing empiric regimens to consider recent antibiotic therapy that might have resulted in selection of resistant pathogens. Empiric treatment must be streamlined once the cultures confirm a pathogen to avoid selection of resistant flora.

The use of recombinant human activated protein C, aggressive volume resuscitation, daily hemodialysis in patients with acute renal failure, and early noninvasive ventilation recently have been added to the armamentarium in treating patients with septic shock [42].

Therapy of Mixed Bacterial Infections

Combination therapy is necessary to provide broad effective coverage in specific infections expected to involve diverse microorganisms. For example, intra-abdominal and intrapelvic infections frequently involve complex infecting flora, including aerobic and anaerobic pathogens. Definitive treatment of such infections often includes an extended spectrum β-lactam (ESBL) or a fluoroquinolone for members of the *Enterobacteriaceae* family; clindamycin or metronidazole for *Bacteroides fragilis* and other anaerobes; and penicillin G, ampicillin, or piperacillin for enterococci. An alternative regimen particularly in the patient with known or suspected (long-term residence in the ICU or recent receipt of broad-spectrum antibiotic therapy) multiresistant Gram-negative bacteria is imipenem, meropenem, or piperacillin/tazobactam.

Synergism of Antibiotic Regimens

Although there are numerous examples of in vitro synergy, in vivo synergy has proved effective in a limited number of clinical scenarios. The best documented application of this principle is in patients with infective endocarditis due to *Enterococcus* sp, where treatment with penicillin G or ampicillin plus an aminoglycoside achieves cure levels unmatched by single therapy [43,44]. Although bacteremic infections with *P. aeruginosa* have been treated traditionally with an antipseudomonas penicillin or cephalosporin plus an aminoglycoside, there is no difference in terms of mortality, clinical efficacy, or prevention of resistance when compared with monotherapy [45].

Fungal Infections

The incidence of fungal sepsis increased threefold between 1979 and 2000 and mycosis-related deaths are on the rise. Fungi account for about 5% of all cases of sepsis, and most cases are caused by *Candida* spp [46]. Trauma, burns, abdominal surgery, parenteral nutrition, broad-spectrum antibiotics, malignancy, cancer chemotherapy, and immunosuppressive therapy following major organ transplantation are factors that increase the risk of invasive fungal infections [25].

Early recognition and aggressive medical therapy is key to the successful treatment of this complication [47]. Recently issued guidelines for treatment of candidiasis recommend fluconazole, caspofungin (an echinocandin with fungicidal activity), or an Amphotericin B preparation [47].

Emerging fungal pathogens include *Aspergillus* spp, *Fusarium* spp, *Trichosporon* spp, *Zygomycetes*, *Pseudallescheria boydii*, and dematiaceous fungi, particularly in neutropenic patients and in recipients of solid organ transplantation. *Cryptococcus neoformans* is a major cause of meningitis (less often pneumonia and fungemia) in patients with AIDS and in patients receiving cytotoxic drugs, anti-TNF, or corticosteroids [48].

Multidrug-Resistant Organisms

Over the past decade, hospitalizations with resistant infections (coagulase-negative staphylococci, MRSA, *C. difficile*–associated disease, vancomycin-resistant enterococcus, *P. aeruginosa*, *Acinetobacter baumannii*, *Klebsiella oxytoca*, and *Candida* infection) nearly doubled [49,50]. Gram-negative bacilli resistance is a persistent problem in the ICU. ESBLs have been identified in the *Enterobacteriaceae*, particularly *Klebsiella* sp, *Escherichia coli*, and *Proteus mirabilis* for several decades, and strains producing carbapenemases have been more recently identified.Strains that produce ESBLs demonstrate resistance to third-generation cephalosporins (cefotaxime, ceftriaxone, and ceftazidime), and the strains producing carbapenemase are in general resistant to all classes of β-lactam agents. These organisms also typically carry other resistance genes and are frequently resistant to trimethoprim-sulfamethoxazole, fluoroquinolones, and aminoglycosides. In addition, *P. aeruginosa* and *A. baumannii* display resistance to β-lactams, including monobactams and carbapenems, as well as fluoroquinolones and aminoglycosides; these bacteria can be pan resistant, defined as resistant to all available antibiotics [51].

Vancomycin-resistant *Enterococcus* spp emerged in the past decade as a major nosocomial pathogen. Enterococcal infections occur in patients as complications of prolonged hospitalization, particularly in patients with intravenous lines, intra-abdominal surgery, on mechanical ventilation, or who received broad-spectrum antibiotics that are devoid of activity against enterococci. Newer antibiotics such as linezolid, daptomycin, and tigecycline are treatment options for the treatment of serious nosocomial infections due to vancomycin-resistant enterococci [52].

The recent discovery of strains of MRSA with reduced susceptibility to glycopeptides (VISA) and with resistance to vancomycin (VRSA) emphasizes the importance of using antibiotics in a rationale manner to minimize the impact of resistance [52,53].

Treatment of Fever

Several factors must be considered when determining whether to treat fever symptomatically using antipyretics. Antipyretic therapy may relieve discomfort and decrease the metabolic rate associated with fever [12]. Despite these premises, neither the detrimental consequences of fever nor the beneficial effects of antipyretic therapy have been confirmed experimentally or clinically, and we recommend that antipyretic therapy be withheld unless the temperature exceeds 41°C.

Physical methods of external cooling are the treatment of choice in hyperthermia, but the use of these methods in the treatment of fever remains controversial because it can lead to adverse effects such as shivering, discomfort, and worsening hemodynamic instability [54].

CHAPTER 77 ■ USE OF ANTIMICROBIALS IN THE TREATMENT OF INFECTION IN THE CRITICALLY ILL PATIENT

IVA ZIVNA, RICHARD H. GLEW AND JENNIFER S. DALY

This chapter reviews antimicrobial agents used in the treatment of bacterial, viral, fungal, and protozoan infections in the intensive care unit (ICU).

PENICILLINS

The classes of penicillins include penicillin G, ampicillin, the antistaphylococcal (semisynthetic) penicillins, and the expanded spectrum (antipseudomonal) penicillins alone and in combination with a β-lactamase inhibitor [1,2]. The serum half-life ($t_{1/2}$) of most penicillins is short, and rapid clearance occurs via the kidneys. Some semisynthetic penicillins, particularly nafcillin and oxacillin, are metabolized to a large extent by the liver; therefore, adjustment in dosage is not required in patients with renal insufficiency; for piperacillin, dosing adjustment is necessary only in severe renal insufficiency. For most other penicillins, moderate adjustments should be made in dosage in patients with severe renal insufficiency (Table 77.1). Penicillins are relatively nontoxic at usual doses, and side effects most commonly involve hypersensitivity reactions. Bone marrow and hepatic toxicity caused by semisynthetic penicillins have been described, with neutropenia more commonly seen with nafcillin and hepatitis more likely to occur with oxacillin.

Penicillin G

In the ICU, aqueous penicillin G is appropriate in the therapy of severe, overwhelming infections caused by susceptible organisms, including pneumococcal pneumonia and bacteremia caused by penicillin-susceptible strains [1], necrotizing fasciitis due to group A *Streptococcus* (in combination with clindamycin), and for streptococcal bacteremia. Because of the prevalence of penicillin-resistant pneumococci, life-threatening infections (especially meningitis) due to these organisms should be treated initially with ceftriaxone, cefotaxime, or vancomycin [3]. Although aspiration pneumonia commonly involves mouth anaerobes that are susceptible to penicillin G, penicillin-resistant anaerobes can be found in putrid, cavitary pneumonia, and empyema, and clindamycin with or without a third-generation cephalosporin (or an extended-spectrum β-lactam plus metronidazole) is the preferred regimen [4–6]. Therapy for penicillin-susceptible *Enterococcus* spp causing endocarditis is penicillin G or ampicillin plus an aminoglycoside, generally gentamicin [7]. The activity of penicillin G and ampicillin against most Gram-negative bacilli is poor [2]. *Staphylococcus aureus* should be presumed to be resistant to penicillin, ampicillin, and piperacillin, as most strains produce a penicillinase.

Penicillinase-Resistant Semisynthetic Penicillins

Because most strains of *S. aureus* are resistant to penicillin G by virtue of β-lactamase production, treatment of severe infections caused by these organisms involves one of the β-lactamase–resistant penicillins (see Table 77.1). Nafcillin and oxacillin are interchangeable: Both exhibit excellent in vitro activity against most susceptible isolates of *S. aureus*, but are slightly less active (although generally effective) than penicillin G against streptococci, and are sufficiently metabolized by the hepatic route so that no adjustment in dose is necessary in patients with renal insufficiency. Because of high prevalence of community-acquired methicillin-resistant *S. aureus* (MRSA), vancomycin should be used for empiric therapy of suspected staphylococcal infections [8]. In patients with overwhelming or disseminated infection caused by β-lactam–susceptible *S. aureus*, therapy should be instituted with 9 to 12 g per day of intravenous (IV) oxacillin or nafcillin, in divided doses every 4 hours (see Table 77.1).

Anti–Gram-Negative Penicillins

The expanded-spectrum penicillin (piperacillin) and the combination agent piperacillin/tazobactam exhibit activity against many *Enterobacteriaceae* that are resistant to ampicillin [9].
